Welcome

The European College of Sport Science (ECSS) welcomes you to Lausanne for its 11th annual Congress. Hosted by the University of Lausanne and Bern, École Polytechnique Fédérale de Lausanne and the Swiss Society of Sports Medicine the ECSS is delighted to stage this major event in the city of the Olympic Movement from 5-8 July 2006.

The scientific programme is composed of more than 1.500 abstracts, which were accepted after being carefully reviewed . This year´s Congress is the largest in the history of the ECSS, underlining both the interest of the sport scientific community and the importance of the ECSS as an interdisciplinary forum for ongoing debate. In view of the multifaceted character of sport science, state-of-the-art presentations cover basic and applied sciences as they relate to sport, exercise and health. The presented abstracts comprise not only all relevant sub-disciplines of sport science but also all continents and 68 different nations. The abstracts are distributed among 4 Plenary Sessions, 50 Invited Symposia, 50 Thematic Sessions and 3 Poster Sessions each presenting close to 400 Posters.

Apart from presentations discussed from the perspective of natural sciences, social/behavioural sciences, humanities, sports medicine and from practice itself, participants will also experience an extensive social programme including complimentary access to the Olympic Museum.

On behalf of the ECSS we wish you all a very pleasant and productive stay in Lausanne and hope that it will be both scientifically and socially successful.

Hans Hoppeler
Congress President

WHY HUMANS NEED TO BE ACTIVE TO STAY HEALTHY

Booth, F., Lees, S., Laye, M.

University of Missouri, United States

The genome evolved in an environment in which the oxygen demands of physical activity helped to establish aerobic metabolic networks. For most of human existence on Earth, gathering food, making shelter, and defending one's self was required for survival. Thus, the oxygen demands of physical activity as well as the rise in atmospheric oxygen played complimentary roles in setting the framework of today's aerobic metabolic pathways. While demands for physical activity have diminished in the recent few decades, DNA sequences of genes remain those established over hundreds of millions of years that have been fixed for the past 1000 to 10000 yrs. The lack of physical activity establishes a new milieu as genes do not express properly in the absence of a threshold of daily physical activity. The natural cycling of the zenith and nadir for many metabolic pathways with physical activity is lost with physical inactivity. The altered metabolic state of physical inactivity (lack of appropriate gene expression and the attenuation of metabolic cycling) leads to pathophysiological changes in the presence of genes predisposing to chronic diseases. Physical inactivity is associated with an increased prevalence of many chronic diseases such as atherosclerosis, breast and colon cancers, obesity, and type 2 diabetes. The interactions of individual variations in predisposing genes among humans and in the ability of the given individual's genes to produce a higher metabolic capacity determine the risk of chronic disease; the identification of genes and their interactions will be new areas for research. A current example of impaired gene expression due to a reduced turnover of lipid stores in the sedentary state will be compared to the physically active state. In summary, humans have to remain physically active to retain metabolic cycling similar to those of our ancestors hundreds and thousands years ago.

QUALITY OF LIFE, WELL-BEING AND EXERCISE

Skevington, S., Gillison, F., Evangelidou, S., Sato, A., Standage, M. and the WHOQOL Group

University of Bath, United Kingdom

While there is growing evidence to support the view that being physically active can maintain and improve physical and mental health, questions remain about whether it improves quality of life and well-being. What does it mean to have a good quality of life and how can we best assess it? First we examine some of the issues and challenges in defining and measuring health-related quality of life, and consider which dimensions might be universal. In doing this, the paper traces the steps taken by an international collaboration of 15 countries convened by the World Health Organisation to develop a new assessment; the WHOQOL. Novel developments in methodology have enabled over 50 different language versions to be created which are highly equivalent in semantic and conceptual terms. The WHOQOL provides a reliable, valid, and responsive instrument that is facilitating multinational trials of interventions, and cross-cultural research. Data from this generic profile will be presented for illustration. Secondly, through a systematic review of randomised controlled trials we summarise the relationship between physical activity and quality of life for sick and well populations. In appraising this evidence we ask under what circumstances being physically active and having a good quality of life go hand in hand? Implications for sports science are discussed.

Plenary session (PLS)

PLS1 Olympism and the Olympic Movement - "Lausanne"

SCOPE OF OLYMPIC MOVEMENT

Oswald D., CH

Without abstract submission.

OLYMPISM FOR THE 21ST CENTURY

Parry, J.

University of Leeds, United Kingdom

The philosophy of Olympism has as its focus of interest not just the elite athlete, but everyone; not just a short truce period, but the whole of life; not just competition and winning, but also the values of participation and co-operation; not just sport as an activity, but also as a formative and developmental influence contributing to desirable characteristics of individual personality and social life. For Olympism is a social philosophy which emphasises the role of sport in world development, international understanding, peaceful co-existence, and social and moral education.

A universal philosophy by definition sees itself as relevant to everyone, regardless of nation, race, gender, social class, religion or ideology, and so the Olympic movement has worked for a coherent universal representation of itself - a concept of Olympism which identifies a range of values to which each nation can sincerely commit itself whilst at the same time finding for the general idea a form of expression which is unique to itself, generated by its own culture, location, history, tradition and projected future.

The contemporary task for the Olympic Movement is to further this project: to try to see more clearly what its Games (and sport in wider society) might come to mean. This task will be both at the level of ideas and of action. If the practice of sport is to be pursued and developed according to Olympic values, the theory must strive for a conception of Olympism which will support that practice. The ideal should seek both to sustain sports practice and to lead sport towards a vision of Olympism which will help to deal with the challenges which are bound to emerge.

The search for a universal representation at the interpersonal and political level of our common humanity seems to me to be the essence of the optimism and hope of Olympism and other forms of humanism and internationalism. I have elsewhere tried to present a philosophical anthropology of Olympism as part of an explication of its ideology, and as a contribution to a theory of sport and physical education. This paper argues that Olympism is well placed to provide the basis for the world-wide development of physical education as a valued element in everyone's general education.

This is the challenge for the 21st century: to make universalism and humanism in sport an everyday reality.

Invited symposium (IS)

IS1-01 Gender, mass media and Olympic Sports - "Lausanne"

THE GLOBAL WOMEN IN SPORTS MEDIA PROJECT - INTRODUCTION

Pfister, G.

University of Copenhagen, Denmark

The global women in sports media project - Introduction

Sport is still a men's world – at least in the mass media. Worldwide women's sport is marginalized in the media; it gets around 5 to 15 % of the coverage. The interest of the media in female athletes increases during the "big sport events" like the Olympic Games. However, there are huge differences between the different news papers in different countries, and the coverage of female athletes depends on various factors like the attractiveness of a sport, success, the popularity of the athlete etc.

In this session we will present the results of an international research collaboration which assesses media coverage of sportswomen during the 2004 Olympic Games. Scholars from more than 20 countries participate in this project. We understand gender as a social construct which is supported and enacted by media and media sport.

The project focuses on a quantitative content analysis. The main aim is to find out how much coverage women athletes and teams receive during the 2004 Olympic Games. In addition, a textual (or qualitative) analysis shall look at the way, how men and women are presented.

Here the results of three countries, France, Germany and Denmark, are presented, compared and discussed.

THE COVERAGE OF MALE AND FEMALE ATHLETES AT THE 2004 OLYMPIC GAMES - GERMAN RESLUTS

Hartmann-Tews, I.A., Rulofs, B.

German Sport University Cologne, Germany

As part of an international research cooperation on the representation of women athletes in mass media during the Olympic Games in Athens 2004 the results of a content analysis of the coverage of the Olympic Games by the Frankfurter Allgemeine Zeitung (FAZ) and Bild Zeitung (BILD) are presented. The BILD represents the biggest tabloid national newspaper in Germany and has the highest circulation of daily national newspapers in Germany selling 3.6 mio papers a day. The newspaper has approx. 11.8 million readers across the age categories and across social strata. The circulation of the Frankfurter Allgemeine Zeitung is 0.4 million papers a day and the highest among the broadsheet newspapers in Germany. It has a high reputation as regard to the economy section and the sport section. The editorial board of the sport section received numerous awards for the best German editorial staff in sport (including the years 2004 and 2005).

The theoretical background of the analysis refers to theories of social construction of gender. In contrast to a long tradiiton of media analysis in angloamerican countries there are only very few content analysis focusing the social construction of gender in the sports media in Germany.

Results: In the coverage of the Olympics Games female athletes are less often focused in textunits (44.0% vs. 56.0%) and less often depicted in photographs (45.0% vs. 55.0%). This quantitative discrepancy is far less in comparison to daily newspaper coverage where male athletes tend to receive about 90% of the total space. However, the quantitative data on coverage has to be compared with the proportion of paticipation of athletes in the Olympic Games. Taking this into consideration the proportion of textunits and photographs shows a small overreporting of female athletes of 3% and 4% in comparison to their participation rate.

There are differences between the papers concerning the quantitative and qualitative coverage of the athletes: In the broadsheet paper there is a clear dominance of verbal communication and no quantitative gender bias (neither in texts nor in photographs) and no gender bias in content (neither in texts nor in photographs). The tabloid paper has a balanced verbal/visual communication profile, and in the visual communication male athletes outnumbered female athletes in photographs portraying action or competition.

These and aditional data will be presented and analysed on the backgound of more recent German data of gender representation in sportmedia.

THE COVERAGE OF MALE AND FEMALE ATHLETES AT THE 2004 OLYMPIC GAMES - FRENCH RESULTS

Ohl, F., Quin, G., Wipf, E.

Université de Lausanne, Switzerland

This paper presents the French results of an international research collaboration that assesses media coverage of sportswomen during the 2004 Olympic Games. In France, we analysed two newspapers L'Équipe and Le Monde. The first one, L'Équipe, is a specialized newspaper that plays an important role in sport. The second one, Le Monde, is the most important national paper considering his role in the media field. In both papers, we can observe that during the Olympic Games the media coverage of women is higher than outside this period. Nevertheless, coverage of men (around 55% of the paper) is still higher than sportswomen coverage (from 10% before the games to 20%). Differences are also qualitative. For example, women media coverage is more on emotional aspects of sport; women are less often presented during action and more outside sport. Even when French women are very successful, like in swimming, the media coverage is lower than for men. Thus, considering data we can observe some changes in the media coverage but the Olympic coverage still underrepresented women and present gender in very traditional way.

THE COVERAGE OF MALE AND FEMALE ATHLETES AT THE 2004 OLYMPIC GAMES – DANISH RESULTS

Pfister, G.

University of Copenhagen, Denmark

In Denmark, two news papers, Politikken, the most important paper, and BT, a boulevard paper, have been analyzed. Both papers focused on Danish athletes and those sports got the highest coverage where Danish participants were successful. Female athletes were highly underrepresented in both news papers. In Politikken, 57 % of the coverage of the Olympic Games was given to male athletes, 25 % to female athletes, 8 % to both sexes. 10% of the coverage did not refer to gender. In the search for the reasons for the gender imbalance we analyzed among other things the correlations between the percentages of women in the Danish team and among the medal winners on the one and the media coverage on the other hand. But this did not provide explanations. It seems to be the "taste" of the male journalists which prioritize men´s events and performances and thus produce a gender imbalance in the Olympic coverage.

INTERNATIONAL COMPARISON OF GENDER REPRESENTATION IN SPORTSMEDIA AT THE OLYMPIC GAMES 2004

Hartmann-Tews, I.A.

German Sport University Cologne, Germany

Gender representation in (sports-) media has long been characterized as anihilation and stereotyping of female athlets. The data of the international cooperation, encompassing the analysis of the coverage of the 2004 Olympic Games in more than 15 countries, confirm some of the long standing results but at the same time show deviating international variations. On the basis of the examples of three countries – France, Denmark and Germany – the presentation will outline some general features of stereotyped and stereotyping coverage and some national variations. Latter shall be integrated into a model that identifies structural and culutral elements that are supportive for a more gender-equitable quantitative and qualitaive coverage.

Invited symposium (IS)

IS1-02 Transport related physical activity and health - "Innsbruck"

RELATION OF CYCLING AND PREMATURE DEATH

Andersen, L.

Norwegian School of Sport Sciences, Norway

Physical activity in general prevents a number of diseases and premature mortality. However, little is known about the effect of specific types of habitual activity such as cycling commuting. Cycling as transportation is usually a type of activity of quite low intensity because most people want to get to work without sweating too much. Cycling as transportation is on the other hand a type of physical activity which could be easy for the individual to integrate into everyday living, and knowledge of health gain in relation to this type of physical activity is therefore important. We have earlier published cycling commuting in relation to all cause mortality, but it is not known whether improving cycling habits will decrease mortality.

Data from the prospective studies in Copenhagen was analysed.

The Copenhagen City Heart Study:

– Cycling in hours per week was assessed among 6,510 women and 8,466 men, 20-93 years of age, and changes in cycling habits was assessed after five years. During 162,016 person-years of observation 3,787 subjects died. Changes in cycling habits was assessed in 3,291 men and women who experienced 618 deaths.

Center for Preventive Medicine, Glostrupundersøgelserne and the Copenhagen Male Study:

– Cycling as transportation to work was assessed in 6,171 mænd og 783 kvinder. During 145.555 person-years of follow-up 2,291 died.

About 50% of the men and 40% of the women cycled at least ones a week, but cycling decreased with increasing age, and more in women than in men. Between the age of 20 and 45 years two third of all subjects cycled every week. Among women this percentage fell to 20% in the 65+ years old, but among men 45% in the age group 65-90 years still cycled. The amount of physical activity resulting from cycling is substantial in Denmark, and 30% of the whole adult population cycled more than three hours per week, which is sufficient to fulfil the international guidelines of 30 minutes of physical activity of moderate intensity per day.

After adjustment for other types of physical activity, socioeconomic back ground, smoking, blood pressure and cholesterol levels a mortality rate of 0,7 was found in cyclists compared to those who did not report weekly cycling. A similar difference was found when only cycling to work was analysed. These two analyses were conducted on different cohorts which show a consistent pattern. Further, changes in cycling habits over five years was analysed in relation to subsequent mortality, and a mortality rate of 0.66 was found among subjects who increased cycling compared to subjects who decreased cycling. Deaths among cyclists included subjects who were killed in traffic accidents.

COMMUTER CYCLING IN FLANDERS

de Geus, B., Joncheere, J., Aerts, I., Breynaert, J., Hellemans, S., Meeusen, R.

Vrije Universiteit Brussel, Belgium

On population level, the substantial health-enhancing potential of physical activity can be accomplished preferentially by incorporating physical activity into the daily life routine. Physical active commuting to work (PACW) provides a promising mode for such activity.

However, before PACW can be recommended, some questions have to be answered.

The Policy Research Centre Sport, Physical Activity and Health, funded by the Flemish Government started a four year project were several research questions concerning PACW were put forward: (1) does a substantial number of people within the Flemish working population have motivational and practical possibilities for PACW?; (2) what are the factors favouring or hindering PACW?; (3) and is there a difference in perception between those who cycle to work on a regular basis, and those who never cycle to work?; (4) what is the effect of cycling to work on physical and psychological parameters; (5) is there a dose-response relation between the energy expenditure and the measured physical and psychological parameters; and (6) what is the intensity of cycling to work at a self-chosen intensity?

In order to answer the first three questions a self-administrated questionnaire was used. The questionnaire inquired about certain factors such as distance and frequency of travelling to work, demographic and anthropometric data, psychosocial factors, environment and transport.

To investigate the possible effects of commuter cycling on physical performance and functional status and the quality of life, an one year intervention study was set up in Flanders. Sixty-five untrained subjects cycled to work at least three times a week to their workplace over a one-way distance of minimum two kilometres. All subjects were tested on three occasions in order to measure their maximal aerobic capacity and maximal external power. During the same day a RAND Short Form-36 (SF-36) questionnaire was filled in to assess functional status and well-being or quality of life and venous blood samples were collected after overnight fasting for total cholesterol, HDL cholesterol, LDL cholesterol, and VLDL cholesterol, triglycerides, uric acid and CRP. In order to calculate the dose, cycling data (frequency, distance, and duration) and participation in physical activities (type, duration and intensity) were recorded and written down in dairies during the whole period.

To answer the last question, a field study was set up to investigate what the intensity is of cycling to work on its own pace and whether this spontaneously selected physiological loading meets the requirements of HEPA.

Acknowledgement:

This study is funded by the Flemish Government.

Policy Research Centre Sport, Physical Activity and Health.

ENVIRONMENTAL FACTORS AND HUMAN POWERED MOBILITY FOR CHILDHOOD SCHOOL TRAVEL

Bringolf-Isler, B., Mäder, U., Ruch, N., Grize, L., Braun-Fahrländer, C.

Institute of Social and Preventive Medicine of the University of Basel, Switzerland

Introduction: Environmental factors influencing human powered mobility (HPM) for school travel has become an important Public Health topic. Very limited data exist about travel patterns of schoolchildren in Switzerland and about the extent of walking or bicycling to school. Therefore the SCARPOL study surveyed the commuting mode of Swiss children and determined which objective and subjective factors influence active commuting.

Method: The present study included 1345 Swiss children of three different age groups (kindergarten/1st class, 4th class and 8th class students) living in three communities (Bern: German speaking, Payerne: French speaking an Biel-Bienne: mixed language community). Parents responded to a questionnaire about the children's common commuting mode to school. For 1096 children the home address was available allowing us to allocate GIS-data about the home and the school environment (geographic information system) to these children.

Results: Overall, the prevalence of commuting by car or by bus appears to be rather low among Swiss children (21% in summer and 24% in winter) but differs between the language areas. Whereas in Bern more than 90% of children use HPM to get to school, only 75% do so in Biel-Bienne and less than 60% in Payerne. The reason for this difference cannot be reduced to cultural differences. According to the GIS-data children from Payerne have significant longer ways to school than children from the other two communities and they have to cross more dangerous crossroads. This fact is important because parents who perceive the way to school as dangerous accompany their children more often and this influences the mode of transport to school. In contrast to studies from Anglo-Saxon countries only 5% of Swiss parents are worried about violence by adults the children may experience on their way to school whereas nearly 90% perceive traffic as a major hazard for their children.

Conclusion Although passive commuting is still not very common among Swiss school children efforts are necessary to maintain active commuting rates or even to increase them. To encourage human powered mobility for children's commuting to school a broad range of environmental and family related factors have to be taken into account.

Invited symposium (IS)

IS1-03 Exercise and oxidative stress - "St. Moritz"

MOLECULAR MECHANISMS OF APOPTOTIS AND OXIDATIVE STRESS IN MUSCLE; ROLE OF EXERCISE INTERVENTION'

Leeuwenburg, C., Judge, S., Seo, A.Y., Hofer, T., Kalani, R., Jang, Y.M, Selman, C., Phillips, T., Prudencio M, Carter, C, Pahor M, Sung, B., Chung HY, Kim, J.H., Kwak, H.B., Lawler J, Smith, A, Hagen T, Speakman JR

University of Florida, Pusan National University, Texas A&M University, Linus Pauling Institute, Oregon State University, University of Aberdeen, United States

Aging causes a dysregulation in redox status due to an enhanced oxidant production and reduced antioxidant protection, which may lead to changes in specific signaling pathways including a pro-inflammatory response and altered tissue morphology. We investigated whether long-term voluntary exercise and mild 8% calorie restriction (CR) could attenuate these changes in the heart, liver and skeletal muscle. Four groups of male Fischer-344 rats were compared: young (6 mo) ad libitum fed (YAL), old (24 mo) ad libitum fed (OAL), old lifelong calorie restricted (8%CR: OCR) and age-matched old lifelong 8% CR with daily voluntary wheel running exercise (OExCR). After the age of 6-mos, running activity was maintained at an average of 1145  248 meters/day until all animals were sacrificed at 24-mos of age. Daily energy expenditure, as determined by the doubly-labeled water technique, was approximately 70% higher in runners compared to sedentary rats. In general, we found that oxidant production (hydrogen peroxide (H2O2), nitric oxide (NO•), and peroxynitrite (ONOO-)) was increased with age in several tissues, and moderate CR and wheel running exercise were able to attenuate the age associated increases. In addition, antioxidant status in tissues and in plasma (sulfhydryl (-SH), glutathione (GSH) and total antioxidant status) was decreased with age, and exercise and CR were also able to attenuate the age-associated decline. Moreover, old rats had significantly increased nuclear presence of NF-κB and in connection, increased levels of regulatory cytosolic phosphorylated I-κBα and decreased dephosphorylated I-κBα in the liver, suggesting an increased inflammatory response. Interestingly, a significant increase in liver RNA oxidation (8-oxo-7,8-dihydroguanosine) in the old ad libitum fed rats was detected and DNA oxidation (8-oxo-7,8-dihydro-2'-deoxyguanosine) also tended to increase. The age-associated increase in oxidative stress and upregulation of pro-inflammatory proteins was attenuated in the tissues from both the CR and the exercise + CR groups. Moreover, lifelong exercise + 8% CR showed a marked decrease in plasma CRP levels compared to 8% CR, while levels of CRP in 8% CR were also markedly lower. We also showed that lifelong voluntary exercise and mild caloric restriction preserve fast-twitch muscle morphology in the aging plantaris. In addition, both 8%CR and exercise protected against the large increase (+373%) in connective tissue found in OAL plantaris when compared with YAL. Furthermore, exercise protects skeletal muscle mass and muscle morphology against the effects of aging, while mild caloric restriction lessens age-induced changes in muscle morphology. In summary, lifelong exercise and 8% caloric restriction reduce oxidative stress and pro-inflammatory effects of aging in rats. This research was supported by grants to CL from the National Institute on Aging (AG17994 and AG21042) and an American Heart Association Fellowship to SJ (0215053B) and TH (0525346B).

CAN OXIDATIVE DAMAGE INDUCE GENE REGULATION? ROLE OF EXERCISE

Radák, Z.

Semmelweis Univeristy, Hungary

The ability to respond for stress plays and important role in the quality of life and effects the lifespan as well. So, it goes for a single cell and normal cellular metabolism is continuously jeopardized by internal and external stressors. Protection of cellular DNA, which contains all of the necessary codes for cell components, is vital for cells for survival. Although, nuclear and mitochondrial DNA is continuously damaged, the well constructed DNA repair systems are able to minimize the extent of damage. The protein p53 is induced by DNA damage and stabilize and activates several genes that causes cell arrest in G1, prior to the S-phase, to provide sufficient time to repair

DNA before replication takes place to prevent genetic instability. Therefore, it is not surprising that p53 regulates genes that are involved in nucleotide excision repair (NER) and base excision repair (BER). The later one is mainly specialized for repairing the oxidative damage to DNA caused by reactive oxygen species (ROS). Available information suggest, that the level of p53 is positively correlates with the activity of certain BER-enzymes. Conversely, p53 knockout cells show a very limited activity of 8-oxoguanine DNA glycosylase (OGG1), the enzyme which preferentially repair 8-oxodG in the DNA (Chatterjee et al. 2005). Interestingly, in certain cell lines H2O2 could not induce OGG1, while addition of p53 resulted in increased activity and content of OGG1. Therefore, it appears that DNA damage itself, has a potential to induce the activity of BER enzymes, via p53 and possible by other factors as well. Extensive contractions has been shown to up-regulate a number of genes, including p53, hence it cannot be ruled out that exercise-induced oxidative damage to DNA itself can activate the repair process resulting in increased activity of DNA repair enzymes.

Needless to say, that ROS are also targeting proteins and all of the amino acids residues are sensitive to modifications caused by ROS. Accumulation of oxidative protein damage can be prevented by increased degradation of modified proteins by proteasome complex, and the age-associated increase in carbonyls, marker of oxidative damage to proteins, is generally accompanied by decreased activity of proteasome. It is suggested that exercise-induced activation of proteasome, is at least some part, mediated by the generated oxidative damage to proteins.

THE ROLE OF REACTIVE OXYGEN SPECIES GENERATED BY SKELETAL MUSCLE IN SIGNALLING ADAPTIVE RESPONSES TO CONTRACTIONS

Jackson, M.J., Close, G.L., McArdle, F., Vasilaki, A., Pye, D., Palomero, J., McArdle, A.

University of Liverpool, United Kingdom

Skeletal muscle has a unique ability to adapt rapidly to changes in the pattern of activity that it performs. Following unaccustomed and demanding contractile activity numerous structural and biochemical changes in muscle have been recognised to occur. During contractile activity skeletal muscle cells generate increased amounts of reactive oxygen species (ROS) through a number of different pathways and we have obtained data that indicate these contraction-induced ROS modulate at least some of the adaptive responses that occur in skeletal muscle following contractile activity. This process involves activation of redox-regulated transcription factors, such as AP-1, NFB and HSF-1 and leads to increased expression of cytoprotective proteins that protect muscle cells against potential damage following subsequent rises in ROS activity.

MOLECULAR SPECIFICITY OF THE LOCAL TRAINING RESPONSE IN HUMANS

Flück, M., Schmutz, S., Hoppeler, H.

University of Berne, Switzerland

Background: It is commonly accepted in Sports that the adaptive potential of skeletal muscle to a given type of training is preset by the specific training state. Aerobic capacity may constitute a main determinant of the degree of adjustment for muscle oxidative metabolism with endurance training as it largely defines the relative metabolic stress with repetitive muscle contractions.

Hypothesis: The muscle gene transcript response to acute endurance exercise relates to the aerobic training state and allows a grading of the local exercise responsiveness of individuals.

Methods: Meta analysis was carried out on published results from Schmutz et al (Pflugers Arch 451(5): 678-87, 2006). During this protocol, six not-specifically trained young male volunteers pursued 6 weeks of ergometer training, 5-times a week for 30 minutes at 65% of the maximal workload (Pmax). Before and after the training, body composition, cardiovascular and respiratory performance of the subjects was characterized. Local adaptations to training were determined by ultrastructural analysis of vastus lateralis muscle and by gene expression profiling of 220 muscle-relevant transcripts throughout the first 24 hours of recovery from a 30-minute bout of exercise which matched the intensity of the 6-week training. Expression data were related to pre-biopsy values and verified for major patterns in the transcript response by public available cluster algorithms.

Results: Training improved the initial maximal power output [298 ± 22 Watt] and maximal oxygen consumption [VO2max; 42.3 ± 6.0 ml/min/kg] by 12% and 9%, respectively. This was reflected by a doubling of steady-state levels of transcripts for oxidative metabolic and related redox mechanism in vastus lateralis muscle in correspondence to a 40%-enhanced total mitochondrial volume density after training. The acute muscle response of gene transcripts to endurance exercise at the same relative intensity was blunted in the endurance-trained state. A virtually unchanged transcript expression pattern after the first exercise also discriminated the fittest individual with exceptional respiratory and cardiovascular values, i.e. a VO2max of 56 ml/min/kg, from the other untrained subjects.

Conclusion: The data support the contention that the systemic oxidative capacity modifies the molecular training response in humans. Thereby training responders appear tentatively identifiable from the analysis of the time-course of the gene response during recovery from a single bout of exercise.

Discussion: A cohort study with a well-matched human population is indicated to validate the use of combined molecular-biological and respiratory diagnostics in the prediction of the efficiency of endurance training.

Invited symposium (IS)

IS1-04 On the coordination dynamics of skill acquisition: a neglected dimension of expertise - "Albertville"

TIME SCALES AND EVOLVING LANDSCAPE MODELS OF MOTOR LEARNING

Mayer-Kress, G., Liu, Y., Newell, K.

Penn State University, United States

In physics, the analysis of time scales is a powerful tool to characterize the nature of systems that might otherwise not be accessible to us. Spectra of light from distant stars represent the internal time-scales of atoms and molecules and thereby provide us with insight not only of the composition of the stars but also their distance and most recently their rhythmic modulation reveals much information about

planets circling that star. Half-life times and growth rates - the other canonical manifestation of time scales in nature - can be observed in many pre-historic and ecological systems and tell the expert characteristic properties of the hidden processes.

Our approach to motor learning with an evolving landscape paradigm attempts to apply the powerful tools from physics to the realm of human movement. Instead of focusing on a reductionist approach of analyzing mechanical degrees of freedom we shift our attention to the extraction of characteristic time scales from learning/performance data.

From the observation of behavioral and performance data, analytical methods from the theory of non-linear dynamics of complex systems allows us to estimate the dimension of the processes generating the data. The method, known as time-delay reconstruction constitutes a significant generalization beyond traditional degrees of freedom based on mass spring models. For instance dimensions of single mechanical degrees of freedom (single finger joint) can vary over a large range as a result of psycho-physiological factors etc.

The Bernstein notion of redundancy of degrees of freedom is generalized in a landscape model to a concept of motor degeneracy in the sense that contour lines in a landscape, corresponding to a smooth continuum of different behavioral patterns (geographical points in the landscape) can produce identical performance outcomes (elevation values in the landscape). This geometrical interpretation allows a quantitative description of movement variability at invariant performance levels corresponding to Bernstein's release of degrees of freedom for skilled athletes.

We present a re-analysis of several classical data sets from the motor learning literature - such as the seminal paper 1926 paper by G.S. Snoddy - and illustrate our method with computer simulations that lead to predictions for novel experiments. The modeling effort that we explore is based on discrete, multi-dimensional iterative maps, which we find both conceptually more intuitive and not relying on the mathematically more convoluted concept of differential equations. One advantage of iterative maps is that they provide explicit time-scales in the modeling process and are naturally adopted to computational implementation.

A main future challenge is the theoretical understanding of the complete learning process involving both practice sessions as well as internal dynamics during rest periods. We present preliminary theoretical efforts along those lines.

HIT THE TARGET - HOW TO HANDLE STOCHASTIC INFLUENCES IN GOAL ORIENTED

Müller, H.

Saarland University, Germany

A central ability of the motor system is to achieve specified goals with great reliability, like we see in expert dart throwers, basketball players or shooters. This is only partly due to the fact that the extent of uncontrolled fluctuations can be reduced over practice. Furthermore there are two more components contributing to improved performance. A method is presented that decomposes this improvement into three orthogonal factors: "Tolerance", "Covariation" and "Reduction of stochastic noise". Central to this decomposition is that performance success is investigated in relation to variables in execution. Execution variables define a task space where successful performances form a subset or solution manifold.

In a virtual skittles task I will demonstrate that the actors improvement over a long sequence of trials, indicated by increasing accuracy in hitting the target, can be accounted for by the three factors mentioned: reduction of noise and Tolerance and, to a lesser degree, covariation. Different from that, the use of covariation provided considerable contributions in Darts and a boule-throwing task. This is particularly remarkable since, both ballistic movements where too short to allow sufficient closed-loop error processing. Data will be presented that are in favor of an alternative explanation. With ongoing practice learners increasingly approach an "equifinal trajectory".

Consequences of the observed phenomena to our understanding of error processing in the learning of goal oriented tasks will be discussed.

DYNAMICAL INFORMATION UNDERPINS ANTICIPATION SKILL IN PERCEIVING TENNIS SHOTS

Huys, R., Smeeton, N., Beek, P., Williams, M.

CNRS & Université de la Méditerranée, France

What information underpins visual anticipation skill in a complex discrete sport task? We examined this question in the context of anticipation to tennis shots from the premise that the invariant information resides in the dynamical features inherent within macroscopic kinematic patterns. In Experiment 1, we used principal component analysis to analyse three-dimensional kinematic data gathered from six skilled tennis players as they performed passing shots to different locations on the court. Five components captured more than 96% of the data's variance. No single component or combination of components was uniquely associated with a specific shot. However, significant differences in the eigenvector coefficients for the first five components were observed, especially as a function of shot direction. Thus, whereas shot-specific properties are allocated locally with varying degrees of variability, the same low dimensional dynamical structure governs the control of different tennis shots. In Experiment 2, we assessed the contribution of these dynamic features to anticipation skill. Skilled and less skilled tennis players anticipated the direction of simulated shots presented on a computer screen. Only dynamical features were manipulated and compared with a control condition in the form of the original shots. Simulations were generated by including components 1 to 5 in a cumulative manner. Skilled players were more accurate in anticipating shot direction than their less skilled counterparts. Furthermore, performance was not significantly different from the control condition when at least three components were included in the simulations. Moreover, the less skilled players tended to improve their performance under these simulations. In Experiment 3, the first five individual components and various combinations of components were used to create the simulations while we controlled the variance included in these simulations. Only the combination of components 1 and 3 and components 2 and 3 allowed for accurate perception of shot direction. These results indicate that multiple (i.e., three) low-dimensional dynamical components inform about shot direction and suggest that anticipation skill entails the extraction of these dynamics from high-dimensional displays.

IS1-05 Physiotherapy in sport - facts or myth - "Berlin ABC"

SPORTS PHYSIOTHERAPY INTERVENTIONS OF ANKLE SPRAINS. WHERE IS THE EVIDENCE

Clijsen, R., Taeymans, J., Clarys, P.

Akademie Physiotherapie Thim van der Laan Landquart , Switzerland

Epidemiological data show a high injury incidence of the lateral capsular ankle ligaments. About half of the ankle injuries occur during sporting activities, due to an inversion trauma. Although inversion injuries of the ankle are a common problem in physical therapy, there is a converse variety of treatment strategies and differences in therapy outcome. There still seem to be a lack of evidence-based physical therapy strategies for this problem. The aim of this study was to scrutinize to reported literature for the effectiveness of the physical therapy in patients with ankle sprain.

Relevant studies were collected by conducting a literature search using the online databases; MEDLINE, PubMed, Pedro, and the Cochrane Database of Systematic Reviews. The following keywords were used: ankle, ankle injuries, acute ankle sprain, exercise therapy, physical therapy and ankle sprain, review, guidelines for physical therapy, cryotherapy, ultrasound and laser therapy. The selection criteria were randomised trails, clinical trails, review articles, and meta-analyses.

A total of 36 studies met these criteria; among them were 18 articles, 3 reviews and 15 CCTs.

For the diagnosis there seems to be no correlation between the medical classification of injury severity and the prognosis of recovery or between the severity of the ankle ligament injury and clinical findings. This may be partially caused due to the lack of a proper diagnosis definition of ankle sprain. Especially the use of a functional score, as often used in physical therapy, within the first five days after the initial injury is a valid and reliable diagnostic method to distinguish between mild and severe injury.

In general, there is no or only marginal evidence for the effectiveness of different physical therapies such as cryotherapy, electrotherapy and ultrasound. There is body of evidence that functional treatment is much more effective than immobilisation. Because there is a wide variety of treatment modalities and because in most studies multiple treatment regimens are used, no conclusions can be drawn concerning the effectiveness of specific treatment.

For chronic ankle problems, literature indicates that a conservative treatment is superior compared to surgery. There is intermediate evidence about therapy effectiveness of chronic ankle problems. The therapy should involve an exercise program, training proprioception, muscle strength, ADL activities and normalizing mobility. Most studies conclude that there is a lack of valid instruments for a standardized assessment of the different therapy interventions in physical therapy. Inconsistent definition of both treatment aims and therapy outcome impede an estimation of the effectiveness of different forms of conservative therapy.

MECHANICAL AND NEUROMUSCULAR EFFECTS OF EXTERNAL ANKLE STABILIZERS

Alt, W., Brand, S.

University of Stuttgart, Germany

The major reason for recurrent ankle sprain is chronic instability. Large prospective and retrospective studies have demonstrated the prophylactic effects of taping and of individual ankle joint orthoses. Many other studies revealed a postexercise loss of mechanical stability.

It seems that besides external mechanical stabilization, neuromuscular stabilization could contribute to protect the ankle from injury. Stabilizing effect of external ankle support should be assed by injury simulation while recording velocity and magnitude of displacement. Many authors used "trap door" mechanisms or special "tilt platforms" in order to simulate an ankle injury by degrees of 20 to 50 degrees of inversion. Only few studies investigated the electromyography recordings (EMG) of neuromuscular activity during injury simulation - and if EMG was recorded then only latencies or maximum amplitudes were considered. In order to investigate neuromuscular or sensorimotor function of external ankle stabilizers it seems much more interesting to calculate the reflex induced integrated EMG activity during testing with and without ankle support (Alt et al., 1999). Testing a series of different ankle stabilizers in 6 different studies (tape, bandages, orthoses and shoes) a significant reduction of the induced ankle displacement magnitude could be observed for all tested ankle stabilizers with significant differences among the different stabilizers. Reflex induced EMG of lower leg muscles (m. peroneus long., m. tibialis ant.) was reduced by 5 to 15% compared to the integrated EMG without ankle stabilizer. The ratio of emg-reduction and mechanical reduction also showed significant differences. Thus one could conclude that these ankle stabilizers had different neuromuscular stimulation effects during the simulated injury. Despite improved experimental setups with increasingly complex trapdoor mechanisms the vast majority of the methods still simulate traumata under static conditions. In order to simulate the real traumatic paradigm more realistically, setups should include a dynamic situation (landing or leaping movements) without prior knowledge of the subject, which side and what movement will be induced. We managed to construct an experimental setup similar to Ubell et al. (2003) which we believe takes us one step closer to the real traumatic incidence. Our subjects wear shoes with interchangeable soles attached via a simple locking mechanism. Unaware of the character of the sole subjects perform two-footed landings and are tested under the conditions of inversion right or inversion left or no inversion.

THE EFFECTS OF ANKLE TAPING ON PROPRIOCEPTION: A SYSTEMATIC REVIEW

Cabri, J., Esteves, J., Sousa, J.P., Oliveira, R.J., Donaghie, M.

Technical University of Lisbon, Portugal

Objectives: to look for the evidence to support or challenge the use of ankle taping as a prophylactic measure or in the treatment of ankle injuries was undertaken.

Methods and Material: The literature search was carried out using three databases: PubMed, Physiotherapy Evidence Database (Pedro) and the Cochrane Library. The search was limited to articles published from 1985 to 2005 in the English language. The search terms used were: "ankle tape" or "ankle taping" combined with "proprioception" or "proprioceptive" or "joint position sense" or "kinaesthesia" or "postural sway" or "peroneal reaction time" or "peroneal latency".

Three independent trained physiotherapists were asked to review each article according to the review criteria of the Pedro Database. The reliability of Pedro scale rating is reported elsewhere [1]. All reviewers were provided with a data sheet for each article, containing the eleven Pedro criteria. Accordingly, each publication was evaluated and received a rating from 0 to 10. After the rating procedure, a consensus meeting was held where the reviewers could exchange their opinions where disagreement existed with respect to the ratings.

Results: A total of 89 references were identified from the searches. Through a number of selection procedures, only nine papers were withheld for rating. The Pedro rating scales ranged from 3.3 to 5.7 (mean) and from 3 to 6 (modus). No real randomized controlled studies were found.

With respect to the measurements of proprioception, peroneal reaction time after sudden movement (inversion of plantar flexion or a combination of both) was measured in six of the studies, whereas movement reproduction or detection were used in two. Only one of the selected reports dealt with postural sway as a measure of proprioception.

Five studies reported that ankle tape had no effect on the proprioception measurements, in one study a decrease in postural sway was found before exercise but no differences were observed after exercise, two referred that ankle tape may influence positively proprioception and consequently the ankle dynamic stability and, one publication found a delayed peroneal reaction time with ankle tape.

Discussion: As it is evidenced in this systematic review there is no extensive collection of studies investigating the effects of ankle tape on proprioception available. Better-designed, randomised controlled trials with higher methodological quality are required come to conclusive results on the effects of ankle taping on proprioception.

MUSCLE ACTIVATION DURING CYCLING AT DIFFERENT CADENCE: EFFECT OF MAXIMAL STRENGTH CAPACITY

Bieuzen, F., Hausswirth, C., Brisswalter, J.

University of Toulon-Var, France

The purpose of this study was to examine the influence of maximal strength capacity on muscle activation, during cycling, among three randomly selected cadences: a low cadence (50 rpm), a high cadence (110 rpm) and the freely chosen cadence (FCC). Two groups of trained cyclists were selected from their different maximal isokinetic voluntary contraction values (MVCi) of lower extremity muscles as following: Fmin (lower MVCi group) and Fmax (higher MVCi group). All subjects performed three four minutes cycling exercises at a power output corresponding to 80 % of the ventilatory threshold under the three cadences. Neuromuscular activity of vastus lateralis (VL), rectus femoris (RF) and biceps femoris (BF) was studied quantitatively (integrated EMG, EMGi) and qualitatively (timing of muscle bursts during crank cycle). Cadence effects were observed on the EMG activity of VL muscle and on the burst onset of the BF, VL and RF muscles. A higher EMG activity of VL muscle was observed for the Fmin group than the Fmax group at all cadences. At FCC and 110 rpm, the burst onset of BF and RF muscles of the Fmax group started earlier in the crank cycle than the Fmin group These results indicate that in addition to the cadence, the maximal strength capacity influence the lower extremity muscular activity during cycling.

NEUROMUSCULAR FATIGUE DURING PROLONGED TENNIS PLAYING

Girard, O., Lattier, G., Micallef, J.P., Millet, G.P.

University of Montpellier, Faculty of Sport Sciences, France

Introduction: Although alterations of neuromuscular function and origin of strength loss after prolonged continuous exercises (i.e. running, cycling or ski skating) have been investigated, only scarce information is available on the impairment of performance resulting from neuromuscular fatigue in activities with discontinuous high-intensity load profile such as racquet games. The aim of this study was therefore to examine the time course of impairment in neural and contractile processes of knee extensors (KE) muscles during a prolonged tennis match play. Methods: Maximal voluntary contraction (MVC) and maximal voluntary activation level (%VA) of KE muscles were measured during brief interruptions before (T0), during (30, 60, 90, 120, 150 and 180 min: T30, T60, T90, T120, T150, T180) and 30-min after (T+30) a 3-h tennis match in 12 trained players. Changes in muscle excitability were assessed by examining the characteristics of the M-wave (i.e. duration, amplitude, surface) of vastus medialis and vastus lateralis muscles and the twitch contractile properties (i.e. peak twitch, twitch contraction time, half relaxation time, maximal rate of twitch tension development and relaxation) at the same time intervals. Finally, short (0.75-s) tetanus at 20 Hz and 80 Hz were electrically evoked (model DS-7, Digitimer Stimulator, UK) and peak tetanus tension at 20 Hz (P20) and 80 Hz (P80) were recorded. The torque (Captels, FR) and EMG data (MP30, Biopac, CA) were stored (2000 Hz) with commercially available software (Acqknowledge 3.6.7, Biopac, CA). Results: MVC decreased from 250 ± 32 N.m-1 at T0 to 219 ± 48 (-13%; $P < 0.001$), 227 ± 48 (-9%; $P = 0.011$) and 222 ± 34 N.m-1 (-10%; $P < 0.01$) at T150, T180 and T+30, respectively. %VA gradually decreased throughout the exercise from T0 until T150 (83.9 ± 5.6 vs. 74.3 ± 13.2%; -11%; $P = 0.12$) before returning near initial values at T180 (85.1 ± 6.1%). No change in M-wave duration and amplitude nor in contractile properties was observed. P80 did not change significantly with exercise whereas P20 decreased by 12%; so the P20/P80 ratio was 12% ($P < 0.001$) lower in the fatigued state. The MVC/P80 ratio declined significantly (-16%; $P < 0.01$) from T0 to T180. Discussion/Conclusions: These findings indicate that changes in sarcolemmal excitability or at the crossbridge level cannot explain muscle fatigue during prolonged tennis playing. Rather, central activation failure and alterations in excitation-contraction coupling (low-frequency fatigue) are probably the main mechanisms contributing to the moderate impairment of the neuromuscular function during this activity. It is postulated that the coupling effects of accumulation of H+ and Pi, known to limit Ca2+ release, to reduce Ca2+ sensitivity and to decrease the number of strong binding cross bridges are probably among the most underlying causes.

INFLUENCE OF ENHANCED VISUAL FEEDBACK ON POSTURAL CONTROL AND SPINAL REFLEX MODULATION

Leukel, C., Taube, W., Gollhofer, A.

University of Freiburg, Germany

Introduction

Postural balance depends on many interactive processes within the central nervous system. The visual system is an important sensory source which helps to stabilize posture. Reduced visual feedback was shown to decrease postural stability and reduce the excitability of the spinal reflex system (Hoffman and Koceja 1995). Therefore, it was hypothesized that enhanced visual feedback should increase postural stability. The aim of the present study was to compare the influence of normal and enhanced visual feedback on postural stability and the excitability of the spinal reflex system.

Methods

13 healthy subjects participated in the study. Enhanced visual feedback was achieved by pointing on a blackboard with a handheld laser pointer. Stance stability was tested on a spinning-top which intensified the requirement in maintaining balance. Postural sway (center of pressure) of the standing subjects was measured with normal and enhanced visual feedback. The excitability of the spinal reflex system was ascertained with H-Reflex stimulation of the soleus muscle. The entire sway paths as well as the peak to peak amplitude of the H-Reflexes and M-waves were calculated as dependent variables for each condition. A Wilcoxon signed-rank test was used to examine differences between the conditions. An α-level of 0.05 was accepted. Data are shown as mean±SEM values.

Results

Sway path

Enhanced visual feedback resulted in less postural sway compared to normal visual feedback (176.0±13.6 cm vs. 189.3±13.5 cm, $p = 0.03$).

H-Reflexes

Enhanced visual feedback resulted in higher H-Reflex amplitudes than normal visual feedback (0.75±0.11 mV vs. 0.65±0.10 mV, $p = 0.001$). There were no differences in the stimulation intensity between the conditions. Six out of 13 subjects showed distinct M-waves with normal (0.23±0.08 mV) and enhanced visual feedback (0.23±0.08 mV, $p = 0.60$).

Discussion

The most prominent finding of this study is that enhanced visual feedback caused a significant increase in postural stability and an increase of the H-Reflex amplitudes. The spinal reflex system is thought to be suppressed when stance is unstable, probably to avoid reflex-mediated joint oscillations (Katz et al. 1988, Koceja and Mynark 2000). However, enhanced visual feedback which stabilized posture may have released the restrictions of the spinal reflex system. Presynaptic inhibition is the most likely mechanism for the change in the excitability of the Ia-afferents (Katz et al. 1988). It may be argued that constraints in the visual perception of body sway disallowed the system to minimize postural sway.

A COMPARISON OF CORE BODY TEMPERATURE MEASUREMENTS DURING PROLONGED, MODERATE-INTENSITY CYCLING AT 20°C AND 35°C

Mündel, T., Carter, J.M., Wilkinson, D.W., Jones, D.A.

The University of Birmingham, United Kingdom

The aim of the present study was to compare three different measures of core body temperature (Tcore) during exercise since there are practical problems associated with each method and, sometimes, uncertainty as to which is the appropriate measure. Seven trained males (VO2max: 61 ± 7 ml/kg/min; mean ± SD) completed two 60-min cycling trials at 65% peak aerobic power at either 20°C (CON) or 35°C (HOT) (33 ± 2% relative humidity; mean ± SE), which constituted a relative intensity of 69 ± 2% and 71 ± 2% VO2max ($p < 0.05$). Measures of core temperature were made with oesophageal (Toes) and rectal (Trec) thermistors and of the gastro-intestinal tract temperature (Tgi) with a temperature-sensitive disposable radio-pill. Mean weighted skin temperature remained constant during the trials (CON: 30.1 ± 0.5°C, HOT: 32.7 ± 0.2°C; $p < 0.001$). During CON, all three measures of Tcore increased by ~1°C in the first 20 min but thereafter Toes began to plateau and was significantly lower than Trec and Tgi at all subsequent time points, with values at 60 min of 37.7 ± 0.1°C, 38.4 ± 0.1°C and 38.2 ± 0.2°C, respectively ($p = 0.01$). During HOT, resting Toes was lower than Trec and Tgi (36.5 ± 0.1°C compared to 37.0 ± 0.1°C; $p < 0.01$). The initial rise in Toes during HOT began to slow by 20 min, so that values were significantly lower than Tgi and Trec after 30 and 40 min, respectively ($p = 0.001$). Values at fatigue were: Toes: 38.3 ± 0.2°C, Trec: 38.8 ± 0.2°C and Tgi: 38.7 ± 0.2°C ($p < 0.05$). In summary, Toes displays a more rapid response during the initial stages of cycling in thermo-neutral conditions and in the heat. However, as exercise progresses Trec and Tgi approach Toes and continue to rise to significantly higher values. As a consequence, during lower limb exercise, there appears to be a mis-match between core temperatures measured at different deep body locations.

OP1-02 General 1/1 - "Turin ABC"

DEFINING 'OLYMPISM' IN THE DISCOURSE OF THE LATE/ HIGH MODERNITY

Chatziefstathiou, D.

Canterbury Christ Church University, United Kingdom

The aim of this paper is to attempt to define 'Olympism' in late or high modernity, after identifying and evaluating the changing nature of the values associated with the ideology of Olympism in the discourse of the modern Olympic movement. Moreover, it will also seek to

address and highlight some of the key challenges that Olympism is facing today. The paper draws arguments from the findings of a large-scale study that evaluated the changing nature of the ideology of Olympism in the modern era. The method adopted was that of Ethnographic Content Analysis (ECA), a variation of the qualitative content analysis (Altheide 1996), conducted upon the writings of key sets of actors (Baron Pierre de Coubertin, Carl Diem, invited lecturers of the International Olympic Academy). The multi-causal approach of globalisation theories, which takes into account the association of Olympism and the Olympic Movement with contemporary globalisation processes and the form of society and governance they are generating, has provided an adequate explanatory framework in understanding the articulation of values associated with the ideology of Olympism in late or high modernity.

This study demonstrated how the values associated with the ideology of Olympism have changed against the contemporaneous historical, socio-political and economic contexts during the period of one hundred and eleven years (1887-1998). Values such as amateurism and women's exclusion have now been considered outdated, whereas new values such as environmentalism have been incorporated in the Olympic agenda. The nature of Olympism has been a contested one, full of inconsistencies and paradoxes throughout the modern history of the movement. The ideal of internationalism has, to a degree, been subverted by the national structure of the Olympic Games and the projection of nationalist values which has become strongly associated with the fabric of the Games, especially during the last four decades. Moreover, the ideals of universalism, multiculturalism and equality have been undermined by elitist, racist and ethnocentric references of the key players of the Olympic movement, and several practices evident in the Olympic Games such as doping, commercialisation and professionalisation. Finally, the study has highlighted the culturally diverse meanings and values associated with Olympic sport in the contemporary world, and emphasised that one of the key challenges facing those who value Olympism in a multicultural and multipolar world is the construction of consensus around its values. Olympism may be defined not as a set of immutable values, but as a process for consensus construction in terms of values in the world of global sport, since, as the last century of Olympism has illustrated, one of the few 'constants' on which one can rely is change.

DECONSTRUCTING OLYMPIC GAMES

Sentuna, B.

Middle East Technical University, Turkey

The aim of this paper is to present and figure out and link the concepts of deconstruction an Olympic Games. It is made up of three parts. First part of this paper deals with the presentation of the concept of Deconstruction and the philosophy of Derrida. Second part of this paper aims at, presentation of the concept of avenir and the deconstruction of the crucial text of Olympic philosophy, The Olympic Charter. The third part of this paper deals with the philosophical concept of Derrida, host, guest and ghost and their transfer to the Olympic taxonomy. The last part and conclusion part of this paper deals with the synthesis of this philosophical analysis and considers possible alternatives on the crisis points in the form of What should be done?

Deconstruction is popularly known as Derrida's theory in recent philosophy. It is nearly impossible and unnecessary to give a definition of deconstruction. On the other hand what it does can be figured out. . It acts together with binary oppositions, present in the context and finds the dominant and the critical element Deconstruction mainly deals with what is at hand, present at hand and, reconsiders the dominance resulting from, logo centrism, power, and politics and considers the way to resolve it, especially in the texts, taking history of philosophy into account.

The deconstruction point about the Olympic Games is mainly the "peace" ideal of the Olympic Games. Peace for Derrida is "avenir": that is future to come as it is in, democracy, and justice. It is possible as an experience of impossible which is a very hard concept. It is both linked with the political philosophy and the history of philosophy. The concept of avenir will be examined in this paper together possible experience of the impossible. The Olympic ideal of peace as it is stated in the Olympic Charter will be the main text to be deconstructed.

Another focus will be on the, strange and hard concepts of Derrida, host, guest, and ghost. Derrida not only puts these concepts into philosophical taxonomy but also puts the relations between them. The interesting and the differentiating character of this paper is, when transferred to the Olympic terminology they turn out to be Host City and the Guest Countries, and possibility of ghost interventions such as nationalism. The philosophical background of the Derridian concept will be given and their relation with the Olympic Games will be established. What does it mean to be host? What does mean to be guest and what are possible ghosts? With respect to Olympic Games are the main questions of this part of the paper.

The conclusion part of this paper is aimed at a synthesis of the deconstruction and the possible new way of presenting the Olympic ideas. The possible solutions will be discussed in detail about the Olympic Charter and the politics. Both regarding the peace and the education of the youth and also regarding the host city and the guest countries and the possible ghosts.

ESCALATION OF VIOLENCE AT THE MAKSIMIR STADIUM IN 1990 – THE BEGINNING OF WAR IN EX-YUGOSLAVIA?

Custonja, Z.

University of Zagreb, Croatia

A day after the first democratic election results in Croatia after World War II were announced, the football match between FC Dinamo, Zagreb, and FC Red Star, Belgrade, was to be held in Zagreb at the Maksimir Stadium. The match has never been played.

Main purpose of the paper is to explain historical circumstances connected with the political moment of the never played football match on 13th of May, 1990. Hooligan riots and escalation of violence, intervention of police, as well as social and historical significance of the mentioned match will be investigated. In the paper the primary and secondary sources will be used, that is, a copy of TV broadcasting and Sports News, the leading daily sport's paper in Croatia.

The "Biggest incident in the history of Yugoslav football" (Sports News, 15th of May 1990, p. 3) must be seen and discussed in a wider social and political sense. In a situation when Croatian Democratic Union had won first free and democratic elections in Croatia with independence of the state of Croatia as its main political platform, when nothing could had stopped fall of communism in Yugoslavia, and, on the other hand, when Slobodan Milosevic publicly had been speaking about Big Serbia, the football match between the greatest Croatian and Serbian football teams never had any chance to stay in the boundaries of sport.

Delije, the Red Star supporters, started to break down billboards above them before the beginning of the match. They managed to crash the fence and entered the south stand sitting area on the stadium. There were few hundreds supporters of Dinamo. Most of them started to run towards exits while some retaliated. On the TV broadcast record it is clearly visible, and it was later confirmed in the official police report, no one from either the security or the police did even try to stop the Red Star supporters from demolishing the south part of the

stadium or did anything to prevent or stop the inevitable clash of opposing supporters. At that moment Bad Blue Boys, the hard core Dinamo supporters, from the north stand started to throw stones on the police, demolished the fence and entered the pitch. Massive fight between them and the policemen started.

There are enough indices to conclude that the Red Star supporters were politically manipulated and instructed to provoke the supporters of Dinamo. Their aim was to present Dinamo supporters as violent and aggressive nationalistic people who fought against police, law and social order, and, consequently, against Yugoslavia. Main purpose of the provoked hooligan riots at the Maksimir stadium was destabilization of political scene in Croatia and prevention of peaceful and democratic transition of communist government to the new democratically elected government.

PERFORMANCE PREDICTION IN ENDURANCE SPORTS

Kleshnev, V., Whyte, G.

English Institute of Sport, United Kingdom

Performance predictions in endurance sports (running, swimming, rowing, etc) can be useful in a number of ways: In shorter terms it defines tactical plans of the race. In longer terms it can be used for setting up targets and intensity zones for training. Team managers and head coaches use so called "prognostic" or "gold standard times" for athletes' selection and optimization of squads.

Factors affecting performance in endurance sports are: training volume and profes-sionalism; training methods; technique development; equipment development; using drags and doping control.

Environmental factors (water and air temperature, wind speed and direction) have sig-nificant influence in rowing and canoeing. These factors have random nature, which creates high uncertainty and difficulties in performance prediction in these sports. We analysed long term 1900-2005 trends of world records in similar endurance events: rowing, 1500 and 3000m running and 400m swimming. The trend lines in all sports have quite similar patterns. We can define five common periods:

Before 1920. Fast growth of performance 1-1.5% per year, which can be explained by initial development of sporting technique and training methods.

1920 – 1950. Slow growth (0.5% per year) caused by two World Wars, amateur status of the athletes and lower competition due to separation of the East and West sport systems.

1950 – 1980. Very fast growth of performance 1-2% a year. Eastern block joined Olym-pic sport in 1952. Sport became a political factor and professional activity, which boomed de-velopment of training volume, methods and use of drags in sport. This performance growth was even faster in women, because it coincided with initial development in some women's events.

1980 – 1996. Slower growth 0.5-0.8% a year. Training volume approached its biological limit; effective training methods became widely known, improvement of the drag control. Rowing performance continue to grow relatively faster (1.5% a year) than in athletics and swimming. The reasons were equipment development (plastic boats and oars, big blade, etc.) and active FISA position in wider promoting of rowing and popularisation of modern training technologies.

T5 1996 – now. Stable period and even decreasing of performance, which can be seen in the latest trends of the yearly world best times in athletics.

We can speculate that the reasons could be further development of doping control methods (such as blood doping test) and sociological factors. Nevill and Whyte (2005) believe that "many of the established …endurance running world records are nearing their limits. …the athletic and scientific community may continue to explore greater performance gains through use of pharmacology and the evolving science of gene doping.

LONG-TERM THERAPY: A KEY ROLE TO TREAT OBESITY IN ADOLESCENTS

Prado, W.L., Tock, L., Caranti, D.A., Piano, A., Cristofalo, D.M., Lederman, H., Siqueira, K.O., Stella, S.G., Tufik, S., Mello, M.T., Dâmaso, A.

São Paulo Federal University, Brazil

Actually is well established that exercise is an essential non-pharmacological therapeutic to control obesity, but in literature we didn't find many researches using long-term therapy (>24 weeks). The purpose of this study was to analyze the effects of long-term treatment on body composition measurements in obese adolescents. We evaluated 18 boys and 22 girls aged between 13 and 19y with IMC>30 wt/ht2. Body composition variables were asses by pletismography; visceral and subcutaneous fat by ultrassonography. All patients were performed 24 weeks of moderate aerobic training, intensity corresponding ventilatory threshold, 3 times each week. After basic statistics, no differences were founded for neither variable, for this reason, both boys and girls were analyzed together. Despite no differences on IMC, body mass and fat%, this adolescents decreased visceral (3,58+ 1,20 to 2,75+ 0,75cm*), subcutaneous (3,14 +0,60 to 2,93+ 0,83cm*), fat mass (40,26+ 8,57 to 34,99+ 12,07kg*) and augment lean body mass (57,86+ 6,84 to 62,30+ 12,10*kg). We can conclude that long-term therapy was a powerful strategy to treat obesity in adolescents.

LOW PHYSICAL ACTIVITY LEVEL AND INCREASED BODY FATNESS IN CHILDREN AND ADOLESCENTS WITH TYPE 1 DIABETES

Trigona, B., Farpour-Lambert, N.J., Keller-Marchand, L., Oehrli, M., Martin, X., Beghetti, M., Schwitzgebel, V.

University Hospital of Geneva, Switzerland

BACKGROUND: Physical activity is recognized as an important component of the treatment of type 1 diabetes patients. However, little is known about their physical activity level. OBJECTIVE: To measure physical activity and fitness level in children and adolescents with type 1 diabetes, and to evaluate their relationships with body fatness. METHODS: Cross sectional study including 41 children and adolescents with type 1 diabetes and 61 matched healthy controls (mean age 10.5 +/- 2.6 yrs). Subjects were matched for gender, age, height, and pubertal stage. We measured 7-day physical activity count using an accelerometer Actigraph MTI; past 12-month physical activity by a questionnaire and maximal aerobic capacity (VO2peak) by a maximal treadmill test. In addition, we calculated body mass index (BMI) and assessed the percentage of body fat by DXA. RESULTS: Children with diabetes had higher BMI (18.6 +/- 2.7 vs 17.2 +/- 2.4 U, p=0.009), body fatness (22.1 +/- 7.9 vs 21.2 +/- 7.2 %, p=0.008) and lower 7-day physical activity count (305.0 +/- 91.1 vs 354.1 +/- 104.2 cpm, p=0.03) compared to controls. In the diabetic group, 34.9% were overweight and 16.3% were obese. Body fatness was negatively correlated with physical activity (r=-0.35, p=0.031) or VO2peak (r=-0.62, p=0.001). CONCLUSIONS: Children and adolescents with type 1 diabetes have reduced physical activity level and increased body fatness. As physical activity is known to reduce cardiovascular diseases risk factors, these patients should be encouraged to participate in sports.

BODY MASS INDEX, FUNCTIONAL CAPACITY AND COGNITION ACCORDING TO PHYSICAL ACTIVITY LEVEL: FOLLOW-UP LONGITUDINAL ELDERLY'S STUDY

Ferreira, M., Matsudo, S.M., Matsudo, V.K., Ramos, L.

São Paulo Federal University - UNIFESP and Physical Fitness Research Laboratory from São Caetano do Sul CELAFISCS , Brazil

PURPOSE: to compare the body mass index (BMI), functional capacity and status cognitive or cognition among elderly people according to the physical activity level (PAL). METHODS: Sample consisted of 949 elderly people from 67 to 100 years old (x: 74.9  6.7 years) derived from the first follow-up (1993/1994) of a prospective longitudinal survey, called EPIDOSO, started in 1991/1992 at São Paulo City, Brazil. PAL was determined through questions about frequency (times/week) and duration (min/week) of PAs. BMI was calculated based in body weight and body height; cognition function assessed by Mini-Mental State Examination (MMSE) and functional capacity (FC) through the AVDs and AIVDs scale. Subjects were divided in three groups according to PAL: a- Regularly Active: those who met the current PA guidelines: vigorous PA: 3d.wk-1, 20 min/day; or moderate activity: 5d.wk-1 30 min/day; b- Insufficiently Active: subjects below that recommendation; and c- Sedentary: those who did not report any PA. Statistical analysis used was one way ANOVA, Bonferroni test and delta percentual. RESULTS: The regularly active elderly people group (n: 110) reached better values of FC (0.95 points; - 57.7%; p <.01) compared to the sedentary elderly group (3.64 points) and better values for cognition (27.77; 9.63%; p <.01) compared to the sedentary elderly people group (25.33 points). The insufficiently active elderly people group (n: 52) also achieved better values in FC (1.54 points; 62.10; p <.01) and cognition (28.06 points; 1%; p <.01) compared to the sedentary elderly group (n: 787). There were not significant diference in BMI among all groups (sedent: 26.95; Insuf. Active: 27.13; Reg. Active: 27.13 kg/m2). CONCLUSION: PA level seems to have a positive relationship with performance on cognition and functional capacity tests of elderly population from a developing country.

PHYSICAL EXERCISE INCREASES ADIPONECTION RECEPTOR-1 EXPRESSION LEVELS AND IMPROVES INSULIN SENSITIVITY IN KKAY MICE

Huang, H., Tada Iida, K., Sone, H., Yamada, N., Ajisaka, R.

University of Tsukuba , Japan

Background and aims: Adiponectin is an adipocytes-derived factor, which plays pivotal roles in lipid and glucose metabolisms in skeletal muscle and liver 1). Recently, two adiponectin receptor types were identified. Adiponectin Receptor 1(AdipoR1) is abundantly expressed in skeletal muscle, whereas Adiponectin Receptor 2(AdipoR2) is predominantly expressed in liver2). Potential pathophysiologic role for alterations in AdipoR1 has been supported by the correlation between receptor expression and insulin resistance. This study aimed to investigate the effects of acute and chronic physical exercises on AdipoR1 mRNA expressions in skeletal muscle and liver and insulin sensitivity of mice.

Materials and methods: First, we used 8-week old male mice (C57BL6J, n=12) to investigate acute exercise effects on AdipoR1 expression of skeletal muscle and liver with treadmill running protocol. Furthermore, we divided 8-week old male obese/diabetes mice (KKAy, n=12) into exercise training group and control group. The mice were accustomed to the treadmill running exercise for 8 weeks. We evaluated insulin sensitivity by Intravenous Glucose Tolerance Test (IVGTT) and Intraperitoneal Insulin Tolerance Test (IPITT), and underwent Northern blot analysis for AdipoR1 mRNA expression in skeletal muscle and liver. All of the protocols were approved by the institutional animal care and use Committee at University of Tsukuba.

Results: The acute exercise increased AdipoR1 mRNA expression levels 1.1-fold at 2h and 1.4-fold at 16h after exercise bout in skeletal muscle, and 1.3-fold at 2h after exercise bout in liver ($p<0.0493$, $p<0.005$, and $p<0.0257$, respectively). The 8-week exercise training improved insulin resistance but not changed plasma adiponectin concentration and adiponectin mRNA expressions in white adipose tissue. However, the expression levels of AdipoR1 mRNA was approximately 1.8-fold greater in the skeletal muscle, 1.3-fold in the liver of the exercise training group as compared to the control group ($p<0.0006$, $p<0.0215$, respectively). In addition, AdipoR1 mRNA expression levels were associated with Acly Coenzyme A Oxidase (ACO), Carnitine Palmitoyl Transferase 1(CPT1), and Peroxisome Proliferator-Activated Receptor Alpha (PPARa) mRNA expression levels in liver, but not in skeletal muscle. Therefore, the increase of AdipoR1 expression by physical exercise in skeletal muscle may be independent transcriptional regulation, not through PPAR family.

Conclusion: Both acute exercise and 8-week exercise training induced a significant increase of AdipoR1 mRNA expression levels in skeletal muscle and liver, and it may contribute to improving insulin sensitivity in KKAy mice.

THE EFFECT OF EXERCISE AND OXIDANT-ANTIOXIDANT INTERVENTION ON THE LEVEL OF NEUROTROPHINS AND FREE RADICALS IN CEREBELLUM AND SPINAL CORD OF RATS

Siamilis, S., Jakus, J., Nyakas, C., Silye, G., Radák, Z.

Semmelweis University, Budapest, Hungary, Hungary

Reactive oxygen species (ROS) are unavoidable products of oxygen utilization and it has been shown that when central nervous system cells are exposed to ROS there is an increased production of neurotrophins particularly brain-derived neurotrophic factor (BDNF) and glial cell line-derived neurotrophic factor (GDNF). In addition, it is also known that neutrophins can improve brain function and increase the viability of neuro cells. Exercise training has a capability to significantly improve memory and other functions of the brain with effecting the redox state and neurotrophin content.

In this study we endeavor to establish a cause and effect relationship between BDNF, GDNF levels and ROS concentration in cerebellum and spinal cord in exercise study.

We tested the hypothesis that alteration of ROS concentration by H2O2, antioxidant treatment or by exercise differently modulates the BDNF, and GDNF level and physiological function. Methods: Thirty-six, 5-months old male Wistar rats were randomly assigned to one of six experimental groups: non-exercised control injected with saline (NEC), non-exercised injected with H2O2 (NEH), non-exercised injected with PBN (NEP), exercised control injected with saline (EC), exercised injected with H2O2 (EH), and exercised injected with PBN (EP).The treatment protocol consisted of 10 weeks involuntary running 5 days/week with moderate intensity 27 m/min on treadmill, between weeks 9th and 10th all groups were injected subcutaneously with saline, H2O2 and PBN respectively every other day one hour prior to running. Results: Hydrogen peroxide injection resulted in an increased BDNF concentration in spinal cord of NEH and EH groups. Exercise alone had little effect in BDNF production. The ESR indicated a significantly higher ROS concentration in the spinal cord of these groups. The BDNF concentration in spinal cord was significantly correlated with the ESR signal. The GDNF production in the same tissue did not affected by exercise but it was increased in NEH group. In the cerebellum hydrogen peroxide injected groups had both BDNF and GDNF concentrations elevated significantly. Once more the effect of exercise alone was inefficient in inducing increment in these two neurotrophins. Interestingly the ROS concentration in cerebellum was negatively correlated with both BDNF and GDNF concentration. Conclusions: These results suggest that involuntary exercise itself did not enhance BDNF and GDNF production in spinal cord but rather oxidants were more or less responsible for this increment. ESR suggests that the ROS concentration in spinal cord determine more or less the level of BDNF production in this tissue. On the other hand, results of ESR in cerebellum are more complex suggesting that this tissue reacts in opposite fashion in ROS concentration as compared to spinal cord suggesting that further investigation is needed in establishing cause and effect relationship between neurotrophins and ROS.

SOLEUS AND MEDIAL GASTROCNEMIUS SPINAL REFLEXES MODULATIONS DURING MAXIMAL VOLUNTARY CONCENTRIC AND ECCENTRIC MUSCLE CONTRACTION

Duclay, J., Pousson, M., Martin, A.

INSERM ERM 207, France

During voluntary contraction, the combined H-reflex and first volitional wave (V-wave), which is an electrophysiological variant of the H-reflex (Aagaard et al., 2002), can be used as a tool to evaluate the modulation of the spinal loop. Despite their different magnitudes, the Hmax/Mmax ratios of soleus (SOL) and medial gastrocnemius (MG) were modulated in the same manner during passive lengthening and shortening actions (Pinniger et al., 2001). This suggests that H-reflex modulation, observed at rest, was not related to muscle composition. To our knowledge, no study yet identified how the MG H/M ratio is modulated by dynamic maximal voluntary contraction (MVC).

The aim of the study was therefore to investigate if H-reflex and V-wave behaviour, observed during passive and active dynamic actions, differs between, SOL and MG due to the well known differences between these two muscles.

Experiments were performed on 16 healthy males. Maximal H-reflexes and M-waves were evoked at an ankle angle of 90° during passive shortening and lengthening actions (i.e., Hmax MmaxR, respectively) and during maximal voluntary concentric and eccentric plantar-flexion (i.e., Hsup MmaxA, respectively). During both concentric and eccentric contraction, supra-maximal stimulus intensity was used to record the V-wave (V). The Hmax/MmaxR, Hsup/MmaxA and V/MmaxA ratios were calculated in order to assess the efficacy of the synaptic transmission.

At rest, the Hmax/MmaxR ratio was significantly reduced during passive lengthening, whatever the muscle. During passive shortening, the SOL Hmax/MmaxR ratio was higher than the corresponding MG Hmax/MmaxR ratio ($P<0.001$), while during passive lengthening these ratios were not significantly different for the two muscles. Whatever the muscle, the Hsup/MmaxA ratio was higher ($P<0.001$) than Hmax/MmaxR during lengthening actions. The SOL Hsup/MmaxA ratio was lower ($P<0.001$) during eccentric than during concentric MVC, while the MG Hsup/MmaxA ratios were not influenced by the muscle action type. During shortening, the Hmax/Mmax and Hsur/Msur ratio of the soleus were higher than corresponding gastrocnemii ratio ($P<0.001$), while during lengthening these ratios were similar for any muscle. The V/MmaxA ratio did not change with the muscle or muscle action type.

SOL H-reflex seems to be more affected by presynaptic inhibition and the homosynaptic post activation depression phenomenon than MG during passive lengthening. During eccentric contraction, the increase in H-reflex, supports the concept that the spinal loop is specifically modulated by the supra-spinal center and/or neural mechanisms at spinal level (Duclay and Martin, 2005). Concerning the MG, these modulations would be sufficient to compensate for the reduction of the efficacy of the transmission in the Ia afferent -  motoneuron synapses observed during the lengthening of the muscle.

AGE RELATED EFFECTS OF SUBMAXIMAL FATIGUE ON THE MUSCLES' NEUROMECHANICAL PROPERTIES AND ON THE POSTURAL STABILITY AFTER FORWARD FALLS

Mademli, L., Arampatzis, A.

Sport University Cologne, Germany

It is generally accepted that stumble rates increase in old age and that the related injuries represent a serious social problem [1]. Further it is reported that the age related degeneration in the neuromuscular system affects the ability of the humans to regain balance after a sudden perturbation [2]. However little is known about the influence of muscular fatigue on the neuromechanical properties of the muscle tendon unit (MTU) and the related ability of the sensorimotor system to restore balance after a sudden perturbation in ageing. This study aimed to examine (a) whether submaximal fatigue has an age specific effect on the neuromechanical properties of the lower extremity MTUs and (b) whether the fatigue related changes in the neuromachenical properties have an age specific effect on the recovery behaviour after an induced forward fall.

Twelve young and twelve older male subjects participated in a series of four experiments: The first two examined the effects of submaximal fatigue on the mechanical properties and architecture of the triceps surae (TS) and quadriceps femoris (QF) MTU. The third one measured the activation level of the TS before, during and after submaximal fatigue. Finally, the fourth experiment examined the mechanics during forward falls before and after submaximal muscle fatigue, where the subjects were asked to recover balance with one single step. Statistics were done using a two way ANOVA (age x fatigue).

The old adults had lower maximum moment and tendon stiffness of the TS and QF MTU, shorter gastrocnemius medialis fascicles ($p<0.05$), but longer time to failure during fatigue. Submaximal fatigue did not alter the tendon compliance of the examined MTUs ($p>0.05$). At the end of fatigue both groups showed similar activation deficits and afterwards a similar muscle strength recovery behaviour. The ability to regain balance with a single step was reduced in old subjects as compared to young ones (51.4 vs. 80.5%). This was related to the TS and QF MTUs capacities ($R=0.531$), which correctly classified 76% of the subjects into single and multiple steppers. Submaximal fatigue did not affect the ability to restore balance in any group. Both groups were able to decrease the horizontal velocity of the centre of mass in a similar way as prior to fatigue by adjusting the knee flexion amplitude. However the gear ratios at the ankle joint were higher after fatigue, indicating mechanical disadvantages for the TS muscle. Concluding: Submaximal fatigue had no age specific effect on most of the examined neuromechanical parameters or on the compensations done to regain balance after sudden perturbation. The presence of postural corrections after fatigue suggests that the relationship between sensory signals and motor commands was being updated to match with the actual state of the capacities of the MTUs in the lower extremities.

CHANGES IN JUMP PERFORMANCE AND MUSCLE ACTIVITY FOLLOWING PROLONGED FOOTBALL-SPECIFIC EXERCISE

Oliver, J.L., Armstrong, N., Williams, C.A.

University of Exeter, United Kingdom

The aim of the study was to determine whether participation in prolonged football-specific exercise led to decrements in jump performance and alterations to muscle activity. Ten adolescent boys (15.8 ± 0.4 y) completed three jump tests before and after 42 min of football-specific intermittent exercise performed on a non-motorised treadmill. Participants performed a squat jump (SJ), countermovement jump (CMJ) and drop jump (DJ) from a height of 35 cm on a force plate. Simultaneously bipolar surface electromyography (EMG) was used to monitor the activity of the vastus lateralis (VL), biceps femoris (BF), tibialis anterior (TA) and soleus (SOL) muscles during the jumps. All data were sampled at a rate of 1000 Hz. The raw EMG signal was digitally high-pass filtered at 20 Hz, rectified and low-pass filtered at 50 Hz to produce a linear envelope using Butterworth 4th order zero lag filtering. The average EMG activity was determined for the total ground contact period and also for preactivation (100 ms preceding ground contact) and short latency component (SLC, 30-60 ms preceding ground contact) during the DJ. Following the prolonged exercise jump height was significantly reduced by 1.4 ± 1.5 cm in the SJ ($P < 0.05$), 3.0 ± 2.9 cm in the CMJ ($P < 0.05$) and 2.3 ± 1.7 cm in the DJ ($P < 0.01$). Impact force during the DJ significantly increased with fatigue by 364 ± 301 N ($P < 0.05$). The change in total EMG activity during ground contact did not significantly change during the SJ (-13.6 ± 28.6 %), whereas the reduction in muscle activity approached significance for the CMJ (-17.3 ± 23.6 %, $P = 0.065$) and the reduction was significant during the DJ (-19.1 ± 17.1 %, $P < 0.05$). Reductions in DJ total EMG activity were caused by significant reductions (all $P < 0.05$) in VL, TA, and BF activity (-32.7 ± 31.1, -21.2 ± 34.5 and -23.0 ± 26.8 %, respectively), whilst there was a non-significant increase in SOL activity (14.2 ± 33.5 %). There were no significant changes in preactivation (-1.6 ± 16.9 %) or the SLC (-17.1 ± 27.9 %) following prolonged exercise. Increases in impact force during the DJ reflect a reduced tolerance to impact with fatigue and may reflect a reduced ability to store and utilise elastic energy during the DJ and CMJ when fatigued. Greater reductions in EMG activity during the stretch-shortening cycle (SSC) jumps support the influence of proprioceptive feedback mechanisms resulting from muscle stretch. However, there was no significant change in the SLC, nor preactivation, during the DJ. Whilst SOL activity was maintained, decrements in VL, BF and TA activity during the DJ support the possibility of changes in whole limb muscle recruitment with fatigue, which could be a response to the impact and muscle stretch experienced during the DJ. In conclusion, both jump performance and muscle activity decreased after the prolonged football-specific exercise, with decrements greatest in the jumps that utilised the SSC.

ACUTE CHANGES IN HAMSTRINGS MUSCULO-ARTICULAR VISCOUS PROPERTIES INDUCED BY CYCLIC AND STATIC STRETCHING

Nordez, A., McNair, P.J., Casari, P., Cornu, C.

Universtity of Nantes, Nantes Antlantique Universities, France

Introduction

Passive stretching exercises are commonly performed in sports and rehabilitation. The acute effects of stretching on the musculo-articular viscoelasticity are a topic of continued interest to researchers. While several studies have assessed changes in passive torque or stiffness following stretching interventions [1,3]; changes in viscosity have received little attention in the literature. The ramifications of changes in viscosity are related to damping and hence the shock absorbing ability of the musculo-articular unit. This study was subsequently designed to measure changes in musculo-articular viscosity induced by passive cyclic and static stretching.

Material and methods

Eight healthy subjects were placed on a Biodex® dynamometer with the hip angle set at 60°. They performed five passive knee extension/flexion cycles before and after six 30s-static stretching repetitions. Energy stored (E) and energy dissipated (ED) were calculated for each cyclic stretching repetition as the area under the loading torque-angle relationship and the area under the loading curve minus the area under the unloading curve respectively. Musculo-articular viscosity was assessed by calculating a dissipation coefficient (DC) as ED divided by E. Surface electromyographic (SEMG) activity of the hamstring muscles were also recorded.

Results and discussion

SEMG activities of hamstring muscles were minimal and not changed by cyclic stretching repetitions nor after static stretching ($p>0.05$). E and ED decreased through cyclic stretching repetitions and after static stretching ($p<0.01$). The DC decreased through cyclic stretching repetitions (-28.8%, $p<0.001$), while it was slightly increased after static stretching (+3.8%, $p=0.037$). The decrease in DC through cyclic stretching repetitions was similar to the findings of Magnusson et al [2]. During cyclic stretching repetitions, passive torque was significantly decreased only in the early portion of the range of motion, while it was significantly decreased toward the end of the range of motion following static stretching.

The decrease in viscosity during cyclic stretching repetitions provided some evidence that the musculo-articular system displays thixotropic behavior. Three physiological mechanisms could explain the musculo-articular thixotropy: i) Stable actin–myosin bridges could participate in the passive tension and be broken during cyclic stretching repetitions, ii) the more mobile constituents of muscles (e.g. polysaccharides and water) might be redistributed, iii) collagen fibers might be aligned in the direction of the stress. The lack of a decrease in viscosity following static stretching suggests that different mechanisms have to be considered to explain changes in passive torque following our static stretching protocol.

RECONSTRUCTION OF THE HUMAN TRICEPS SURAE MUSCLE-TENDON UNIT BASED ON MRT IMAGES

Albracht, K., Baltzopoulos, V., Arampatzis, A.

Institute of Biomechanics and Orthopaedics; Institute for Biophysical & Clinical Research into Human Movement, Germany

Knowledge of the external (volume, shape) and internal (fascicle arrangement) characteristics of a muscle's architecture is required to assess in vivo muscle performance and provide a better understanding of muscle function through modelling. Available data on human muscle architecture is mostly based on cadaver tissue [1, 2], although recent imaging techniques as magnetic resonance (MR) imaging or ultrasonography allow obtaining such parameters in vivo. The triceps surae (TS) has often been modelled in spite of the little information available on its three-dimensional (3D) geometry throughout the entire volume in vivo. Therefore, the aims of this study were to reconstruct the 3D geometry of the TS including its internal architecture and to create a relevant database from in vivo measurements to be used in muscle modelling.

Transversal MR images (4mm contiguous slices) were acquired from the right calf of 10 male subjects (height 1.8 ± 0.4 m, weight 76 ± 6 kg, age 29 ± 6 years) in neutral anatomical position. Seven sets of MR images were needed to cover the entire TS. The boundaries of the three TS muscles were outlined manually for each slice. From these transversal contours a B-Spline muscle model of the MTU was created as proposed by Ng-Thow-Hing (2001). Tibia and Fibula were also digitised and served to define a reference coordinate system. Fascicle length and pennation angle of all three muscles were determined by ultrasonography.

Finally we obtained a geometrical reconstruction of the soleus (SO), the gastrocnemius medialis (GM) and lateralis (GL) providing a detailed 3D description of the TS geometry. The muscle volumes and MTU lengths were 466±54cm3 and 41.5±2.0cm for the SO, 284±45cm3 and 50.0±2.5cm for the GM, and 146±24cm3 and 47.6±2.4cm for the GL. The shapes of the GM and GL were similar whereas the SO shape was obviously different. This is indicated by the fact that the location of the of maximum cross section area in relation to muscle length differed across muscles (SO 62±4% GM 46±7% GL 49±4%). When normalised to the tibia length, muscle length or MTU length the variability of the retrieved parameters ranged from 5 to 10 % across subjects. Only a few parameters as the ratio between fascicle length and muscle length (SO 25% GM 17% GL 13%) showed a higher variability.

The observed non-uniformity of the external and internal architecture between the TS muscles may influence their predicted interactions and therefore underpins the importance of accurate assessment of this parameters for muscle modelling. All together, the reconstructions and the low inter-individual variability of the the parameters determined in the present study indicate that it is possible to assess the architectural characteristics of the TS and to create a scaleable muscle model.

SPORT, WELLBEING AND DEVIANT BEHAVIOR: A CROSS-SECTIONAL STUDY WITH SWISS ADOLESCENTS

Moesch, K., Birrer, D., Seiler, R.

Federal Institute of Sports Magglingen & University of Berne, Switzerland

Introduction: Sport is considered an effective means in reducing deviant behaviour in adolescents. Nevertheless, no empirical evidence has found a direct correlation between sport involvement and deviant behaviour (e.g. Brettschneider et al. 2005). This study examines the impact of wellbeing as a mediating variable between sport and deviance. We hypothesised that sport involvement has a positive effect on wellbeing, and high wellbeing reduces deviant behaviour. Gender differences were also predicted.

Method: 250 male and 292 female adolescents from the German speaking part of Switzerland aged 12 to 18 consented to participate in the study and completed a batch of questionnaires. Sport involvement was measured with the Sport and PHysical activity INdeX (SPHINX) developed by Brettschneider et al. (2005). The SPHINX integrated five variables including both attitudes toward sport and overt sport behaviour. Wellbeing was assessed with the questionnaire for adolescents (BFW, Grob et al., 1991). Deviance was measured through five different scales (Heitmeyer, 1998; Tillmann et al., 2000): attitudes towards and justification of deviance, delinquent behaviour, psychological and physical violence. These five variables were summarised to one single factor through a rank order procedure. For descriptive statistics, the five scales were examined separately. The proposed SEM was calculated for both genders, using generalised least square (GLS) estimation.

Results: As hypothesised, girls showed significantly lower values than boys in all deviance scales with gender explaining variances between 2.9% and 12%. For both genders, the SEM revealed a positive effect of sport involvement on wellbeing. The regression coefficients were .37 and .33, respectively, with marginally higher values for girls. Further, regression coefficients -.45 (girls) and -.48 (boys), respectively, revealed a negative relationship of wellbeing on deviance.

Discussion: In agreement with the hypothesis, results revealed that wellbeing might be a mediating variable in the relationship between sport involvement and deviance. However, it should not be overlooked that the Fit Indices were only moderate. More research is needed to elucidate the role of sport as well as other possible mediators on deviant behaviour.

RELATIONSHIP BETWEEN STPI-Y SCALES AND LIFESTYLE DEFENSE MECHANISM INVENTORY MEASURES AT MALE AND FEMALE PE STUDENTS

Levente, B., Sipos, K.

Semmelweis University Faculty of Physical Education and Sport Sciences, Hungary

Introduction:

This study reports on examination results on two recently standardized test; State-Trait Personality Inventory-Y (STPI-Y) and Lifestyle Defense Mechanism Inventory (LDM), aiming to get information about some characteristic features of different level of high school athletes. In the earlier study we compared STPI (Spielberger, at al., 1980, Hungarian version Oláh, 1987) results of male (N=59) and female (N=48) PE students in a smaller population. The gender difference in STPI was found in State Anger, and Trait Anxiety: males had higher Anger ($p<.02$) and lower Anxiety level ($p<.05$) than females (Kudar, 2003).

Subjects:

253 PE students (120 second year student in the academic year of 2003/2004 and 133 second year students in 2004/2005; average age: 20,38 years; SD 1,78) 115 males and 138 females are active in different sports. The Hungarian versions of STPI-Y and LDM scales were administered in classroom situation. We have compared the groups of top level and leisure-time athletes and have accounted relationship between the STPI-Y and LDM scales. SPSS program was applied for the statistical analysis of data.

Method

State–Trait Personality Inventory-Y (Spielberger, 1995, Hungarian version Sipos et al., 2004). STPI-Y contains: State/Trait Anxiety, -Curiosity, -Anger, and –Depression scales. The Lifestyle Defense Mechanism Inventory (Spielberger, 1987) has two scales: Rationality-Emotional Defensiveness (R/ED) and Need for Harmony (N/H) scales. Both LDM scales have two subscales: R/ED has Rationality (R) and Anti-emotionality (A), while N/H has Harmony (H), and Self-sacrifice (S)

Results

The results show gender differences for trait anxiety in both samples (Group A: 2003/2004 year; and group B: 2004/2005 year). The male PE students are less anxious than females, In the group A they are less curious-, in the group B they are less depressed than females

Concurrent validity: the three "negative" emotions (anxiety, depression, and anger) of STPI-Y correlates significantly in negative direction with R/ED scale results of LDM inventory for both male and female samples. Trait curiosity correlates positively with both LDM scales for females while such connection has not occured among males. Correlation of STPI-Y State anger scale scores and the LDM scales results reveals the sensitivity of the LDM scales. State anger and R/ED scores go parallel, State anger and N/H values have inverse correlation only for males.

Conclusion:

In both gender groups the higher level of negative emotions (anxiety, anger, and depression) goes parallel with the lower level of both coping mechanisms (R/ED and NH). These negative correlations are much stronger at males than at females. But in the female group there are strong positive correlations between the curiosity and the two coping strategies. It seems that negative emotions prevent the males to use coping skills, while the positive emotion of curiosity (openess in other words) assists the females to use both LDM strategies.

AN INTERVENTION-STUDY BASED ON THE TRANSTHEORETICAL MODEL

Pfeffer, I.

University of Leipzig; Faculty of Sport Science, Germany

Physical activity has positive effects on several health parameters. Despite this knowledge, only 10-15% of the adults in the western civilised countries are regularly physically active (Sallis & Owen, 1999). Thus, to encourage people to an active lifestyle is a central challenge in health sciences.

The transtheoretical model (TTM) conceptualises behaviour change as a process based on three central constructs: five stages of change, processes of change (cognitive and behavioural) and cognitive variables (self-efficacy and decisional balance). The processes of change describe why and how a person can progress from one stage to the next. The TTM was originally developed in health psychology, but has become popular in exercise psychology as well. But, according to the results of a meta-analysis, Rosen (2000) states, that the postulated stage-specific use of the processes is probably not transferable to exercise behaviour.

To challenge the findings of Rosen (2000), the present study examines effects of two different psychological interventions based on the TTM (cognitive and behavioural) on postulated psychological variables and stage progression. A longitudinal quasi-experimental study with treatment-control group design (pre-, post-test and follow-up) was planned. Participants were 113 individuals (97 females) which were not regularly physically active before. They took part in 12-week endurance courses. Measures were standardised scales of self-efficacy (motivational and coping self-efficacy), decisional balance (expected positive and negative consequences) and processes of change (cognitive and behavioural processes). The stages of change were measured by a standardised algorithm.

The results of a MANOVA with repeated measures (independent variable (iv): intervention; dependent variables (dv): self-efficacy, decisional balance and processes) show, that there is no effect of intervention on self-efficacy, decisional balance and processes. However, there is a significant time-effect for these variables. Data show an increase in use of both, cognitive and behavioural processes, an increase in coping self-efficacy, and a decrease in expected negative consequences over time. A second MANOVA with repeated measures (iv: stage transition; dv: as before) shows a significant main effect of stage transition. Improvers use significantly more behavioural processes than non-improvers and are much more confident to be able to continue exercising regularly as well as to cope with difficult situations. There is also a significant interaction effect stage transition*time. Improvers show an increase in behavioural processes and motivational self-efficacy, while non-improvers level off.

ARE FALLS INFLUENCED BY PERSONALITY, SEX, AND AGE?

Engelhard, K., Kleinert, J., Bock, O.

German Sport University, Germany

According to the BAuA statistics 38% of the registered accidents without fatal consequences were commuting accidents. Previous studies provided inconclusive evidence about the reasons for falls. Based on the ideas of Marbe (1923) the present study investigates whether there is support for a personality based disposition for falls.

30 young (M = 25.40; SD = 3.22) and 30 old people (M = 65.52; SD = 4.47) participated in the study. Walking speed was 0.8 m/s for seniors, and 1.2 m/s for younger participants. While walking on a treadmill, they had to cross obstacles both as a single task (OC_S) and with a concurrent secondary task (signal detection task; OC_C). Up to six weeks after the experiment participants completed questionnaires regarding the personality traits fear, and locus of control. A cluster analysis based on the questionnaires resulted in two groups, which could be characterized as being less anxious and rate rather low on external locus of control (cluster 1) versus being rather anxious and rate rather high on external locus of control (cluster 2). Influence of age, sex, and cluster on motor performance (number of obstacle contacts) in OC_S, and OC_C were examined.

We found a statistically significant effect for condition (OC_S > OC_C; $p < .01$). but none for age ($p = .24$), or sex ($p = .20$). Influence of personality just bordered on statistical significance (cluster 1< cluster 2; $p = .07$). Thus, results indicate that despite not reaching statistical significance, personality does influence motor performance more than sex and age. Therefore, development of prevention programs has to consider personality as a relevant factor.

THE RELATIONSHIP BETWEEN ATHLETIC SELF-PERCEPTIONS, EXERCISE MOTIVATION, AUTONOMY, SOCIAL CONNECTEDNESS, AND PHYSICAL ACTIVITY IN OLDER ADULTS

Rose, E., Stewart, A., Cox, K., Puddey, I.

Edith Cowan University, Australia

One of the most important changes in the Australian population in recent decades is that people are living longer. In the interests of physical and psycho-social health in older age, and reduced strain on resources, programmes have been designed to encourage adults to have better quality of life through physical activity. The key to success of such initiatives may lie in motivational theory that links self-perceptions, self-determination, autonomy, and social relationships to level of participation in physical activity. We hypothesized that higher levels of athletic self-perceptions would be positively related to self-determined aspects of motivation, autonomy, social connectedness, and higher levels of physical activity. The findings presented are from a pilot of the Physical Activity Time for Health study designed to increase physical and psycho-social benefits in older adults. Volunteers (male, n = 21; female, n = 25) (age range 50 to 80 years; M = 71.2, SD = 5.84) recruited from senior interest groups and the larger community completed the a) Adult Self-Perception Profile, b) Social Connectedness Scale - Revised, c) Measure of Actualization of Potential - Autonomy, (d) Exercise Motivation Scale (7 sub-scales, measuring motivation from self-determined to externally self-determined), and e) Physical Activity Scale for the Elderly. Associations were analysed using Pearson's Product Moment Correlation. Significance was set at $p < .05$. The mean physical activity level score was 175.3 (SD = 71.41) indicating an active group. Only athletic self- perceptions were positively related to level of physical activity ($r = .38$, $p = .009$). Athletic self-perceptions were inversely related to the externally determined dimensions of exercise motivation: amotivation ($r = -.32$, $p = .032$), external regulation ($r = -.43$, $p = .003$), and introjected regulation ($r = -.32$, $p = .028$). In contrast, athletic self-perceptions were positively related to more self-determined dimensions of exercise motivation: integrated regulation($r = .31$, $p = .038$), intrinsic motivation to learn ($r = .35$, $p = .017$), intrinsic motivation to achieve ($r = .39$, $p = .008$), and intrinsic motivation to experience, ($r = .35$, $p = .019$). There was no significant relationship between athletic self-perceptions and identified regulation ($r = .03$, $p = .829$). Athletic self-perceptions were positively related to autonomy ($r = .43$, $p = .003$) and to social connectedness ($r = .39$, $p =. 008$). This study supports previous findings, that individuals with high athletic self-perceptions are generally more autonomous, more socially connected, and are more likely to be self-determined in their motivation towards physical activity. Importantly, they also have higher levels of physical activity. In designing programmes to promote physical activity, there is need to consider enhancement of older adults' athletic self-perceptions and implications for self-determination, autonomy, and social connectedness in exercise.

COGNITIVE AND PERCEPTUAL MECHANISMS SUPPORTING EXPERT ANTICIPATION AND SITUATIONAL ASSESSMENT

Ward, P.

Florida State University, United States

In the absence of differences in the structure of heuristic search between chess players at the expert and grand master level (de Groot, 1965), Chase and Simon (1973) focused on large individual differences in the encoding and recall of briefly presented chess positions as a function of expertise. This pioneering research on expertise spawned a host of studies examining recall and recognition, and the associated knowledge assumed to be responsible for superior performance. However, numerous examples now exist across various domains where experience and tests of recall and recognition performance do not adequately capture or explain expert superiority (Ericsson & Lehman, 1996). Accordingly, this presentation is primarily concerned with the utility of the expert-performance approach to elicit superior performance on representative tasks as opposed to domain-general tests, such as memory and visual function, and then to examine the perceptual-cognitive processes underpinning such superiority. In the first experiment, elite and sub-elite soccer players from 8 to 18 years of age were tested on a battery of domain-specific simulations and domain-general tests that assessed the visual, perceptual and cognitive skills underpinning superior game-reading. Rather than being endowed with superior visual function or relying upon superior recognition of patterns, elite players made more accurate predictions about future events through anticipating an opponent's next move and making a superior situational assessment (see Ward & Williams, 2003). In a subsequent study, the most predictive simulation tasks (anticipation and situational assessment) were combined to assess the nature of the cognitive and perceptual mechanisms supporting performance. Concurrent think-aloud reports were recorded while elite and sub-elite adult soccer players made anticipations and assessed designated game situations with and without continued perceptual access (see Ward, Ericsson, & Williams, 2006). Elite players demonstrated superior accuracy on each task. The data provide support for a dual function in long-term working memory (Ericsson & Kintsch, 1995). Elite players representations facilitate direct access to information necessary to make immediate predictions as well as provide memory support (e.g., planning, monitoring, and evaluation) for performance. As opposed to explanations of expertise based on automatic and pattern-recognition-type processes, the data support explanations of expert performance based on complex representations and comprehension-type mechanisms (e.g., Kintsch, 1988, 1998; Ericsson & Kintsch, 1995). Discussion is offered on how mechanisms, such as the situation model, might be used to generalize across performance in traditional and more dynamic and real-world domains that often necessitate operation under time pressure and stressful circumstances.

IDENTIFYING THE CRITICAL INFORMATION SOURCES UNDERPINNING SKILLED PERCEPTION IN SOCCER

North, J.S., Williams, M.

Liverpool John Moores University, United Kingdom

Anticipation is essential to elite performance in sport. Pattern recognition is thought to be central to anticipation skill (Williams et al., 2006). We present a series of experiments designed to identify the features underpinning anticipation and pattern recognition skill in soccer. In Experiment 1, skilled and less-skilled players' visual search behaviours were assessed when recognising patterns of play in film and point light display format. In Experiment 2, retrospective verbal reports were collected immediately post-performance to identify the cognitive mechanisms underlying performance. In Experiment 3, a temporal occlusion paradigm was used to assess the critical time period for information extraction during pattern recognition. Finally, the relationship between anticipation and pattern recognition was examined. Initially half the participants passively viewed dynamic soccer sequences, while the other half had to anticipate pass destination. Participants later performed a recognition task. Visual search behaviours were recorded to compare processes underpinning anticipation and recognition and performance was correlated across the tasks. It was predicted that skilled soccer players would utilise the relational information between players to recognise patterns rather than more superficial display features. If pattern recognition is an essential component of anticipation, performance on the tests was predicted to be correlated and the processing strategies not to differ.

Skilled players were better at anticipating and recognising patterns of play regardless of whether sequences were presented in video or point light format. Visual search data showed that information from central attacking players was particularly important. Verbal report data indicated skilled players showed greater awareness of a wider range of players and spent less time thinking about the ball and player in possession than less-skilled players. Superior performance was observed when responding to clips lasting 3 sec rather than 1 or 5 sec. Elite performers develop task specific knowledge structures that facilitate effective anticipation and pattern recognition in soccer (Ericsson & Kintsch, 1995). Skilled performers view the display in the same manner whether asked to anticipate or not. However, the processing strategies underpinning anticipation and recognition are fundamentally different. Also, the relationship between anticipation and recognition is not strong. In conclusion, skilled soccer players utilise relational information between players when perceiving patterns of play. However, pattern recognition may not be an essential component of anticipation.

DECISION-MAKING SKILLS IN YOUTH SOCCER

Vaeyens, R., Lenoir, M., Williams, A.M., Philippaerts, R.M.

Ghent University, Belgium

Skilled perception precedes and determines appropriate decision-making in sport. This assumption has stimulated researchers in the perceptual-cognitive domain to implement an information-processing framework in their quest to isolate the fundamental characteristics of expertise (Williams et al., 2002). Thus far, progress in identifying the important mechanisms underlying decision-making skill has been

fairly limited, especially in youth soccer. The aim in this paper is to examine the validity of a film-based test for measuring decision-making skill in soccer. Moreover, differences in visual search behaviour and practice history profiles are discussed.

Participants included 87 youth soccer players (13.0-15.8 yrs) varying in skill and experience (elite, sub-elite, regional level and non-soccer group). We used 33 realistic film simulations involving offensive microstates of play, i.e., 2 vs. 1, 3 vs. 1, 3 vs. 2, 4 vs. 3, and 5 vs. 3 offensive situations. Performance was assessed using movement-based response measures (decision time and response accuracy) and an eye movement registration technique. In a subsequent analysis, 40 youth soccer players were assigned to a successful (S) or unsuccessful (U) group based on their test performance.

As predicted, significant differences in performance were observed between players and non-players and across three groups of soccer players matched on playing experience but differing in skill level. The majority of the soccer players were classified in agreement with the skill level grouping. Kappa analysis showed a fair kappa value (κ = .26, P = .51, p < .005). For the S and U group categorization, analysis revealed a substantial kappa value and a high proportion of agreement (κ = .62, P = .82, p < .001). More pertinent visual search strategies enabled S youth soccer players to exhibit superior decision-making skill, as characterized by faster decision times and greater response accuracy, when compared with their U counterparts. Overall, successful decision-makers employed a search pattern involving more fixations of shorter duration, spent more time fixating the player in possession of the ball and alternated gaze more frequently between this player and other areas of the display.

The current results suggest that film-based tests can be used to discriminate players of comparable experience level and that tactical proficiency determines, at least partially, both the observed visual search behavior and the processing requirements imposed on youth soccer players in dynamic offensive team simulations. Successful players may use the player in possession of the ball as a central point of reference to explore the information in open offensive microstates of play.

Williams, A. M., Ward, P., Knowles, J. M., & Smeeton, N. J. (2002). Perceptual skill in a real-world task: Training, instruction, and transfer in tennis. Journal of Experimental Psychology: Applied, 8(4), 259-270.

ENHANCING THE RESPONSE SPEED, ACCURACY, AND DECISION MAKING OF SENIOR TENNIS PLAYERS USING A PERCEPTUAL SKILLS TRAINING PROGRAM

Janelle, C., Caserta, R.

University of Florida, United States

Senior athletes encounter numerous physical and psychological barriers that render participation in dynamic sports increasingly difficult as they age. Athletes of all ages who successfully participate in open sports such as tennis must be able to efficiently gather, sort, and process massive amounts of information to anticipate, make decisions, and respond appropriately. Researchers have suggested several factors that permit performance maintenance and improvement in master level athletes (Starkes, Weir, & Young, 2003). This seminal work has implicated perceptual and cognitive skills as requisite for the preservation of expertise. As such, perceptual skills training (PST) would be expected to benefit senior level athletes, particularly those involved in an open sport such as tennis. Though PST has consistently been shown to benefit sport performance among college-aged and young adult athletes in a wide range of reactive sports, whether and to what extent PST might benefit senior athletes remains unknown. The primary purpose of this investigation, therefore, was to determine if PST (i.e., situation awareness, anticipation, and decision-making) improved on-court performance in older adults when compared to a physical training program (i.e., stroke and footwork development). We hypothesized that senior tennis players trained with situation awareness, anticipation, and decision-making would demonstrate enhanced perceptual-cognitive skills (i.e., respond faster and more accurately as well as make more appropriate decisions during tennis match situations) when compared to those provided with physical or no training. Senior tennis players (N = 27, males n = 10), were randomly assigned to one of three groups who were provided with (1) PST, (2) physical skills training, and (3) no training, respectively. Prior to training, each participant was individually pretested in a 4-game singles match against a PTR certified tennis professional. After the respective week long training sessions (40 minutes daily), each participant was posttested in another 4-game singles match against the same tennis professional. Results indicated that participants receiving PST had significantly faster response speeds, higher percentage of accurate responses, and higher percentage of correct performance decision-making in posttest match situations. Findings provide clear evidence that perceptual-cognitive skills can be trained in aged individuals. Given that seniors represent a segment of the population that might benefit most from enhancement of perceptual skills, implications and suggestions for future research are offered.

Invited symposium (IS)

IS1-07 What is wrong with obesity? - "Innsbruck"

INTRODUCTION

Schuetz Y., CH

Without abstract submission.

PHYSICAL ACTIVITY BEHAVIOUR: AN UPDATE

Oppert, J-M.

University Pierre et Marie Curie-Paris6, France

Obesity affects an increasing number of individuals worldwide and is associated with serious health risks. Body weight gain over time depends on a complex interplay of behavioural, environmental and genetic factors. It is generally accepted that physical inactivity is an important factor in the development of obesity. This however has to be put in the nutritional context of the population under study. Independent of physical activity level, sedentary behaviours such as television viewing have been associated with obesity and related meta-

bolic complications. Decreasing sedentary behaviour as well as increasing the level of habitual physical activity appear therefore warranted for obesity prevention.

In patients, physical activity is recognized as an integral part of obesity management. A major benefit of physical activity is the association with better long-term weight maintenance of weight loss. Physical activity has also been shown to substantially decrease the risk of obese subjects for metabolic and cardiovascular disease. A critical, and still unresolved, question is the optimal volume of physical activity that would allow prevention of weight regain in obese patients. A progessive, step-by-step, individually-tailored approach to increasing physical activity is needed in the long-term management of the obese patient. One of the challenges in this area is to better understand how to improve adherence over time.

FOOD BEHAVIOUR : NEW APPROACHES

Golay, A.

Geneva University Hospital, Switzerland

Prevention of weight regain must be integrated in the follow-up of an interdisciplinary programme of weight loss and maintenance.

Therapeutic patient education is a patient-centred approach, focused on obese patients' needs, resources, values and strategies. It allows obese patients to improve their knowledge and conceptions not only concerning their chronic illness and eating disorder, but also their weight loss programme. It brings a better quality of life, a greater therapeutic compliance and a reduction in weight regain. The most difficult part of therapeutic education occurs when patients must change their behaviour.

Motivational interviewing techniques contribute greatly and allow both the preparation and support of patients during progressive "step by step" change. The work on resistance to change is fundamental, and ambivalence must be discussed and negotiated. Patients become partners and we become "coaches". The negotiation of objectives must allow patients to choose their own strategies, which normally should cost them the least possible psychologically and bring them the maximum benefit.

Psycho-social obstacles coming from patients and their environment are very common and should be detected. Emotions, negative thoughts, cognitive restriction, cognitive distortions are approached by cognitive-behavioural therapy.

Finally, the motivational interviewing and the cognitive-behavioural approaches are perfect complements to therapeutic education for long term weight loss maintenance with more than 50 % success over 5 years. The patients become active and co-responsible for their own weight maintenance programme with the aim of improving their quality of life as well as reducing potential relapse.

PLASTIC CHANGES IN BRAIN ACTIVATION AS A RESULT OF LEARNING A NEW MOTOR SKILL: DYNAMICS OF LEARNING-RELATED INCREASES AND DECREASES IN BRAIN ACTIVATION

Swinnen, S.P., Puttemans, V., Wenderoth, N.

K.U.Leuven, Belgium

Functional magnetic resonance imaging was used to trace the shifts in brain activation from an initial to a skilled and finally over-learned stage. Performers were scanned prior to training (PRE) and after one (MID) and two weeks (POST) of intensive practice on a new bimanual coordination task. Kinematics revealed major improvements during the intitial stages of practice whereas performance leveled off towards the end of practice. The analysis of the brain activations revealed increases as well as decreases that were associated with the development of skillful performance. Activation was found to decrease in bilateral ventrolateral-prefrontal cortex, bilateral opercular areas, the right ventral premotor and supramarginal gyrus, and the anterior cingulate sulcus during the initial stages, and in the supplementary motor area (SMA) during the automatization stage. These changes are hypothesized to reflect decreases in attention-demanding sensory processing as well as suppression of preferred coordination tendencies as a prelude to acquiring new coordination modes. Conversely, learning-related increases were observed in the primary motor cortex, posterior cingulate zone, putamen and right anterior cerebellum. Importantly, motor cortex and posterior cingulate activation decreased again to initial level during automated performance whereas only the putamen and anterior cerebellum remained more activated across both learning and automatization stages, supporting the crucial role of subcortical areas in long-term motor memory formation for coordination tasks. The results will be discussed in view of the neural correlates of building central movement representations as a result of practice and experience.

CENTRAL ADAPTATIONS TO STRENGTH TRAINING AND IMMOBILIZATION

Nielsen, J., Jensen, J.L., Petersen, T.H., Geertsen, S.P.

Institute of Exercise and Sport Sciences, Denmark

Optimization of the connectivity of neuronal circuitries in the motor areas of the brain and spinal cord is the basis of improved task performance during motor learning. We have recently demonstrated that learning a new visuo-motor skill is accompanied by increased excitability of the corticospinal projections, increased corticomuscular coherence and depression of the central component of the stretch reflex of the trained muscle (Perez et al. 2004; 2005). Here, we investigated whether adaptations at spinal and cortical level also accompany strength training and immobilization.

10 healthy human subjects strength trained the ankle dorsiflexor muscles 3 times a week for 4 weeks. 1RM increased by 8% ($P < 0.001$) and 14% ($P < 0.001$) following 2 and 4 weeks of strength training, respectively. No changes were observed in the threshold and size of motor evoked potentials (MEPs) in the tibialis anterior (TA) muscle. There were also no changes in the suppression of the voluntary TA.EMG following the training, indicating that there were no major changes in corticospinal drive. Functional magnetic resonance imag-

ing (f-MRI) also failed to demonstrate any significant changes in the blood flow in the primary motor cortex following training. These findings indicate that strength training is not accompanied by similar changes at cortical level as seen during motor skill training.

Following two weeks of immobilization of the ankle joint a significant increase of the soleus H-reflex was observed. Soleus MEPs on the other hand were unchanged. Post-activation depression of the Soleus H-reflex decreased following immobilization, suggesting that the increase of the H-reflex was caused by changes in the probability of transmitter release from Ia afferent synapses secondary to reduced afferent activity during the immobilization.

NEURAL CORRELATES OF RHYTHMIC AND REACTIVE SENSORIMOTOR COORDINATION

Oullier, O., Jantzen, K.J., Steinberg, F., Kelso, J.A.

Université de Provence-CNRS (Marseille, France) & Florida Atlantic University (Boca Raton, USA), France

Previous imaging studies have reported differences in the neural networks supporting synchronized (moving on the beat) and syncopated (moving off the beat) sensorimotor coordination. Syncopation generates greater BOLD amplitude across a broad network that includes SMA, premotor cortex, cerebellum and basal ganglia. These regions are often ascribed roles in planning, preparation and timing leading to the hypothesis that while synchronization is carried out automatically, syncopation is planned on a movement by movement basis. This hypothesis suggests syncopated movements may be carried out in a discrete as opposed to rhythmic fashion.

Here we investigate neural similarities and differences in the networks engaged for the performance of synchronized, syncopated and reactive movements. BOLD activity was measured while subjects (n=11) executed rhythmic or discrete sensorimotor coordination patterns. Subjects timed uni-manual finger opposition movements with respect to an auditory metronome delivered a constant rate (1.25 Hz). In the rhythmic tasks, subjects moved with each beat of the metronome (synchronization) or in between each beat (syncopation). In the discrete task, subjects were asked to react only after the occurrence of each beep (reaction).

When statistically compared to synchronization, reaction and syncopation demonstrate increased BOLD activity across a number of common brain areas. Greater activity for these two conditions was mainly located into the cingulate gyrus, the thalamus, the middle frontal gyrus and the SMA illustrating the additional preparation and planning necessary to perform these two modes of coordination compared to the more automated synchronization pattern.

While syncopation and reaction share some common neural features, reaction is distinguished by activity within a distinct fronto-parietal network. When the discrete (reactive) condition was compared to synchronization and syncopation significant differences were found in frontal and parietal areas as well as the thalamus and the cerebellum. Brain imaging studies have reported coactivation of the prefrontal and parietal cortices in task involving working memory and response selection. It may be that the activity in these areas reflects the stimulus driven nature of the reaction movement. The fact that activity is not seen during syncopation may indicate that the off-the-beat movements, while coordinated with the metronome are performed based on an internal representation of the coordination task and not directed solely by external stimulus input.

In line with recent studies, we found than in addition to areas involved in rhythmic coordination (synchronization), a specific network of activity underlies discrete tasks (reaction). This indicates that in spite of sharing common additional premotor and planning processes compared to purely rhythmic coordination (synchronization), syncopation differs from a purely discrete/reactive task.

INTRODUCTION TO THEORIES: WHAT, WHY, WHEN AND WHERE

Biddle, S., UK

Without abstract submission.

SELF-CONCORDANCE AND THE DEVELOPMENT OF HABITUAL PHYSICAL ACTIVITY

Fuchs, R., Seelig, H.

University of Freiburg, Germany

According to the Motivation-Volition-Model (MoVo-model; Fuchs, 2005) two aspects of goal intentions sensu Gollwitzer (1999) can be distinguished: goal strength and goal self-concordance. In previous studies goal strength has been shown to be a strong predictor of physical activity whereas the empirical status of goal self-concordance (Sheldon & Elliot, 1999) is still undetermined. Based on longitudinal data (N= 210) with two points of measurement (time interval: 10 weeks) two models were tested: Model A considers goal self-concordance to be an antecedent of goal strength which in turn predicts physical activity; model B conceptualizes goal strength and goal self-concordance to be concurrent factors in predicting physical activity. Structural equation analyses (AMOS 4.0) support model B suggesting that goal self-concordance and goal strength are two distinct components of goal intentions relevant to the adoption and maintenance of habitual physical exercise.

CAN TEACHERS REALLY MOTIVATE SCHOOL CHILDREN TO BE ACTIVE IN LEISURE TIME? STUDYING AUTONOMOUS MOTIVATION ACROSS CONTEXTS

Hagger, M.S.

University of Nottingham, United Kingdom

Given the evidence supporting the health benefits of regular vigorous physical activity to the health of young people, researchers have adopted social psychological models to investigate the psychological influences on physical activity behaviour. These models aim to use existing networks, such as physical education (PE), to promote physical activity. This paper will report four studies adopting the trans-contextual model, a social cognitive approach that aims to investigate the motivational influences on young people's physical activity intentions and behaviour in PE and leisure-time contexts. The purpose of the model is to investigate whether promoting autonomous (intrinsic) forms of motivation in a PE context will influence autonomous motivation and intentions to engage in physical activity in a leisure-time context. The first study tested the effectiveness of the model in explaining physical activity intentions in a sample of school children (N = 295). Perceived autonomy support influenced physical activity behaviour indirectly through a motivational sequence involving autonomous motivation in both contexts, and attitudes, perceived behavioural control (PBC), and intentions in a leisure-time context. These findings provided preliminary support for the trans-contextual model. In a second study, an identical design was used to study the generalizability of the model in national samples from Greece (N = 93), Poland (N = 103), and Singapore (N = 133). The study found few sample-specific differences and supported consistency in the effects of the model across cultures. A third study augmented the model to include perceived autonomy support toward leisure-time from peers and parents. Testing this model using a three-wave design in samples from Britain (N = 210), Estonia (N = 268), and Hungary (N = 235) revealed that perceived autonomy support from PE teachers had a pervasive effect on autonomous motivation and leisure-time physical activity intentions independent of the influences of perceived autonomy support from the other sources. A final study provided an experimental text of the trans-contextual model. High school students (N = 87) were presented with health-related activities in their PE lessons under three conditions: an information-only condition (control), a planned behaviour condition (supporting attitudes and PBC), and a trans-contextual model condition (supporting autonomous motivation). Results indicated that participants in both experimental conditions had elevated levels of intention with the planned behaviour condition exerting its effects on attitudes and the autonomy support condition showing effects through leisure-time autonomous motives. Together these results support the trans-contextual model to explain the processes underlying the transfer of motivation from a PE context to a leisure-time physical activity context and also as a framework for intervention.

MOOD REGULATION: AN UNDERESTIMATED MOTIVE FOR UNDERSTANDING EXERCISE BEHAVIOUR

Taylor, A.H.

Exeter University, United Kingdom

Many behaviours (eg, sugar snacking, cigarette smoking) are driven by the need for self-regulation of mood but a search of the research literature reveals no clear framework for understanding mood regulation as a motive for exercise behaviour. The only extensive literature is within the context of exercise addiction (ie, the need to maintain positive affect and avoid negative affect resulting from withdrawal).

From a public health perspective there is a need to understand how mood regulation drives physical activity and inactivity. Rest is commonly seen as a way to achieve relaxation, and recover from daily stress and general fatigue. A framework is needed to understand how best to promote exercise for acute and chronic mood regulation, under different emotional states. For example, perceived stress and fatigue have been shown to increase some behaviours (eg, sugar snacks, caffeine, alcohol and cigarette use) thought to act as stimulants and relaxants and reduce others (eg, physical activity)(eg, Steptoe et al, 1996).

Using a multi-dimensional conceptualisation of affect (eg, two-dimensional Circumplex model: activation and valence) recent evidence is fairly convincing that low-moderate intensity exercise (eg, brisk walking) can increase activation and valence (Ekkekakis & Acevedo, 2006). If, during states of deactivation, exercise can mimic other products traditionally used as stimulants, then mood regulation could be promoted as a primary motivational force.

Interest in multiple health behaviour change in the field of public health is growing. Thayer et al, (1993; 1994) suggested that exercise regulated mood, to then reduce ad libitum smoking and snacking. Recent experimental work has shown that exercise can acutely reduce cigarette cravings, mood and physical withdrawal symptoms (Taylor & Katomeri, 2006) even when faced with stress and cigarette cues. Understanding how exercise may mimic possible psychobiological processes involved in motivating other behaviours may provide an insight into understanding how best to promote exercise for mood regulation.

IS1-10 Neuromuscular skeletal muscle and aging - "Berlin ABC"

ADDRESSING THE NEURONAL MUSCULAR AND HORMONAL ALTERATIONS WITH AGE AND THEIR FUNCTIONAL CONSEQUENCES

Narici, M.V.

Manchester Metropolitan University, United Kingdom

Old age is notoriously associated with muscle wasting and weakness. From 20 to 80 years of age, about 40% of muscle mass is lost (1). This process, known as sarcopenia, has a multifactorial origin since it involves neuropathic, nutritional, hormonal, immunological and lifestyle factors. The neuropathic changes, chacterised by alpha motoneuron loss due to decreased superoxide dismutase activity, result in a progressive decline in motor unit number. In addition, apoptosis of muscle fibres, due to activation of proteolytic pathways involving a cascade of caspases, also plays a role in the loss of muscle mass (1). Among the nutritional factors, a decrease in food intake (although diet restriction may be beneficial for longevity!) and in vitamin D level (frequently associated with raised level in parathyroid hormone) contribute to sarcopenia (1). Probably the most significant hormonal changes responsible for a progressive withdrawal of anabolism are decreased levels of growth hormone (GH), insulin-like growth factor-1, testosterone and dehydroepiandrosterone sulfate (DHEAS). Although the effects of GH replacement in old age remain controversial, supplementation of IGF-1 increases lean body mass and muscle protein synthesis in older individuals (2). As for testosterone, its levels fall by about 50% from 20 to 80 years of age and this is associated with a decrease in appendicular muscle mass and strength (3). Instead, testosterone supplementation increases lean body mass and strength in hypogonadic patients (4) and in older men with low testosterone levels of (5). Similarly, DHEAS levels decline by about 10% per decade and its circulating levels are correlated with muscle strength and cross-sectional area in men aged 60-79 years (6). Among the immunological factors contributing to increased catabolism, the levels of inflammatory cytokines, TNF-alpha, IL-1 and IL-6 all increase in old age. Sarcopenia, can also arise from a reduction in physical activity (PA) level. This phenomenon, more widely spread than generally recognized, contributes together with a fall in anabolic hormones, to muscle fibre atrophy, particularly of fast-twitch fibres. The decrease in fibre number and size are a major cause of muscle weakness in old age. However, the losses of muscle strength and power typically exceed those of muscle size and volume, pointing to deterioration in muscle quality. Several factors contribute to this phenomenon, but recent evidence shows that this likely originates from the combined action of muscular, tendinous and neural changes.

PHYSICAL ACTIVITY AND NEUROMUSCULAR FUNCTION IN AGING

Gollhofer, A., Granacher, U.

University of Freiburg, Germany

In different studies clear evidence has been provided that the aging neuromuscular system is associated by structural and functional changes which lead to a general slowing down of neuromuscular performance. As a consequence, the process of aging is associated with decreases in muscular strength, reduced RFD (rate of force development), and alterations in reflex pathways on the afferent and on the efferent side. These impairments are partly caused by selective decline of large alpha-motoneurons accompanied by selective atrophy of type-II skeletal muscle fibres. Age-related changes in reflex activity have been attributed to desensitization of muscle spindles [Mynark&Koceja 2001], demyelination of sensory axons, with a subsequent decrease in number of sensory neurons, changes in presynaptic inhibition [Earles et al 2001], and a reduction in number of alpha- and gamma motoneurons.

Functionally, these degenerative processes also affect postural control. They are partially responsible for the dramatically increase of the risk of falling in old age. Several studies investigating the effects of heavy resistance (HR) training on maximum voluntary contraction (MVC) and rate of force development (RFD) observed, that HR training results in an increase in maximal as well as explosive force production capacity. Studies concentrating on the effects of a sensorimotor training (SENSO) in aged subjects revealed that SENSO training leads to increased RFD and improved postural stability due to an increase in reflex activation (Gollhofer 2003). In recent controlled studies the selective impact of HR- and SENSO training on reflex characteristics in the elderly has been verified (Granacher&Gollhofer 2006). The results clearly indicate that SENSO training has an impact on spinal motor control mechanisms in the elderly. Improvements in perception and procession of afferent information could be responsible for the increased reflex activity. Due to these adaptive processes, selective intervention programs seem appropriate for fall preventive training in elderly people.

IMPROVED MENTAL HEALTH AND QUALITY OF LIFE IN PHYSICALLY ACTIVE ELDERLY?

Conzelmann, A.

University of Berne, Switzerland

The paper deals with the effects of physical activity on mental health and quality of life in elderly people. "Mental health" will not primarily be considered under a medical perspective (being free of "mental illness") but rather be regarded as an equivalent to subjective (physical,

psychic and social) well-being. „Quality of life" refers to the satisfaction with personally relevant spheres and therefore focuses on a cognitive aspect of subjective well-being.

During the last decades numerous studies have explored the effects of physical activity on health and subjective well-being. The results show that effects on health-relevant parameter such as lower risk for heart attacks or better function of vital organs can be established much easier than positive effects on subjective well-being (e.g. Fuchs, 2003). Whereas physical activity influences health parameter in a direct way, the interrelations with subjective well-being are more complex for various reasons. (1) Besides physical activity other factors (e.g. sociodemographic variables) influence subjective well-being, thereby implying that the isolated consideration of physical activity as an influence is insufficient to explain the variance of subjective well-being. (2) Biographical life experiences form the basis of an individual understanding of the effects of physical activity on subjective well-being. Thus, great heterogeneity in aging courses does exist, becoming manifest in different forms and fates of getting old(er) (Thomae, 1987). (3) Subjective well-being is rather dependent on subjective domain evaluations than on objective life conditions. Thus, subjective health is a useful (direct) predictor for subjective well-being, again being influenced, however, by the number of contracted illnesses (Smith et al., 1999). In this context, physical activity can be seen as an indirect influence. Evaluations and estimations are cognitive processes dependent on cognitive traits such as competence and control beliefs or attribution style.

Consequently, the influence of physical activity has to be considered under a differential perspective, including the whole lifespan and taking cognitive processes into account. Complex models, for example up-to-date theories on successful aging (e.g. the SOC-model; Baltes & Baltes, 1989) are promising approaches.

PLASMA LEVELS OF TNF-α AND ADHESION MOLECULES IN ATHLETES WITH SICKLE CELL TRAIT AND α-THALASSEMIA: EFFECTS OF TWO EXERCISE MODALITIES

Monchanin, G., Serpero, L., Connes, P., Ngongang, J., Tripette, J., Wouassi, D., Bezin, L., Francina, A., de la Peña, M., Massarelli, R., Gozal, D., Thiriet, P., Martin, C.

UFRSTAPS - Université Claude Bernard- Lyon1, France

Sickle cell anemia (SCA) is caused by the mutation of hemoglobin (Hb) A into HbS. This mutation leads to polymerization and red blood cell (RBC) shape changes during Hb deoxygenation. Sickle cell trait (SCT) carriers is the heterozygous form of SCA. SCT is usually asymptomatic, although it has been associated with increased risk of sudden death and diminished physical performance under stressful physiological conditions. Some authors reported that the co-existence of SCA with α-thalassemia occurs frequently in the Black population, and such co-existence may in fact be protective for SCA or SCT subjects. We recently reported that SCT carriers exhibited impaired blood rheology at rest, and that such alterations were dampened by the co-existence of α-thalassemia [1]. Since these impairments are thought to increase blood flow resistance in microvessels, they could accelerate endothelial dysfunction and vascular injury [2].

To examine the effects of 2 exercise modalities on circulating tumor necrosis factor α (TNF-α), vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) in sickle cell trait (SCT) athletes with or without α-thalassemia, 6 athletes with SCT, 7 athletes with both SCT and α-thalassemia (SCTAT) and 7 control athletes (CONT) performed an incremental test on cycloergometer followed 72 hours later by a 60-min endurance exercise with a workload set at 70% Ppeak. We assessed levels of soluble sICAM-1, sVCAM-1 and TNF-α at rest, after exercise and 1, 2 and 24 hours after exercise.

Although, CONT and SCTAT groups exhibited similar basal plasma levels of inflammatory and adhesion molecules, SCT group had higher sVCAM-1 basal concentrations. Incremental exercise resulted in a significant increase of sVCAM-1 in all subjects, which remained elevated only in the SCT group during the recovery period. Endurance exercise increased sVCAM-1 and sICAM-1 in SCT group only, with no difference emerging between SCTAT and CONT groups.

In conclusion, our findings support the concept that SCT athletes might be at risk for microcirculatory disturbances. Although this vascular dysfunction has never been demonstrated to induce vaso-occlusive crisis in SCT subjects at rest, this dysfunction should be amplified under stressful physiological conditions and could raise the risk for vaso-occlusion events several hours after exercise [3]. Finally, Alpha-thalassemia might be considered protective among exercising SCT subjects.

EFFECT OF ORAL CONTRACEPTIVES ON PATELLAR TENDON COLLAGEN SYNTHESIS AT REST AND IN RESPONSE TO EXERCISE

Hansen, M., Langberg, H., Koskinen, S., Petersen, S.G. , Døssing, S., Magnusson, S.P., Kjær, M.

Bispebjerg Hospital, Copenhagen, Denmark , Denmark

Introduction: Women are in a higher risk of sustaining curtain kind of injuries and diseases related to the collagen-rich tissue of the skeletal muscle system compared to men. This study was design to exam whether use of oral contraceptives (OC) and thereby enhanced level of ethinyl-estradiol affect tendon collagen metabolism, in vivo, at rest, and in response to strenuous exercise. Based on animal and in vitro studies we hypothesis that OC would have an inhibiting effect on tendon collagen synthesis.

Material and Method: Healthy, young women; oral contraceptive users (OC)(n=8) and never-OC-users (n=8) in the follicular phase of the menstrual cycle, when the level of estradiol is low, were studied the day after 1 h of 1-legged kicking exercise at 67% of Watt max. Microdialysis catheters were placed in the peritendinous space in front of the patellar tendon. The collected dialysate was analyzed for aminoterminal propeptide of type I collagen (PINP), a marker of collagen formation. Cross-Sectional Area (CSA) of the patellar tendon was

measured by magnetic resonance imaging. Besides, fractional protein synthesis rates (connective tissue, myofibrillar protein and tendon tissue), whole body protein synthesis, protein oxidation and protein degradation were measured by infusion of stabile isotope labeled amino acids ([1-13C]leucine, [13C]proline) followed by biopsies (rest and 24h post ex) from mm. vastus lateralis and patellar tendon.

Results: At rest no differences between OC-users and never-OC-users in PINP in the dialysate were observed. However, the never-OC-users experienced an exercise–induced increase in collagen synthesis (PINP (ng/ml) Mean +/- SD, Rest 7.9 +/- 2.9 vs Exercise; 11.3 +/- 5.6, $p < 0.05$), whereas no significant change was observed in the OC-group (Rest 5.9 +/- 3.5 vs. Exercise; 6.6 +/- 3.4, $p = 0.49$). No differences in the patellar tendon CSA was observed between OC-users and never-OC-users. Discussion/Conclusion: A stimulating effect of exercise on tendon collagen synthesis has earlier been shown in young men. For the first time in vivo an inhibiting effect of OC was observed on the exercise-induced increase in tendon collagen synthesis. However, in the situation with naturally low level of estradiol we were able to detect a stimulating effect of exercise on tendon collagen synthesis. No difference in tendon CSA was detected, but the change in collagen turnover may influence collagen density and biomechanical properties of the tendon. Forthcoming results will hopefully shed light on additionally aspects of the effects of OC on protein metabolism.

COMPENSATING LOSS OF FORCE BY STIMULATION OF THE NA,K-PUMP IN RAT SKELETAL MUSCLE

Mikkelsen, U.R. 1, Gissel, H. 2, Fredsted, A. 2, Clausen, T. 2

1 Copenhagen University Hospital, Bispebjerg, 2 University of Aarhus, Denmark

Intensive exercise leads to loss of muscle force, which may be long-lasting and associated with muscle cell damage. Muscle cell excitability and the ability to generate force depend on maintenance of the Na+ and K+ gradients across the cellular membrane. The Na,K-pump actively extrudes Na+ and accumulates K+ in an electrogenic fashion resulting in a membrane potential of -75 mV. Following fatiguing stimulation there is a rundown of Na+ and K+ gradients resulting in depolarization of the membrane and loss of force. This study aimed to investigate the effect of the following agents on force recovery. The Na,K-pump is activated by cAMP and we use beta-2-agonists (epinephrine and salbutamol) that act via beta-2-receptors and G-protein to activate adenylyl cyclase converting ATP to cAMP, calcitonin gene related peptide (CGRP) which increases cAMP by binding to specific CGRP-receptors, and a direct increase in cellular cAMP by adding dibutyryl (db)-cAMP. We test the hypothesis that excitation-induced loss of force can be compensated by beta-2-agonists.

To simulate the loss of force following intense exercise extensor digitorum longus (EDL) muscles from 4-wk old rats were fatigued for 5-60 min using intermittent 40 Hz stimulation. Following stimulation, force recovery and membrane potential were measured during 4 hrs recovery. The above-mentioned agents were added during recovery.

Following 30-60 min of stimulation tetanic force was reduced to ~10 % of the prefatigue level, followed by a spontaneous recovery to ~20 %. Loss of force was associated with a decrease in K+ content, gain of Na+ and Ca2+ content, leakage of the intracellular enzyme lactic acid dehydrogenase (LDH, 10-fold increase), and depolarization (13 mV). Stimulation of the Na,K-pump with either the beta-2-agonist salbutamol, epinephrine, CGRP, or cAMP improved force recovery by 40-90 %. Epinephrine significantly improved force recovery (by 47 %) at concentrations down to 10-8 M, which is close to the plasma level (0.6 x 10-8M) reached in running rats. The beta-blocker propranolol abolished the effect of epinephrine on force recovery but not that of CGRP, proving that the action of epinephrine is via its specific receptors. The salbutamol-induced force recovery was associated with repolarization of the membrane potential (12 mV) to the level measured in unfatigued muscles. The rise in LDH-release (loss of cellular integrity) caused by fatiguing stimulation was unaffected by addition of salbutamol, thus the force recovery induced by salbutamol cannot be attributed to resealing of the cell membranes.

Conclusion: In muscles exposed to fatiguing stimulation leading to loss of force, cell membrane leakage and depolarization, beta-2-agonists or CGRP induces repolarization and improves force recovery due to a cAMP mediated stimulation of the Na,K-pumps. This may prove important in many situations where force is lost due to fatigue or loss of cellular integrity.

ACUTE DOPAMINE REUPTAKE INHIBITION ENHANCES PERFORMANCE IN WARM, BUT NOT TEMPERATE CONDITIONS

Roelands, B., Hasegawa, H., Watson, P., Buyse, L., De Schutter, G., Piacentini, M.F., Meeusen, R.

Vrije Universiteit Brussel, Belgium

Introduction

Previously, we reported that acute dual dopamine/noradrenaline (DA/NA) reuptake inhibition (bupropion) significantly altered the hormonal response to exercise in temperate conditions (Piacentini, 2004) and significantly improved time trial performance in the heat (30°C; Watson, 2005). The aim of the present study was to determine which neurotransmitter system is responsible for the improved performance in the heat. Therefore we studied the effects of acute administration of a DA reuptake inhibitor.

Methods

Eight healthy well-trained male cyclists (Age 26,0±4,7y; Ht 182±6cm; Body Mass 77,9±6,4kg; Wmax 361±18W) participated in this study. Subjects completed a preliminary maximal exercise test, a familiarization trial and four experimental trials, two temperate (18°C) and two warm trials (30°C), in a double blind-randomized crossover design. Subjects ingested either a placebo (PLAC; lactose 20mg) or Ritalin (RIT;20mg) one hour before the start of exercise. Subjects cycled for 60 min at 55% Wmax, immediately followed by a time trial to measure performance. Core temperature (Tcore), skin temperature, heart rate, sweat loss, ratings of perceived exertion (RPE), thermal comfort, blood lactate and hormonal data were recorded. Statistical analysis were conducted using two-way (temperature-by-drug) repeated measures ANOVA to evaluate differences between and within trials. The significance level was set at $p<0,05$.

Results

Exercise performance was not influenced by RIT in temperate conditions ($P=0.397$), but subjects completed the TT 16% faster in the RIT trial (38.1±6.4min) than in the placebo (45.4±7.3min; $P=0.049$) when exercise was performed in a warm environment. Power output was higher in the RIT trial in the heat, compared to the PLAC trial ($P<0.05$). Tcore was not different between conditions in the temperate trials. In the heat Tcore was significantly higher at rest ($P=0.009$), at the start of exercise and throughout the TT ($P<0.05$) in the RIT trial. Throughout the TT with RIT heart rates were significantly higher during exercise in the heat at all times ($P<0.05$). After the 60 minutes of fixed intensity exercise in the heat subjects' RPE were significantly higher ($P=0.034$) in the placebo than in observed in the RIT trial.

Discussion/Conclusion

These data indicate that acute RIT administration enhanced performance by 16%. No such effect was apparent under temperate conditions. The present findings support previous work suggesting that higher DA activity increases tolerance to exercise in the heat (Bridge, 2003), increased catecholaminergic neurotransmission enhances exercise performance in a warm environment (Watson et al. 2005) and that dopamine may influence thermoregulation during exercise (Hasegawa, 2000).

CALCIUM CONTENT AND EXPRESSION OF CALPAIN AND CALPASTATIN IN HUMAN SKELETAL MUSCLE FOLLOWING REPEATED BOUTS OF ECCENTRIC EXERCISE

Overgaard, K., Vissing, K., Fredsted, A., Schjerling, P.
University of Aarhus, Denmark

Introduction
Skeletal muscle adapts markedly to a single bout of eccentric exercise, providing protection against muscle damage in subsequent bouts of eccentric exercise (repeated bout effect). The cellular processes, responsible for this repeated bout effect, are unknown. We showed previously that prolonged running increased muscle calcium content (1). Furthermore, expression of the calcium activated protease calpain 2 was observed to be up-regulated and expression of calpain 1 and 3 down-regulated following downhill running (2). Thus, some of the muscle damage following eccentric exercise may be mediated by calcium induced calpain activity and a reduction in calpain activity may be part of the repeated bout effect. Calpastatin is an important endogenous regulator of calpain activity. Therefore, we investigated the hypothesis that following a second bout of eccentric exercise muscle calcium accumulation and expression of calpain would be reduced and/or the expression of calpastatin would be increased.
Methods
Biopsies were obtained from the vastus lateralis muscles of 14 male volunteer subjects performing two bouts of 30 min step exercise separated by 8 weeks (3). Isometric knee extensor MVC was measured with a strain gauge transducer and soreness of the knee extensor region was evaluated on a visual analog scale. Muscle calcium content was measured by atomic absorption spectrophotometry (1). Calpain 1, 2 and 3 and calpastatin mRNA levels were measured by Northern blotting.
Results
Muscle strength in the eccentrically exercised muscles was maximally reduced by 15±2% 3h after bout 1 and was less reduced (by 9±2%, $p<0.05$) after bout 2. Muscle soreness was maximal 48h after step exercise and was lower following the bout 2 as compared with bout 1 (47±5mm vs 30±5mm, $p<0.05$). Total muscle calcium content did not change following either bout 1 or bout 2 ($p>0.05$). Calpain 2 and calpastatin mRNA increased by 41±10% and 66±12%, respectively, and calpain 1 and 3 mRNA were unchanged after bout 1. Bout 2 induced similar mRNA changes for all calpain isoforms and for calpastatin.
Discussion/Conclusion
Total muscle calcium content was not increased after 30 min stepping. However, free cytosolic calcium determines calpain activation and this may change without changes in total muscle calcium content. Interestingly, both calpain 2 and calpastatin mRNAs were up-regulated indicating an influence of eccentric activity on calpain/calpastatin regulation. The overall pattern of calpain and calpastatin mRNA regulation was very similar between the two bouts despite a significant repeated bout effect on soreness and strength. Thus, our hypothesis was not supported. However, measurements of protein levels are required to determine more specifically the possible role of calpain regulation in the repeated bout effect.

OP1-07 Sociology 1/1 - "Turin ABC"

NATIONAL VS. INTERNATIONAL SPORTS COVERAGE

Sattlecker, G., Dimitriou, M., Müller, E.
University of Salzburg, Austria

Many authors criticized sports coverage for different reasons. Two main arguments for that were the preference of national sport and the absence of many kinds of sport in the reporting (see Weischenberg 1978, 188ff, Wernecken 2000, 321ff and Loosen 2004, 13). Most of the surveys took place in Germany, Austrian and Swiss studies are rather seldom. The aim of this study was to compare the current sports coverage in the German speaking countries Austria, Germany and Switzerland. The survey should not only show the differences between the three countries and types of newspaper but also the connection between the two variables. Therefore, three newspa-pers of each country – a tabloid, a quality newspaper and a regional paper – were analyzed within an artificial week in March 2004. The different kinds of sport and the nationalism of the coverage were used as variables for the study. The survey employed content analysis of 2089 articles and 653 photos in the following newspapers: Kronen Zeitung, Standard, Salzburger Nachrichten (Aus-tria), Bild, FAZ, Kölner Stadtanzeiger (Germany) and NZZ, Blick and Tagesanzeiger (Switzerland). It could be expected that soccer was the dominant sport while ice hockey and tennis were at least among the top four in each country. Concerning the other most popular kinds of sport regional aspects can be observed. In Austria alpine skiing was number two, in Germany basketball ranked third whereas in Switzerland tennis was number three. This all could be a consequence of the per-formances of national athletes because sportsmen of these countries are extraordinarily successful in the kinds of sport mentioned above. Zubayr and Gerhard (2004, 39ff) also stated that the popu-larity of sport is in close connection to the successes of national athletes. Between the three types of papers no essential differences could be made up. Concerning national sports coverage, the survey showed that at least 50 percent up to 77 percent of the sports articles and from 66 up to 88 percent of the photos had national athletes as a subject. The variance analysis showed signifi-cant differences between quality papers and the two other types. Therefore, the tabloid and re-gional papers had a higher percentage of national articles and photos. Regarding the three ana-lyzed countries, significant differences between Germany and the two other nations can be stated. Austrian and

Swiss newspapers published more international articles than their German pendants while there was no difference between the photos of the three countries. The results within the three nations showed that the kinds of sport had an influence on the national character of the re-porting. The focus on the German soccer league is responsible for the high percentage of national sports coverage in this country while the concentration on skiing in Austria and tennis in Switzer-land lead to a higher percentage of international sport in these papers.

'GO GENDER BUT NOT ONLINE'. THE SPORTS COVERAGE OF GENDER IN SELECTIVE INTERNET PORTALS

Dimitriou, M., Sattlecker, G., Müller, E.

University of Salzburg, Austria

New technologies, in particular their applications in the field of Internet, digital television and mobile telephony, produce also new distribution platforms and services for the delivery of sports content. Online media have grabbed the attention of communication researchers in the second half of the 1990s, but the focus to date has been primarily on media audiences and their use of these new forms. On the other hand, there have been a number of studies regarding the relationship between sport and gender in television and in print sports coverage.

This study will analyze the type and the themes of reporting and the gender orientation in the online sport coverage. On the other side, this paper examines the extent that selective internet portals use available technologies, including multimedia and interactivity, for the presentation of gender in the sports coverage.

The study employed content analysis of four online sport portals - BBC-sport (GBR), T-Online Onsport (GER), NBC-sport (USA) and Sport1 (AUT) - at two seven-day time periods during March-May 2004 and 2005. In order to select the sport sites to be coded, the Nielsen / Net Ratings top 20 sport news list (GBR, GER, USA) and the OEWA - Austrian Web Analysis- (AUT) were consulted to determine the most prominent sport news sites. To explore this more systematically, the contents of the websites were coded by two principle dimensions. The content transparency evaluated and measured by the presence or absence of six criteria of gender themes (achievement, private, sport background, finance, ethic, aesthetic appeal). In addition websites were coded according to their information transparency, using two categories including such as use of multimedia (three criteria: photo, audio, video) and the appearance of the type of sports reporting (six criteria: results/statistics, commentary, interview/profiles, report, news and other forms).

According the content transparency, the analysis illustrated that all online sport portals focused on men's sport. In concrete the study showed that the presentation of men's sport correlates with themes as achievement, sport background and finance. The internet sites used more textual features by men's subjects and selected more pictures and multimedia possibilities to present the women's sport. Regarding the type of reporting, the online sport portals emphasized more on the categories of the "report" and "interview/profile" in case of men's themes and preferred "news" concerning the woman's stories.

Several studies show that women are dramatically under-represented in the print media, radio and television. The domination of men's sport is also a defining characteristic of the online sport journalism. Finally, the intensive use of the typical advantages of the multimediality and the "news" as single type of reporting for present women's sport documented increasingly the tendency of stereotyping and trivialization in the online sport coverage.

YOUNG PEOPLE, SPORT AND LEISURE: A STUDY OF CONTEMPORARY YOUTH LIFESTYLES

Smith, A., Green, K., Lamb, K., Thurston, M.

University of Chester, United Kingdom

In Britain, as elsewhere, over the past two or three decades there has been growing concern over the extent to which sport and physical activity are becoming increasingly rare features of contemporary youth lifestyles. Indeed, the belief that young people have dramatically reduced their participation in sport and physical activity – both inside and outside of the educational context – and have, as a consequence, become increasingly 'unhealthy' has become something of a received wisdom. What is particularly striking about this belief is its near universal acceptance across a range of societies in the Western world and beyond for, in both more and less developed societies, there is a broad consensus that declining participation in sport and physical activity – alongside the growing prevalence of 'unhealthy' diets, declining levels of daily physical activity and an increasing preference for engaging in sedentary leisure activities that revolve, in particular, around new media technologies – are the main causes of a 'health crisis' said to be emerging as defining characteristics of contemporary youth lifestyles. Notwithstanding these concerns, Coalter (2004: 79) has noted recently that, at present, much of the existing research on young people, sport and leisure has consistently failed to explain adequately or provide 'any clear understanding of sport's (and physical activity's) place in participants' lifestyles'.

This paper reports the original findings of a sociological study conducted with 15- and 16-year-olds from seven mixed secondary schools in the north-west of England, the object of which was to advance our understanding of young people, sport and leisure, and of the relationships between various aspects of young people's lives. In doing so, the paper reports upon data generated by questionnaires completed by 1010 young people and focus groups conducted with 153 of these youngsters. The findings revealed that for many young people participation in sport, and particularly 'lifestyle activities', was an integral aspect of both their school and leisure lives. It was also clear however, that for many young people, and particularly the more frequent participants, playing sport and doing physical activity was just one component in their generally busy leisure lives, which did not prevent them from engaging simultaneously in more sedentary activities (such as prolonged TV viewing and playing computer games) and commercially-oriented leisure activities, as well as consuming legal and illegal drugs. In this regard, it is argued that it is only possible to understand adequately where sport and physical activity fits into young people's lives by examining those lives 'in the round', and by locating the young people themselves within the various networks of relationships to which they have belonged in the past, and which they continue to form in the present.

DO WOMEN PLAY A ROLE IN TEAM SPORTS?

Capranica, L. 1, Piacentini, M.F. 1, Giannini, A. 1, Tiberi, M. 3, Tessitore, A. 1+2

1 IUSM of Rome, 2 Vrije University of Brussels, 3 Asur Marche, Italy

Introduction

Recently, several international actions have been taken to promote participation of women in sport, equal media prominence, and equal sport career opportunities (European Parliament, 2003; International Olympic Committee, 2004). However until now, there is a lack of gender disaggregated data in sport. Thus, the aims of this study were: 1) to have a gender perspective in Italy of the women's role in Basketball and Volleyball, and 2) to measure the women's coverage of the largest circulating Italian basketball and volleyball magazines.

Methods

Only athletes and professional positions (president, vice-president, coach, assistant coach, secretary, marketing manager, organization manager, communication manager, and staff) of clubs competing in the three major championships included in the official list of the Italian Basketball and Volleyball federations were considered. The coverage of the largest circulating Italian basketball (I Giganti del Basket) and volleyball (Hi-Tech Volley) magazines was analyzed by five indicators: the number, the size and the page placement of articles, the size and the type of the photograph, classified into men-only (M), women-only (F), and mixed-gender (FM) categories. Chi-Square was applied to test gender differences ($p<0.05$) in the professional involvement and ANOVA to the area of articles and photographs.

Results

In 2003 the male basketball athletes outnumbered (n =165900; percentage: 85%) their female counterpart (n = 30162; percentage: 15%), while the relative picture for volleyball was 70362 (28%) and 184743 (72%) for male and female athletes, respectively. Professional positions were 1260 for basketball and 1711 for volleyball, with a significantly higher representation of men (89%) than women (11%) for both sports. Coaches were mostly men (basketball: 98%; volleyball: 96%) while the highest percentage of women was found for the secretary position (basketball: 23%; volleyball: 46%).

From June 2002 o May 2003 the magazine Hi-Tech Volley published 68 articles (women's volleyball = 10%, man's volleyball = 13%, technical = 77%), mostly written by men journalists (97%), and 72 photographs (women's volleyball = 40%, man's volleyball = 60%). The magazine I Giganti del Basket published 112 articles (women's basketball = 2%, man's volleyball = 6%, technical = 92%), written only by men journalists, and 151 photographs (women's basketball = 8%, man's basketball = 92%). For both magazines, no gender difference was found relative to the area and placement of the articles. Similarly, no gender difference was found relative to the area and type of the photographs.

Discussion

The present data suggest that the women's role in sport is mainly restricted to their participation as athletes. Furthermore, media coverage does not reflect sport participation.

THE EFFECTS OF HEAVY VERSUS LIGHT RESISTANCE TRAINING INTENSITY ON MUSCLE HYPERTROPHY AND STRENGTH

Pedersen, T.G., Reitelseder, S., Holm, L., Aagaard, P., Kjær, M.

Bispebjerg Hospital, Denmark

Introduction: Regular heavy resistance training (HT) is potent to induce muscle hypertrophy and increase muscle strength among male adults. However the muscular adaptations following regular light resistance training (LT) are sparsely investigated and remain unclear. Therefore we investigated the longitudinal effects of HT vs. LT on muscle mass and morphology, comparing the effects of the two training modes. Methods: 12 moderately active young male subjects performed 36 sessions of supervised HT and LT aimed at the quadriceps muscles (Q). HT was performed at 70% of 1 repetition maximum (RM) and LT at 15.5% of 1RM with a setup designed to equalize the total weight lifted. Measurements of isokinetic and isometric muscle strength and contractile rate of force development (RFD) were conducted in the isokinetic KinCom-dynamometer and anatomical cross sectional area (CSA) at three locations of the thigh, distal, mid and proximal, were determined by magnetic-resonance imaging (MRI) scans, before and after the 36 training sessions. Results: The HT leg increased concentric isokinetic Q-strength from 217.8 +/- 12.1 to 243.8 +/- 13.6 Nm (+/- S.E.M.) ($P<0.05$) and eccentric Q strength from 277.7 +/- 15.5 to 329.0 +/- 22.5 Nm ($P<0.01$). The isometric Q strength increased from 253.4 +/- 13.3 to 290.0 +/- 17.1 Nm ($P<0.01$). Contractile RFD determined within 200 ms relative to onset of contraction seemed to increase from 919.0 +/- 76.8 to 1075.2 +/- 77.6 Nm/s ($P=0.068$). No significant changes in strength were found following LT. The HT leg increased CSA significant at all locations ($P<0.05$-0.001). The LT leg increased CSA at the proximal ($P=0.01$) and at the distal location ($P=0.056$). However at the proximal location the HT increased CSA more than LT ($P<0.05$), 7.5 % vs. 3.2 %, respectively. With the three locations pooled as a total CSA both HT and LT increased CSA significantly, ($P<0.001$ and $P<0.01$, respectively). Discussion/Conclusion: Results from this study show that regular LT (15.5% of 1RM) can potentially increase muscle mass measured on muscle CSA following 12 weeks of training, however this limited training period may not provide stimulus great enough to increase muscle strength and power. If the training intervention is aimed at strength- and power gains conventional HT (70% of 1RM) is more effective.

THE EFFECT OF TRAINING INTENSITY ON MYOFIBRILLAR PROTEIN SYNTHESIS MEASURED AT REST AND ACUTELY AFTER HEAVY RESISTANCE EXERCISE

Reitelseder, S., Pedersen, T.G., Holm, L., Døssing, S., Pedersen, S.G., van Hall, G., Kjær, M.

Bispebjerg Hospital, Denmark

INTRODUCTION: The mechanisms of skeletal muscle protein synthesis are affected by individual training status and acute exercise. Though, to which extent different training intensities function upon these mechanisms remains unclear. For that reason we determined the effect of 12 weeks of heavy (HT) versus light (LT) resistance training on the myofibrillar protein fractional synthesis rate (FSR) at rest and acutely after a bout of heavy resistance exercise. METHODS: Moderately active young male subjects (n=11, 24.7 +/- 1.1 yrs (mean +/- S.E.M.), 23.8 +/- 1.0 BMI) underwent two fasting and diet-controlled studies (pre- and post training). A primed (0.8 g/kg BW) continuous infusion (1 g/kg BW/hr) of 1-13C leucine was administered and vastus lateralis myofibrillar FSR was determined at rest and post an acute bout of heavy resistance exercise during which periods venous KIC enrichment was at steady state. The post training study was performed 4 days after the last training session. The acute heavy resistance exercise bout was performed with the same total load at the post training study as in the pre training study with each repetition at 70% of 1 repetition maximum and a pre training basis of 10 sets of 8 repetitions. In between the study days the 12-week supervised and progressive training period (3 d/wk) was completed with one leg

performing HT (10 sets with 8 repetitions at 70% 1RM) and the contra lateral leg performing LT (10 sets with 36 repetitions at 15.5% 1RM). The training setup was designed to equalize the total load lifted by each leg and all exercise was performed in a leg-extension machine. RESULTS: A mean isotopic KIC enrichment of 5.3 +/- 0.4% was reached with no difference from the pre- to the post training study. Myofibrillar FSR pooled for both legs pre training were at rest and post acute exercise 0.067 +/- 0.026 and 0.140 +/- 0.027 %/hr, respectively (P=0.067). Neither HT nor LT induced any change in resting FSR. After the training interventions post exercise FSR were for HT and LT 0.078 +/- 0.033 and 0.116 +/- 0.021 %/hr, respectively (P=0.270, Kruskal-Wallis test comparing all acute post exercise FSR values). CONCLUSION: The outcome of the two different training interventions indicated a training intensity dependent attenuation in the acute post exercise myofibrillar protein synthesis. Therefore in the HT trained state stronger stimuli may be needed to further increase the acute protein synthesis above the actual resting level. LT did not have the same impact to change the response to acute heavy resistance exercise. Possibly due to methodological limitations the raw data were vitiated with a marked dispersion and a few outliers, which might explain the lack of significance.

AGING AND TORQUE-ANGLE RELATIONSHIPS IN ANKLE DORSI-FLEXION AND PLANTAR FLEXION

Simoneau, E., Martin, A., Van Hoecke, J.

Laboratoire INSERM ERM 207 Motricite-Plasticite, France

Introduction

The investigation of one muscle group should always be accompanied with the examination of its antagonist muscle group (Simoneau et al. 2006). This study aimed at examining the effects of joint angle and age on the maximal voluntary contraction (MVC) torques of the agonist and antagonist muscle groups around the ankle, i.e., the dorsi- and plantar-flexors.

Methods

Two groups of healthy male volunteers took part in this investigation: the first consisted of 11 young men (age 24 ± 2 yrs), and the second of 18 older men (age 78 ± 3 yrs). Plantar-flexion (PF) and dorsi-flexion (DF) MVC isometric torques were measured using a dynamometer with the subjects lying supine (knee at 180°) and the ankle at the neutral angle (0°) and in dorsi-flexed (20° DF) and plantar-flexed (20° PF) positions. Simultaneously, surface electromyographic (EMG) activity of the tibialis anterior and of the triceps surae muscles was recorded in order to assess the levels of muscles' activity and coactivation (RMS of the antagonist muscle normalized by its RMS when it acted maximally as agonist). Moreover, the percutaneous electrostimulation of the motor nerves allowed us to quantify mechanical muscular responses (peak twitch: Pt).

Results

The PF MVC and Pt were significantly affected by joint angle and age group. Statistical analyses revealed an angle effect and no contraction type (voluntary or evoked) nor age effect on the shapes of the PF torque-angle relationships. There was neither an effect of joint position nor of age on the agonists' EMG activity.

The DF MVC and Pt were significantly affected by joint angle only. Statistical analyses revealed an angle effect and a contraction type effect on the shape of the DF torque-angle relationship. The EMG activity of the tibialis anterior muscle and the coactivation in DF were joint angle dependent.

Discussion/Conclusion

The shape of the MVC torque-angle relationship in DF appeared to be especially explained by neural factors, whereas the shape in PF seemed to be mainly due to mechanical parameters. These relationships would not be a discriminating factor between the two age groups: the decline in muscle function that has been found to be associated with aging is not joint angle dependent. It is deduced that it would not be relevant to strength train the ankle muscles of older adults at one specific angle. Moreover, measurements at one ankle joint angle, whatever the angle, are thus enough to examine the differences within age groups and to perform a rapid assessment of the imbalance at the ankle joint.

REGION SPECIFIC PATELLAR TENDON HYPERTROPHY FOLLOWING RESISTANCE TRAINING

Kongsgaard, M., Reitelseder, S., Pedersen, T.G., Holm, L., Kjær, M., Magnusson, S.P.

Institute of Sports Medicine, Denmark

Patellar tendinopathy (jumper's knee) is a prevalent overuse injury readily observed in jumping athletes. Patellar tendinopathy is characterized by tenderness, pain, swelling, increased blood flow and decreased echogenicity (Khan et al., 1999). In approximately 70% of all cases the injury is present at the proximal region of the tendon and only at the distal region in about 15% of all cases (Ferretti, 1986). The reason for this region specific aetiology is unknown.

Additionally, it remains largely unknown to what extent different loading regimes can induce tendon hypertrophy.

The purpose of this study was to: I) Determine region specific differences in patellar tendon CSA, and II) Investigate possible patellar tendon hypertrophy following two different training loading patterns.

Twelve sedentary, lean and healthy young men (mean age: 25+/-1 yr.) were included. All subjects underwent baseline and post-training assessments: In addition to anthropometric measures, cross-sectional area (CSA) measurements were performed at the proximal-, mid- and distal patellar tendon level following magnetic resonance imaging (MRI) of both knees. Furthermore, subjects had 1RM knee extension strength determined bilaterally. Thereafter, one side was randomly assigned to 12 weeks of heavy resistance knee extension training (HR), and the other side was assigned to 12 weeks of light resistance knee extension training (LR). Both legs underwent the same total work during the training period.

Patellar tendon CSA at the proximal tendon level was significantly less than at the mid- and distal tendon level (104+/-4, 118+/-3 and 127+/-2 mm2 respectively, $P<0.05$). On average, 1RM strength increased by 33% on the HR side, and 18% on the LR side following training. The increase in 1RM strength was significantly greater on the HR side compared to the LR side ($P<0.001$). LR yielded a significant increase of CSA (+5.3%) at the proximal tendon level ($P<0.05$), but not at the mid- (+0.1%) or distal (-0.8%) tendon level. HR yielded a significant increase of CSA (+5.0%) at the proximal and distal tendon (+4.5%) level ($P<0.05$), but not at the mid (+0.5%) tendon level.

To our knowledge this study is the first to show that human patellar tendon CSA varies along the length of the tendon, and that the distal tendon region, which is the most prevalent location of patellar tendinopathy, has a significantly lower CSA than the mid- and distal regions of the tendon. Additionally, no previous studies have reported patellar tendon hypertrophy in humans following an acute training

intervention. All other factures equal, an increased tendon CSA will reduce tendon stress during sporting activities and may reduce the risk of overuse tendon injuries.

FOOTBALL INJURIES – APPLICATION OF LAW 12 IN TOP-CLASS TOURNAMENTS

Tscholl, P., O'Riordan, D., Dvorak, J., Gutzwiller, F., Junge, A.

FIFA Medical Assessment and Research Centre (F-MARC), Switzerland

INTRODUCTION:

FIFA's official Laws of the Game state that a free kick will be awarded if "a player tackles an opponent to gain possession of the ball, making contact with the opponent before touching the ball..." unless the tackling player "...plays in a dangerous manner" (Law 12).

This leaves a high degree of liberty on the decision-making of the referees. The objective of this study was to analyse their interpretation of the law in respect of the consequences on the player's health.

METHOD:

Video recordings of 24 representative matches and all injury incidences reported by the team physicians from 6 FIFA tournaments of female players were analyzed for tackle parameters (direction, mode) and referee's decision during the match. For the present analysis, the tackling situations were divided into two groups:

- the ball was touched before the striking player made contact to the ball-leading player (ball-first-tackles)
- first touch occurred to the player, with or without touching the ball after (player-first-tackles)

The injury incidents were only included in the analysis if the ball-leading player was injured by the striking player. Statistical values were obtained by Chi2-test (95% CI).

RESULTS:

3236 tackles (average: 135 tackles per match) and 103 injury incidences (average: 0.6 injuries per match) were analysed. Player-first-tackles occurred 6-times more frequent than ball-first-tackles, however the injury risk was 2.5-times higher for ball-first-tackles (9.3 vs. 3.7 injuries per 1000 tackles, $p<0.001$). The referees sanctioned only 11% of the ball-first and 17% of the player-first-tackles ($p<0.01$). Comparing the non-sanctioned injury incidences, 2.3-times more injuries resulted from ball-first than from player-first-tackles (5.7 vs. 2.4 injuries per 1000 tackles, $p<0.01$). With regard to tackling mechanism, non-sanctioned sliding-in tackles from the front showed a significant higher injury-risk if the ball was played first (4 respectively 34 injuries/1000 tackles; $p<0.05$).

DISCUSSION:

The results show more injuries are caused by contact with the player first. While fewer injuries appear to be caused by the striking player touching the ball first, its injury risk was found to be 2.5-fold higher. The same propensity of injuries was found for non-sanctioned challenges, therefore referees have to penalise more rigorously dangerous tackles, and above all from the front.

Making referees aware of these high-risk tackles could improve the player's safety.

On the other hand players have to be taught techniques as well to evade the impact of ball-first-tackles.

OP1-09 Biomechanics 2/4 - "Turin DE"

THE EFFECT OF RUNNING, RESISTANCE STRENGTH, AND VIBRATION STRENGTH TRAINING ON THE MECHANICAL, MORPHOLOGICAL AND BIOCHEMICAL PROPERTIES OF THE ACHILLES TENDON

Legerlotz, K., Schjerling, P., Langberg, H., Brüggemann, G.P., Niehoff, A.

German Sport University Cologne , Germany

Introduction

In spite of the high prevalence of tendon injuries, the adaptation of tendons to physical activity is not yet completely understood. There is especially a lack of information about the adaptation of tendons in response to strength training. The purpose of the study was to analyse the effect of different types of exercise on the mechanical, morphological and biochemical properties of the Achilles tendon.

Materials and Methods

Sixty-four female Sprague Dawley rats (age 10 weeks), were randomly divided into five groups: a non-active age matched control group (AMC, n=20), a voluntary wheel running group (RT, n=20), a low vibration strength training group (LVST, n=12), a high vibration strength training group (HVST, n=6), and a high strength training group (HST, n=6). After one week of acclimatisation a 12 week training period started. The animals of the LVST, HVST and HST groups trained with a specially designed squat machine which required the rats to lift a weight (150 g at the beginning, later 250-450 g) in a squat-like movement to reach a food tube. When the weight was lifted a vibrating plate under the feet of the rats from the LVST and HVST groups was activated. At the end of the training period the rats were decapitated and the Achilles tendons were dissected. The tendon of the right limb was used to determine the cross-sectional area and cell density. The left tendon was initially exposed to cyclically loading to determine the viscoelastic properties, then tested until failure. In a second step, the total RNA in the tendons was isolated and the level of different mRNAs were determined by Northern Blot and RT-PCR. For analysis of the data the one-way ANOVA (post-hoc Tukey) was used to determine significant differences between the groups ($p<0.05$).

Results

The mean daily weight lifting time was 148 ± 92 s in the LVST group, 459 ± 151 s in the HVST group, and 357 ± 155 s in the HST group. The mean daily running distance of the animals of the RT group was 10.1 ± 2.9 km/day. Neither in the hysteresis area nor in the mechanical parameters which were determined by the failure test (Fmax, stiffness, deformation, energy, stress, strain and elastic modulus), nor in the cross-sectional area of the Achilles tendon were any significant differences detected between the different groups. The RT group revealed however a higher level of TIMP1 mRNA compared to the AMC and LVST group. Also the cell density was significantly lower in the RT group compared to the AMC group.

Discussion

The mechanical load which was achieved in the here presented rat model does not appear to be sufficient to create significant changes in the mechanical properties of the tendon - regardless of the type of exercise. Only the running training seems to have had an influence on the cell density and the level of mRNA. But this does not seem to have affected the mechanical properties of the tendon.

NEURAL FACTORS MAY NOT ACCOUNT FOR THE ACUTE ADAPTATION TO REPEATED DAMAGING STRETCH-SHORTENING CYCLE EXERCISES

Martin, V., Ishikawa, M., T.J., Hoffrén, M., Komi, P.V.

Neuromuscular Research Center - University of Jyväskylä, Finland

It is well established that exhausting stretch-shortening cycle (SSC)-type exercises induce a marked alteration of neuromuscular function (e.g. 1), together with the development of symptoms related to inflammatory processes. However, recovery is faster and symptoms are reduced when the damaging exercise is repeated. This acute adaptation has been referred to as the "repeated bout effect" (see 2). While the conditions required to induce a protective adaptation are fairly well understood, the underlying mechanisms are less clear. Several theories have been proposed, and potential mechanisms may be located at the neural, mechanical and inflammatory levels. Neural adaptations would induce better distribution of the workload among motor units, and could include increased motor unit recruitment, decreased co-activation level, as well as preferential recruitment of slow-type motor units. Some evidence exists to keep this neural hypothesis tenable (3). However, there is no experimental evidence for the first two assumptions. Therefore, the purpose of this experiment was to test these hypotheses.

Ten physically active subjects (3 females) performed a hopping task on a force plate until exhaustion, at an intensity set to 65% of maximal ground reaction force. This first exercise bout (B1) was repeated 2 weeks later (B2). Plantar flexors torque, voluntary activation level (AL) measured with the twitch-interpolation technique, and electromyographic activity of tibialis anterior muscle were studied under isometric (ISO) and eccentric (ECC) conditions. Soreness and serum creakine kinase activity (CK) was also assessed. All the variables were measured before (BEF), after (AFT), as well as 2 hours (2H), 1, 2 and 4 days (1D, 2D, 4D, respectively) after B1 and B2.

As expected, soreness and CK peaked at 2D and 1D after B1, respectively ($P<0.001$). After B2, soreness and CK were significantly reduced as compared to B1 ($P<0.001$ and $P<0.05$). Torque varied over time ($P<0.001$) and between exercise bouts ($P=0.01$) in ISO and ECC conditions. Overall, torque was higher during B2 ($P=0.01$). In ECC condition, this effect was also observed for AL values which were higher during B2 as compared to B1 ($P<0.05$). This was not the case in ISO condition. However, AL increase was not correlated to the torque difference between exercise bouts. Finally, neither time nor exercise bout did affect co-activation level.

These results confirm that the acute adaptation to damaging SSC-type exercise is characterized by reduced muscle damage and consequently attenuated the symptoms. However, this study does not support hypotheses suggesting that neural mechanisms could underlie the prophylactic effect of damaging exercise. Rather, it is suggested that mechanical phenomenon may account for this adaptation.

COMPONENTS OF THE PROPULSIVE FORCES ON THE HAND IN BREASTSTROKE SWIMMING

Suito, H., Okamoto, A., Takahashi, S., Sano, S., Nunome, H., Ikegami, Y.

Nagoya University, Japan

The purpose of this study was to investigate components of the propulsive forces from fluid forces acting on the hand in breaststroke swimming. Subject was Japanese one elite male breaststroke swimmer. The motion in breaststroke swimming at flow velocity 1.25 m/s of the swimmer was recorded by using two synchronized video cameras. Ten landmarks on the light upper body were digitized at 60 Hz and their three-dimensional coordinates obtained using a DLT method. The fluid forces acting on the hand was estimated using the drag and lift coefficients by Schleihauf (1979). Estimated peaks of fluid forces acting on the hand in the breaststroke swimming were observed between glide phase and out-sweep phase, out-sweep phase and in-sweep phase, respectively. The max of fluid forces acting on the hand was 101.9 N. The ratio of the drag and lift that composes the fluid forces was 53.4 % and 43.6 %, respectively. Furthermore, the propulsive forces in fluid forces were calculated from the propelling element of fluid forces. The peak of propulsive forces on the hand in breaststroke swimming was observed between out-sweep phase and in-sweep phase. The max of the propulsive forces on the hand was 26.8 N. In propulsion forces of the swimmer generated by hand pull, lift forces were dominant. Also, the hand pitch angle between out-sweep phase and in-sweep phase was observed range from 30 to 40 degrees. In conclusion, this study would like to state the following two points. First, the propulsive forces on the hand in elite breaststroke swimmer generated by lift forces. Second, the swimmer was high lift forces were obtained by maintaining optimum hand pitch angle.

AGONIST MUSCLE ACTIVATION AND ANTAGONIST MUSCLE CO-ACTIVATION LEVELS DURING STANDARDIZED ISOTONIC AND ISOKINETIC KNEE EXTENSIONS

Remaud, A., Guével, A., Cornu, C.

University of Nantes, Nantes Atlantique Universities, France

Introduction

In order to limit muscular tension and to stabilize the joint, the neuromuscular system is able to reduce the level of agonist muscle activation and/or to increase the level of antagonist muscle co-activation, thus controlling the external torque produced at the joint. The aim of this study was to analyze agonist muscle activation and antagonist muscle co-activation levels during standardized isotonic and isokinetic knee extensions.

Methods

Twelve subjects performed two sessions of tests on an isokinetic dynamometer. The first session allowed the subject to be familiarized with isotonic and isokinetic contraction modes. During the second session, maximum voluntary isometric torque (MVIT) was assessed in knee flexion and extension. Then, the subject had to perform 3 sets of 8 isotonic knee extensions at 40% of MVIT. After a 10-min rest

period, the subject had to perform 3 sets of "n" isokinetic knee extensions at a preset velocity similar to the mean velocity measured during the corresponding isotonic set; "n" represented the number of isokinetic repetitions the subject had to achieve in order to equalize the external amount of work performed during the corresponding isotonic set (Remaud et al. 2005). The range of motion was 105° to 25° of knee flexion (0° = leg in horizontal position). Surface electromyographic signals were collected from vastus lateralis (VL), vastus medialis (VM), rectus femoris (RF), semitendinosus (ST) and biceps femoris (BF) muscles during the second session. To assess activation and co-activation levels, RMS values were calculated for each muscle during isotonic and isokinetic contractions and then normalized to the maximal RMS value recorded during MVIT.

Results

In isotonic mode, agonist muscle activation and antagonist muscle co-activation levels were found to be significantly greater (respectively 7.9% and 14.6%) than in isokinetic mode. When both contraction modes were pooled, VL, VM and RF activation levels were not significantly different ($p > 0.05$) but BF co-activation level was found to be 41.9% greater than ST co-activation level.

Discussion/Conclusion

As we found previously (Remaud et al., 2005), our results confirm that a same number of repetitions is necessary in both contraction modes to perform a same external amount of work. The greater agonist activation level found in isotonic mode may explain in part this result. The hamstring muscles seem to adjust their co-activation level to the activation level of the quadriceps muscle. Due to its lateral insertion on the tibia, BF could be more co-activated to protect knee joint from internal tibial rotation induced by the quadriceps muscle during knee extension (Aagaard et al., 2000). These results may help athletic coaches and clinicians to optimize training methods and rehabilitation programs.

COMPARISON OF CYCLE CRANK TORQUE COMPUTED FROM FORCES APPLIED TO THE PEDALS AND MEASURED WITH AN SRM ERGOMETER

Bailey, M., Nesi, X., Passfield, L., Carter, H.

University of Brighton, United Kingdom

Introduction

This study aimed to use crank torque (CT) calculations to validate the use of two-dimensional force transducers mounted at the shoe-pedal interface.

Methods

A competitive cyclist performed 1-min tests at five different work rates, from 132 to 447 W, using their normal cycling position on a SRM ergometer equipped with the force transducers. During the tests, the subject was asked to maintain cadence at 90 rpm using visual feedback. Markers were applied on either side of the crank spindle, the pedal spindles and the force transducers. Two digital video cameras (50Hz) viewed the sagittal plane. The video data were digitised and smoothed using an Ariel Performance Analysis System to obtain crank angle, pedal angle and crank angular acceleration (CAA). The forces at the pedals were sampled at 50Hz via a 12 bit A/D converter and the CT was sampled at 200Hz from the SRM ergometer (CTsrm). The force and angular position values were interpolated to obtain a sampling rate of 200Hz, and synchronised using peak CAA and CT. The CT was computed from forces applied to the pedal (CTpf) using the crank length and the effective force. For all work rates, the comparison of CT was performed on 8 complete crank revolutions and on the 16 peak torques observed. The CT bias was calculated in absolute units (Nm) and in percentage (CTpf-CTsrm/CTsrm). The precision of bias was shown using 90% confidence limits (90%CL). Wilcoxon and Spearman tests were used to determine difference and correlation between 2 sets of data. A Friedman ANOVA was used to examine the effect of work rate on the CT bias.

Results

Across work rates, the mean ± s.d. peak CTsrm increased linearly from 22.1 ± 0.9 to 80.1 ± 3.9 Nm and the CTpf increased linearly from 23.3 ± 1.2 to 81.9 ± 2.2 Nm. The position of mean ± s.d. peak CTsrm decreased from 114.5 ± 1.8 to 88.6 ± 1.9 degrees similarly the CTpf decreased from 110.5 ± 2.4 to 88.4 ± 2.3 degrees. When comparing complete crank revolutions, the CTpf was significantly different to CTsrm, except at 186W and bias decreased significantly and linearly with workload from 0.20 to 2.03 Nm (6.8 to 7.2%). At each workload, CTpf was strongly correlated with CTsrm (R^2: 0.89-0.98). For the overall tests, the bias was significant (90%CL: 0.69/ 0.52 Nm and 3.0/ 2.0%) and R^2 computed between CTpf and CTsrm was 0.94.

Discussion

Assuming that CTsrm is the "gold standard", the results indicated that CTpf tended to underestimate CT, especially at higher workloads. The crank angle bias analysis indicated that this difference related to lower CTpf values at top and bottom dead centre, whilst the peak CTpf values were slightly higher. Significant differences were observed between the two measurement methods on these preliminary tests, but the moderate 90%CL bias (<1 Nm, <3%) and the strong relationships between the methods, support the potential of the force transducers to be developed into a useful method to study the variation in applied pedal force components.

VALIDITY OF HEART RATE TURN POINT TO SET TARGET HEART RATE FOR PROLONGED ERGOMETER ROWING EXERCISE AND SINGLE SCULLING

Hofmann, P., Jürimäe, T., Jürimäe, J., Purge, P., Mäestu, J., Wonisch, M., Pokan, R., von Duvillard, S.P.

Karl-Franzens-University and Medical University Graz, University of Vienna, University of Tartu, Estonia, Texas A&M University - Commerce USA, Austria

To evaluate athletes it is necessary to keep performance tests as specific as possible (2). On-water exercise testing in rowing presents a number of difficulties, particularly in the collection of expired gases, blood sampling and defined loading. For these reasons, laboratory

tests using specific ergometer systems may provide a reliable alternative (2, 3, 6). The HRTP was shown to be a valid method to describe steady state exercise on cycle ergometer (3, 4, 5) but results in rowers are controversial (1). Aim of the study was to evaluate the use of the Heart Rate Turn Point (HRTP) to set target heart rate (THR) for prolonged rowing ergometer (E) and single scull rowing (R). Methods: Ten trained male and female subjects (mean±SD: age 21.3±4.0 yrs; VO2max 4.77±0.62 l.min-1) performed an incremental exercise test and 30 min prolonged E and R. Expired air and heart rate (HR) were measured continuously. During E and R blood lactate concentration (La) was measured at rest and after 5 (E only), 10, 20 and 30 min. The HRTP was determined as the deflection point of the heart rate performance curve. Ventilatory threshold was determined by the second deflection point in minute ventilation (VETP2) associated with the turning points for VE/VO2 and VE/VCO2. Results: No significant differences were found for work rate (W), HR and VO2 between HRTP and VETP2 and they were significantly related (r=0.94, p<0.001; r=0.96, p<0.001). THR for prolonged exercise was set at the HRTP (168±7 min-1). Mean HR, VO2, VCO2 and VE were not significantly different between E and R. La remained at a steady state in both E and R but was slightly higher in E. Tidal volume (VT) was found to be lower and breathing rate (BR) was significantly higher in R. Conclusion: These results suggest that HR at HRTP from an incremental rowing ergometer exercise test is valid to establish a THR consistent with constant metabolic training intensity in prolonged ergometer and single scull rowing.

RELATIONSHIP BETWEEN MECHANICAL POWER DURING MAXIMAL STROKES AND 2000M INDOOR ROWING PERFORMANCE

Veloso, A., Simões, M., Armada-da-Silva, P.

Faculty of Human Kinetics, Technical University of Lisbon, Portugal

Introduction

The general aim of this study was to examine the relationship between power during maximal strokes and performance during a 2000 m rowing test. Both mean and maximal power (Wmean-10MS; Wmax-10MS) obtained during ten maximal strokes were used to explain changes in mean time (T2000), mean velocity (V2000) and mean power (W2000) during a 2000m rowing test.

Methods

Ten male rowers (body mass 79.8 ± 1.7 kg; 183.8 ± 1.8 cm height; age 19.9 ± 1.0 years) volunteered to participate in this study. All subjects were well familiarised with both the ergometer (Concept2, model C) and the exercise tests used in the study.

The ergometer was damped adjusted in setting 3 and calibrated with the drag factor 129. The software e-Row (version 4.0) was connected to PM2+ performance monitor and used to obtain the pace, velocity and mean power of each stroke.

After a 10-min warm-up, subjects were asked to perform ten strokes at a maximal effort (10MS). They then rested for 5 minutes after which they started the 2000m test.

The relationship between variables was obtained by linear regression. The first and last repetitions of the 10MS were excluded from analysis, so results respect only strokes 2nd to 9th.

Results

Time to complete the 2000m test (T2000) was 400.5 ± 15.2 s, with mean velocity and power of 5.0 ± 0.2 m.s-1 and 353.3 ± 41.0 W, respectively. Mean (Wmean-10MS) and maximal powers (Wmax-10MS) during the 10MS were respectively 577.9 ± 107.0 W and 701.6 ± 121.0 W.

Results showed that Wmean-10MS was strongly correlated with T2000 (y = -0.1361x + 479.21, R2 = 0.918), V2000 (y = 0.0017x + 4.0253, R2 = 0.872), and W2000 (y = 0.3567x + 147.14, R2 = 0.868).

Wmax-10MS was also strongly correlated with the analysed variables: T2000 (y = -0.1188x + 483.9, R2 = 0.894), V2000 (y = 0.0015x + 3.9817, R2 = 0.825), and W2000 (y = 0.3067x + 138.06, R2 = 0.821).

Discussion/Conclusion

The results demonstrated that power generated during ten maximal rowing strokes is a strong predictor of performance of 2000m rowing. These results are consistent with previous studies1,2,3 and support the use of the simple 10MS test as a meaningful way of evaluating the performance ability of rowers.

A SINGLE TEST FOR ASSESSING PHYSIOLOGICAL AND PERFORMANCE PARAMETERS IN ROWERS

Bourdon, P., Buckley, J.

South Australian Sports Institute, Australia

Purpose: To determine the validity of a novel exercise test incorporating incremental exercise and a 2000 m time-trial for assessing blood lactate transition thresholds and rowing performance in well-trained rowers.

Methods: Ten well-trained rowers performed, on separate occasions and in random order, an incremental seven-step rowing test (7-STEP), a 2000 m time-trial (2k), or a combined test involving the performance of six incremental submaximal work loads followed by 15 min of recovery and then a 2000 m time-trial (6+2k).

Results: Absolute peak oxygen uptake (peak VO2) was higher during 6+2k compared with 7-STEP (4.23 ± 0.21 vs 4.14 ± 0.20 l/min, P = 0.02) and was more strongly related to 2000m time-trial performance (r^2 = 0.98 vs r^2 = 0.96). Peak rating of perceived exertion (RPE) was lower during 6+2k compared with 7-STEP (19.4 ± 0.2 vs 19.9 ± 0.1, P = 0.01). There were no differences in time taken to complete the 2000 m time-trials between tests (P = 0.22), nor were there any differences in blood lactate transition thresholds (P > 0.35) or any other test parameters (P > 0.09).

Conclusion: Physiological and performance parameters that have traditionally been assessed using separate incremental and 2000 m time-trial rowing tests can be validly determined during a single exercise test. This single test may provide a more valid assessment of peak VO2 than a standard incremental exercise test, and the finding of a lower peak RPE suggests that it may also be less stressful for the athlete. The adoption of this test would reduce the time and expense associated with the physiological assessment of rowers.

CIRCADIAN RHYTHMS IN VARIOUS METABOLIC RESPONSES TO INCREMENTAL ROWING EXERCISE

Forsyth, J., Reilly, T.

North East Wales Institute of Higher Education and Liverpool John Moores University, United Kingdom

Circadian rhythms in metabolic responses to exercise have been investigated fairly extensively, although there are still discrepancies in the literature regarding whether certain variables, such as maximum oxygen consumption (VO2max) and blood lactate concentration vary rhythmically due to time of day. The purpose of this study was to investigate circadian rhythmicity in various metabolic variables at rest and in response to a multi-stage, 3-min, incremental test to exhaustion on the Concept II rowing. Eleven male, endurance-trained athletes, with a mean (±SD) age of 29.5 (±6.1) years, height of 1.80 (±0.05) m and body mass of 79.5 (±6.7) kg were tested at 02:00, 06:00, 10:00, 14:00, 18:00 and 22:00 h with the order of testing being counter-balanced between subjects and a minimum of two days separating trials. Rectal temperature (Trec) was measured at rest; power output, oxygen consumption (VO2), pulmonary ventilation (VE), heart rate (HR), respiratory exchange ratio (RER) and blood lactate concentration were recorded at rest, throughout the exercise test, and post-exercise. Ventilatory threshold (Tvent) was also determined. A cosinor analysis was performed on group data to detect circadian characteristics of the variables. Significant circadian rhythms were observed for resting values of HR (p=0.01, acrophase 16:52 h), VO2 (p=0.02, acrophase 21:57 h) and VE (p=0.03, acrophase 19:23 h), coinciding in phase with that of Trec (acrophase 17:28 h), but not for maximum values of VO2, VE, power output and HR. Cosinor analysis revealed significant circadian rhythms for pre-test blood lactate concentration (p=0.02; acrophase 09:46 h), and resting and maximum values of RER (p=0.03, acrophase 10:06 h and p=0.03, acrophase 09:02 h, respectively). Blood lactate concentration taken 5 min post-exercise approached significance (p=0.06). Acrophases for these variables (pre- and post-exercise blood lactate concentration and RER) were similar, but were significantly different to that of Trec, suggesting that values were affected by the diurnal pattern of food intake and fasting at night. Power output, VO2 and HR at Tvent did not differ due to time of day, but blood lactate concentration at Tvent did (p=0.009, acrophase 12:16 h), suggesting that there may be a change in blood lactate concentration due to time of day. The results of this study add support to the view that circadian rhythms do exist for certain metabolic variables, in particular VO2, VE, RER and blood lactate concentration, being most apparent at rest, and concur with other studies in that time of day needs to be controlled when making comparisons of metabolic parameters.

HORMONE RESPONSES TO MAXIMAL ROWING BEFORE AND AFTER PROLONGED TRAINING IN ELITE MALE ROWERS

Purge, P., Jürimäe, J., Jürimäe, T.

University of Tartu, Estonia

The assessment of the circulating hormone concentrations during prolonged training has received considerable attention due to its implications for general adaptive mechanisms and for physical conditioning. The purpose of the present study was to examine the effect of a preparatory period on resting anabolic and catabolic hormone concentrations and these hormone responses to maximal 6000-m rowing in elite male rowers. Ten rowers (20.2 ± 2.9 yrs; 192.7 ± 4.9 cm; 91.6 ± 5.8 kg) participated in this study. All rowers had a long and regular endurance training experience (7.0 ± 3.7 years) and they were competing at a national or international level. The subjects were tested before and after the 24-week training period; and body composition, maximal 6000-m performance and maximal oxygen consumption were measured. There was an increase in mean weekly training volume (by 16%; from 13.3±1.9 to 15.4±1.5 h.week-1) at the end of preparatory period. The prolonged training period also increased the aerobic capacity values (VO2max: 6.2 ± 0.4 vs 6.4 ± 0.5 l.min-1; Pamax: 438.8 ± 35.5 vs 459.9 ± 26.2 W). Similarly, 6000-m rowing ergometer performance time was significantly improved (from 1200.8 ± 29.9 to 1188.8 ± 23.4 s) after the training period. Resting testosterone, cortisol, growth hormone and creatine kinase activity values did not differ before and after the 24-week training period and were significantly increased following maximal exercise. Testosterone concentration was significantly lower immediately after the test after the 24-week training period compared to the corresponding baseline value. Testosterone values were reduced to the resting level during the first 30 min of recovery in both measurement sessions. Cortisol values immediately after and after the first 30 min of recovery were significantly lower after the preparatory period compared to the corresponding values obtained at baseline measurement. No differences between measurement sessions were observed in growth hormone concentration. After the preparatory period, creatine kinase activity decreased significantly after 30 min of recovery compared to the value obtained immediately after the test. In conclusion, the results of the present study demonstrated that further improvement in performance capacity in elite male rowers is best reflected by smaller post-exercise increases in testosterone and cortisol concentrations, while resting concentrations of these hormones did not change as a result of training period. Typical preparatory period in elite rowing training also appears to induce faster recovery of increased creatine kinase activity from strenous exercise test.

ADIPONECTIN AND STRESS HORMONE RESPONSES TO MAXIMAL SCULLING AFTER PROLONGED EXERCISE TRAINING IN ELITE ROWERS

Jürimäe, J., Purge, P., Jürimäe, T.

University of Tartu, Estonia

The evaluation of different adipocytokines and stress hormones during prolonged exercise training is of interest due to their implications for general adaptive mechanisms. Prolonged exercise training that has been carried out for several months represents a physical stress condition in which different hormonal responses are apparently linked to changes in physical performance. There is insufficient data

about the responses of specific adipocytokines to prolonged exercise training, and the interrelationship of these adipocytokines and different stress hormones during such training period.The purpose of this study was to investigate the resting and acute exercise-induced hormone responses of male rowers as a result of six-month of volume-extended training season. Body composition, maximal aerobic capacity and on-water 2000-m sculling performance were assessed before and after a 24-week training in elite rowers (n=11; 193.1±5.2 cm; 91.6±5.8 kg; VO2max: 6.2±0.5 l.min-1). Six rowers were selected (SEL; 192.0±6.3 cm; 93.5±7.1 kg; VO2max: 6.4±0.4 l.min-1) and five were not selected (N-SEL; 194.8±4.1 cm; 89.6±4.0 kg; VO2max: 6.0±0.5 l.min-1) for the National Team. Resting adiponectin did not change as a result of prolonged training. Adiponectin did not change after 2000-m rowing at baseline, either. No responses were also observed 24 weeks later in SEL rowers, while a significant decrease (P<.05) was observed in N-SEL rowers. At the same time, leptin also decreased after the first 30 min of recovery in N-SEL rowers. After the training period, immediate post-exercise increases in growth hormone and testosterone were significantly higher in the whole group of rowers. No differences in cortisol responses were observed before and after the training period in SEL and N-SEL rowers. In conclusion, our results extend data about the adiponectin response in athletes after a heavy training period. It appears that resting adiponectin does not change as a result of the heavy training period in highly trained rowers with different performance levels. In contrast, training modifies adiponectin response to an acute bout of maximal exercise depending on the performance level of athletes. Specifically, heavy training period caused significantly higher post-exercise values in rowers with better performance capacity, while significant decreases in post-exercise adiponectin and leptin values were observed in rowers with lower performance capacity. This was thought to reflect the inadequate recovery capacities of these rowers.

INDIVIDUAL DEVELOPMENT OF ROWING SPECIFIC COMPETITION PERFORMANCE IN ORDER TO ENDURANCE PERFORMANCE

Grabow, V., Heyden, G.

Institute for Sport and Science of Sport, Germany

A 2000m-rowing race takes about 6 minutes according to the boat-class at good weather-conditions. Energy distribution of approximately 87 % aerobic, 8 % anaerobic lactic and 5 % anaerobic alactic can be assumed (Hartmann 1987). The present study demonstrates the individual development and connection between rowing specific competition performance and endurance performance. Also it allows conclusions on the individual adaptation of the energy delivering systems.

Within a longitudinal study over a period of 7 yrs 16 top elite rowers (at the beginning: age 20,7 ± 1,4 yrs, height 195,7 ± 3,6 cm, weight 92,4 ± 5,9 kg) took part. All athletes were member of the German National Team. At the beginning, end and during the study each rower performed at least once a year a combined two step test (step duration 8 minutes, 30 seconds rest between the steps) and competition test (step duration approximately 6 minutes) on a concept II (type C) rowing ergometer. Besides the above mentioned parameters average power output (watt), average stroke rate (1/min), heart rate (1/min) and ear capillary blood lactate (mmol/l) was estimated.

Over the time period of the study an average increase of 1,6 kg body weight (BW) was observed. Rowing specific competition performance was improved by 27 watt (+ 5,9%), endurance performance at 4 mmol/l lactate (P4) by 17 watt (+ 5,4%). The share of P4 in the energy provision didn't change significantly and was approx. 69%. But there were clear individual variations of P4, both in the direction of "more aerobic.

CHANGE IN THE CHARACTERISTICS OF THE MUSCLE-TENDON UNIT DURING PASSIVE STRETCHING

Abellaneda, S., Guissard, N., Duchateau, J.

Université Libre de Bruxelles, Belgium

Introduction

The increase in passive tension (PT) during stretching is known to be a limiting factor of the muscle-tendon unit elongation (1). Such limitation rises the question of the structural components involved in the enhancement of PT in vivo. This study examines the changes in muscle architecture during gradual passive stretching and contributes to the discussion of the underlying mechanisms of PT enhancement.

Methods

Twenty subjects (20-24 yrs), participated in the study. During the experiments, the subject layed in supine position, the right foot strapped to a movable footplate. The ankle angular displacement and PT during passive stretching of the triceps surae were measured by means of a potentiometer and a force transducer, respectively. The architectural changes of the Medial Gastrocnemius (MG) and Soleus (Sol) muscles were obtained by ultrasonography. Pennation angles (angle between muscle fascicles and deep aponeurosis) and fascicles length were measured during muscle stretching. The equation of Grieve (2) was used to estimate the relative tendon lengthening compared with the total muscle length change.

Results

PT increased exponentially (r^2=0.9) during the stretching of the triceps surae, from 5.2 ± 1.6 N.m in neutral position (ankle at 90°) to 24.0 ± 2.4 N.m at 30° dorsiflexion. Concomitantly, the pennation angles of the GM and Sol decreased, respectively, from 19.3 ± 3.7° and 13.8 ± 3.6° at 0° to 14.4 ± 3.1° and 10 ± 2.9° at 30° dorsiflexion. In the latter ankle position, fascicles length increased by 40.8 ± 11.7% and 33.9 ± 10.3% in the GM and Sol, respectively, whereas the total muscle-tendon unit lengthened by 7.2% of its initial value. For part of the subjects (n=14), Sol and MG fascicles length increased linearly and tendon curvilinearly (asymptotic horizontal limit) with enhanced dorsiflexion. An opposite behaviour was observed for the other subjects (n= 6).

Conclusion

The subjects showing a curvilinear increase of tendon length and linear increase of fascicles length during ankle dorsiflexion presented a greater ankle flexibility. For this group, tendon elongation can be the limiting factor of muscle stretching. In contrast, for subjects presenting the opposite behaviour, fascicles elongation may be the limiting factor. Indeed, the observation that, at 30° dorsiflexion, tendon

lengthening only attained 2.4 ± 1.4% of its initial value, whereas it reached 4-5% during isometric MVC (3), suggest that this structure was not the major contributor of PT enhancement in the second group. Thus, MG and Sol fascicles should play a key role in PT increase during large amplitude stretching, because greater torque must be generated when their length changes progressively decline (dorsiflexion > 10°). Other structures (joint capsules and ligaments) could have also contributed to limit the stretching of the triceps surae.

A PROPOSED METHOD TO EVALUATE THE ACUTE EFFECT OF AN INCREASED FRACTION OF INSPIRED OXYGEN (FIO2: 0.45) ON THE PARAMETERS OF THE POWER-TIME RELATIONSHIP IN HIGHLY TRAINED ATHLETES

Lemieux, L., Norris, S.R., Smith, D.J., Kolb, J.C.

University of Calgary, Canada

Moritani et al. (1981) had two subjects breathe a hypoxic gas mixture during constant load exercises to establish the power-time relationship via the critical power concept and reported that performance times were diminished. The purpose of this study is to examine the influence of an elevated fraction of inspired oxygen (FIO2: 0.45) on the power-time relationship in highly trained males (subjects are required to have an MAP of 5W∙kg-1 or a VO2max of 62mL∙kg-1∙min-1). Subjects performed one maximal incremental cycle test and twelve constant load tests: three times a series of four exhaustive constant load tests corresponding to approximately 140, 110, 90 and 83% of maximal aerobic power (MAP). Series 1 was performed in normoxia (NORM), series 2 was in hyperoxia (HYPER) (0.45) and series 3 was again in NORM. The order of tests within each series was randomized. Critical power (CP) and anaerobic work capacity (AWC) were determined for each series using the power inverse time model (Whipp et al., 1982) and the work vs time model (Monod and Scherrer, 1965). For each of the constant load sessions, 4 125μL arterialized blood samples were taken at the ear during rest, prior and post wash-in period, as well as immediately post and 3min post exercise. Blood lactate, complete blood gas profile, pulse oximetry (temporal sensor), heart rate and temperature (infrared tympanic) were measured. During the 110% of MAP test in NORM, expired gases were also measured to evaluate if any maturation or confounding effects had taken place during the study. Preliminary results (N=4) indicate that CP increased from 288W in NORM to 303W in HYPER with the work vs time model and increased from 298W in NORM to 313W with the power inverse model. AWC increased from 17452J (NORM) to 19661J (HYPER) using the work vs time model, but the power inverse time model did not reveal a statistical difference between NORM (15703J) and HYPER (16686J). Discrepancies between models may be explained by the low sample size and the level of sensitivity of each model. These preliminary findings indicate that exercising in HYPER not only influences indicators of the aerobic system (CP), but may also influence indicators of the anaerobic system (AWC). HYPER appears to allow subjects to maintain elevated saturation of O2, measured by pulse oximetry and co oximetry, as well as PO2. PCO2, HCO3-, pH, hemoglobin, hematocrit and blood lactate do not appear to be affected by the increased FIO2. (Sample size for this study is likely to reach N=12 in the next few weeks)

SIGNIFICANCE OF THE RESPIRATORY KINETICS DURING RECOVERY IN RELATION TO ENDURANCE PERFORMANCE

Vardaxoglou, K., Frische, M., Stuke, N., Maassen, N.

Medical School, Hannover , Germany

INTRODUCTION:

On the last ECSS Congress we have shown that endurance capacity is related to the increase of the VE (slope) during continuous exercise. To further investigate the relation between Ventilation and performance we examined whether the kinetics of VE during the recovery period after different tests is dependent on the endurance performance.

METHODS:

The kinetics of the ventilatory parameters (Metalyser 3B) were determined during the recovery period of incremental tests until subjective exhaustion (n=46, men of different fitness level Age: 27.6 + 5 years) and endurance tests (80% Wmax; n=23, Age: 27.1 + 2.9 years). Data were fitted to a mono exponential equation with a linear term. The different parameters of the kinetics were correlated to the lactate concentration, to the duration of exercise at constant power and to the [Lac] at different time points of the recovery periods. [Lac] was measured after 1', 3', 5', 7' and 10' of the both recovery periods from the ear lob.

RESULTS:

After the incremental tests, the time constants of VE, VO2, VCO2 do not correlate with the [Lac] at any time point of the recovery period. The time constants of VE and VO2 of the incremental tests do not correlate with the relative power (Watt/Kg) but the VCO2 does ($p<0.05$). The time constants of VO2 and VCO2 correlate with maximal power ($p<0.001$ and $p<0.05$) but the time constant of VE does not. The linear terms show no significant correlation to [Lac] or performance.

After the endurance tests, the time constants of VE do not correlate with the [Lac] after 1' and 3' but correlates with [Lac] after 5', 7', 10' ($p<0.05$) of the recovery period. However, the time constants and the amplitudes of the ventilatory parameters during recovery do not correlate at all with the relative performance (Watt/Kg).

The performance time during the endurance tests correlate negatively with the time constants of VE during recovery ($p<0.01$), the linear term of VE during exercise ($p<0.001$) and with the [Lac] after 1', 3', 5' ($p<0.01$), 7' and 10' ($p<0.001$) of the recovery period. The linear term of the kinetics after the endurance tests is not related to the [Lac].

The linear term of VE during exercise of high intensity correlates very well with the time constant of VE during the recovery period ($p<0.01$).

DISCUSSION:

We found no relationship between the kinetics of VE and [Lac] after the incremental tests. On the other hand a relationship between [Lac] during the late recovery period and the time constant of VE and exists after the endurance test. That is astonishing as the time constant is mainly determined by the early, rapid decrease of VE. Thus a causal relationship between [Lac] in arterial blood and ventilation seems unlikely. The close correlation between the linear term during exercise and the time constant of ventilation after exercise to the endurance time shows a close relation of ventilation to endurance capacity. The physiological mechanism behind that has to be clarified.

RELATIONSHIP BETWEEN ANAEROBIC PERFORMANCE AND MATURATION IN PORTUGUESE AND BRAZILIAN YOUNG BOYS

Ribeiro Jr., D. 1, Tavares, P. 1, Lima, J. 2, Rosado, M.F. 1, Fontes Ribeiro, C.A. 1

1 Faculty of Sport Science and Physical Education, University of Coimbra, Portugal, 2 Faculty of Physical Education and Sports; Federal University of Juíz de Fora, Brazil, Portugal

Despite recognition that studies about anaerobic performance in young people are still sparse, data in the last few years has been strongly produced. In sport competition the anaerobic pathway development, and its comparison with maturation degree, is a key point that could give advantage to some young athletes. Thus, it is of major importance to compare populations of the same age from different countries and/or cultures. However, only a few works were found concerning this approach. Among the published studies, the majority was about female and only one work compared the Brazilian with the French Population (1). Therefore, the aim of this work was to study the influence of maturation degree in the power output of young people from Portugal or Brazil. In order to achieve our goals, male populations were grouped according to their age: Group I (from 10 to 12 years old), Group II (from 13 to 15 years old) and Group III (from 16 to 18 years old). The Brazilian and Portuguese populations were evaluated in their countries by the same research team in order to avoid measurement bias. An anthropometric evaluation of the groups was followed by an indirect maturational evaluation according to Tanner methodology. Young boys from each group performed a Wingate test in order to evaluate the anaerobic peak power and capacity (mean power). For that, a Monark® cycloergometer was used. Before and after the Wingate test a blood drop was collected for lactate analysis. The blood lactate concentration was measured using the Lactate Pro LT-1720®.

From the assessment of maturation (Tanner's stages) we observed that the Brazilian young boys showed a higher development (above normal values) when compared with the Portuguese population (that was under the normal values for each age). The anthropometric measurements showed a normal evolution when compared across the time with the exception of the Portuguese group II that has a higher body mass, percentage of fat and quantity of fat free tissue. This group was also the only one that showed significant differences in the anaerobic output when compared to Brazilian boys. Despite these differences no correlation was observed between maturation degree and anaerobic performance in this group. However, the anaerobic power and capacity were correlated with the body composition and blood lactate concentration. There was, in both populations, also an obvious change in anaerobic performance around 15 years old, as expected.

Our results suggest that the maturation degree (measured by Tanner methodology) did not influence anaerobic performance in group II. This parameter is probably correlated with an increase in body size. However, the groups I and III showed normal results and intra-groups correlations, as expected. The differences found between all groups of both populations seem to be dependent on several factors (genetic or social) that may control the development of the anaerobic pathway.

CONTINUOUS ASSESSMENT OF BLOOD PRESSURE USING THE EARLOBE PHOTOPLETHYSMOGRAM DURING EXERCISE

Kumahara, H., Kawano, H., Matsuda, T., Kiyonaga, A., Shindo, M., Tanaka, H.

Laboratory of Exercise Physiology, Japan

Introduction: Exercise stress test plays an important role in general evaluation of a cardiovascular and exercise tolerance, which can be valuable for ensuring a safety to participate in exercise training. Arterial blood pressure (BP) is an important parameter in the exercise stress. Recently a non-invasive continuous (beat-by-beat) blood pressure monitor based on a photoplethysmogram has been developed (Radia Press RBP-100, K&S Co., Japan). The new device consists a double wave-length spectrophotometry sensor, which is just clipped to the earlobe. It measures perfusion changes and then assesses BP. This may present some advantages such as less-restricted body movement and non-uncomfortable pressure. Beat-by-beat BP offers important and clinically relevant information on cardiovascular stress. The purpose of this study was to compare BP determined by the new device to that of the classical cuff-based Riva-Rocci (Korotkoff sound) method and of the previous validated Finometer (Finapres Medical Systems BV, Netherlands) during exercise.

Methods: Six young males (24±2yr of age and 21.8±0.8kg/m2 of BMI) performed a graded exercise test using a cycle ergometer. The work rate started at 15 watts and then increased by 15 watts every 2 minutes until the heart rate reached 85% of its maximum expected for the age. The systolic blood pressure (SBP) was measured by the earlobe photoplethysmogram method (SBPpl) and Finometer (SBPfi), simultaneously. The brachial arterial SBP measured by an automatic manometer (Tango, SunTech Medical Instruments Inc., USA) based on the Korotkoff sound technique was also employed (SBPko). The SBPpl and SBPfi values were averaged for 10 consecutive beat of just before each stage of exertion, and the SBPko was measured once each stage at the same time period. Double product (DP: SBPxHeart rate), as an index of cardiac oxygen demand, was also calculated. To compare the SBP determined by these devises, all the values during exercise were averaged.

Results: The average values of SBPpl, SBPko and SBPfi were 163.1±21.9, 138.4±24.3 and 147.7±28.8 mmHg, respectively. SBPpl was significantly($p<0.001$) higher than SBPko(25±18mmHg, 95%CI -10,60) and SBPfi(16±27mmHg, 95%CI -39,70). However, significant correlations were observed between SBPpl and SBPko($r=0.716$) or SBPfi($r=0.444$). When the relative change in the SBP from resting (calibration) to exercise period was calculated, these correlation coefficients increased. The DPpl significantly correlated with the DPko($r=0.947$) and DPfi($r=0.898$).

Discussion/Conclusion: The inter-individual variability of the relative error in SBP showed large deviation, however, the relative changes due to exercise loads could comparatively well assessed. These results indicated that careful individual calibration might be needed to provide more accurate assessment. The new device has a potential for the application of efficient exercise prescription.

TOTAL HAEMOGLOBIN MASS - A PROMISING PARAMETER TO DETECT BLOOD MANIPULATION

Prommer, N.

University of Bayreuth, Germany

To counteract against excessive blood manipulations haematological upper limits were introduced during the past years in most endurance sports disciplines. Once an athlete exceeds these limits he is suspended temporarily from competition and a doping analysis is

performed. This procedure, however, has the big disadvantage that changes in plasma volume can veil manipulations or lead to unwarranted sanctions towards the athlete. As the intention of every kind of blood manipulation is to increase total haemoglobin mass (tHb) it would be important and more reasonable to determine this key parameter directly. The aim of the project presented here was 1) to develop an easy manageable and fast method to determine tHb and 2) to evaluate whether tHb is a valid parameter to detect blood manipulation.

Objective 1: The commonly used and established CO-rebreathing method (Proccom) was optimised by changing the procedure of CO-administration and the breathing pattern, i.e. that instead of inhaling an O2-CO gas mixture for 10-15min a CO bolus was applied (Procnew) which reduced respiration time to 2min. Taking into account the modified kinetic of HbCO formation in Procnew capillary or venous blood sampling has to be performed in minute 7 after the onset of CO respiration to achieve identical tHb values as in Proccom (n=23). Reliability was evaluated in test-retests showing a typical error of 1.7%, i.e. that changes in tHb of more than 3.4% ($p<0.05$) are not due to methodical imprecision. Validity was determined by phlebotomy of 550ml (difference between calculated and measured values: 0.8 ±1.5%). HbCO halftime at rest averaged 132 ±77min and was lowered by more than 30% after exercise. Immediately after application of Procnew VO2max was reduced by 3.0 ±3.7%, i.e. that testing should not be performed straight before (6h) a competition.

Objective 2: tHb as a parameter to detect blood manipulation can only be beneficial if its physiological oscillation during a training year is lower than 12% which is characteristic for blood or EPO doping. We therefore examined 11 (6 triathletes, 5 cyclists) competitive athletes and 6 leisure sportsmen in regular intervals 5 times in the course of 12 months. The triathletes showed the highest oscillation with a mean maximum of 6.0 ±2.0%, followed by the leisure sportsmen (4.9 ±1.7%) and the cyclists (4.3 ±2.9%). The individual maximum deviation of the year's mean was 4.9%. Changes in [Hb] and Hct did not show any coherence to the changes in tHb.

It can be summarized that the optimized CO-rebreathing method is a valid tool to determine tHb exactly. As tHb does not show substantial physiological changes at lowlands and implicates individual predisposition it might outmatch the current haematological upper limits. It might therefore be a promising screening tool to pick out suspicious athletes and detect blood manipulation. However, influences of high altitude training, injuries and infections on tHb still have to be examined.

SKELETAL MUSCLE GLUCOSE UPTAKE HETEROGENEITY DECREASES WITH INCREASING EXERCISE INTENSITY

Nesterov, S.V., Kemppainen, J., Fujimoto, T., Nuutila, P., Knuuti, J., Kalliokoski, K.K.

University of Turku, Finland

The influence of exercise on muscle glucose uptake has been studied in plenty; however, changes in heterogeneity of this uptake during exercise still need attention. The purpose of the present study was to investigate the effects of increasing exercise intensity on skeletal muscle glucose uptake heterogeneity in healthy men.

Six practically healthy right-handed young men were studied during cycle ergometer exercise at relative intensities of 30% (LOW), 55% (MODERATE), and 75% (HIGH) of maximal oxygen consumption (VO2max) on three separate days. Glucose uptake in the quadriceps femoris muscle (QF) was directly measured using positron emission tomography (PET) and 18F-fluoro-deoxy-glucose ([18F]FDG). [18F]FDG was injected 10 min after the start of the exercise. Then the exercise was continued for another 25 min. PET scanning was conducted immediately after completion of the exercise. The measured glucose uptake values reflect the situation during exercise due to chemical characteristics of the [18F]FDG. Our particular interest was in measuring heterogeneity of glucose uptake (expressed as coefficient of variance – CV) and glucose uptake (GU) index in the QF of both legs.

As a result of the increasing exercise intensity GU index in QF increased from LOW (2.3±1.3 a.u.) to MODERATE (6.1±2.0 a.u., $p < 0.001$), but not further to HIGH (5.9±2.1 a.u., p = NS). No differences in GUI were found between the muscles of the left and the right legs. The muscles constituting QF differed in their levels of glucose uptake but the difference become smaller with increasing exercise intensity ($p < 0.01$) suggesting more uniform activation of different QF muscles. Glucose uptake became also less heterogeneous within the muscle regions with the increasing exercise intensity (CVs 41±22%, 33±15%, and 28±14% at LOW, MODERATE, and HIGH). Paired differences between LOW and MODERATE and LOW and HIGH were statistically significant but now between MIDDLE and HIGH. No differences in glucose uptake heterogeneity were found between the muscles of the left and the right legs. Heterogeneity values did not differ between the three vasti muscles (medial, lateral and intermedial) but were significantly ($p < 0.001$) higher in m. rectus femoris than in the other three muscles.

Having observed the tendency of exercising muscles to homogenize their glucose uptake, we are likely to conclude that the phenomenon of glucose uptake heterogeneity is an important property of the muscle tissue that diminishes under stressful conditions.

THE LACTATE ION INDUCES RECOVERY OF FORCE AND EXCITABILITY IN K+ DEPOLARIZED RAT SOLEUS MUSCLES

Jørgensen, R., de Paoli, F., Nielsen, O.B.

Institute of Physiology and Biophysics, Denmark

During contractions, muscle cells lose K+ to the extracellular space. This depolarizes the cell membrane and, if the K+ loss is large, it diminishes the cells ability to propagate action potentials, leading to a loss of membrane excitability that may contribute to fatigue. Adding lactic acid to isolated muscles under such conditions has been shown to induce recovery of force and excitability (Nielsen et al. 2001). This effect of lactic acid has been coupled to the accompanying acidosis (Nielsen et al. 2001). A series of pilot experiments indicated that addition of Na-lactate to K+-depolarized muscles led to a substantial recovery of force despite that Na-lactate had almost no effect on muscle pH. To evaluate these findings, we examined the effect of Na-lactate on force, excitability, intracellular pH (pHi) and Na,K-pump activity in muscles where excitability and force were reduced by exposure to elevated extracellular K+ ([K+]o).

Soleus muscles from Wistar rats were mounted on force transducers for isometric contractions in chambers containing Krebs-Ringer bicarbonate buffer equilibrated with 5% CO2 in O2. To mimic K+ conditions under intensive exercise, [K+]o was elevated to 11 mM, which reduces force to ~25% of control force in 4 mM K+. Muscles were stimulated to elicit a 2 s tetanus every 10 min with 0.2 ms pulses at 30 Hz. pHi was measured using fluorescence microscopy. The activity of the Na+,K+-pump was assessed from the ouabain-suppressible 86Rb+ uptake and excitability from measurements of compound action potentials (M-waves).

Addition of 20 mM Na-lactate to muscles at 11 mM K+ recovered force to 88 ± 3% of control force (n=7). At the same time M-wave area was increased from 17 ± 4% to 53 ± 11% of the control level (n=6), indicating a recovery of excitability. In contrast, Na-lactate had no effect on extracellular pH (pHo) and only decreased pHi from 7.19 ± 0.03 to 7.06 ± 0.03 (n=4). To evaluate the significance of this small lactate-induced acidification for the force recovery, the reduction in pHi was in another series of experiments mimicked by increasing CO2 from 5 to 7%. Although this led to a similar reduction in pHi from 7.22 ± 0.04 to 7.04 ± 0.03 (n=6) it only recovered force to 30 ± 4 % of control force (n=4), indicating that only a minor part of the effect of Na-lactate relies on reduced pHi. One could speculate that after addition of

Na-lactate, increased intracellular Na+ load associated with fibre pH regulation would increase Na,K-pump activity, which could contribute to force recovery by counteracting the K+-induced depolarization. This was, however, not the case because neither Na+ load nor Na,K-pump activity was increased after addition of Na-lactate.

In conclusion, this study shows that the lactate ion can improve muscle excitability via mechanisms that are independent of pH. This may protect muscle excitability during exercise involving high [K+]o.

Nielsen, OB; de Paoli, F and Overgaard, K. J Physiol. 536:161-166, 2001.

THE IMPROVEMENT OF EXCITABILITY AND FORCE INDUCED BY LACTIC ACID IN K+ DEPRESSED MUSCLES IS RELATED TO A DECREASE IN INTRACELLULAR PH

de Paoli, F.., Overgaard, K., Pedersen, T.H., Nielsen, O.B.

University of Aarhus, Denmark

During strenuous exercise, extracellular K+ ([K+]o) increases, which has been proposed to contribute to muscle fatigue by reducing muscle excitability. However, addition of lactic acid to isolated muscles counteracts the depressing effect of high [K+]o. This effect of lactic acid has been associated with the ensuing acidification (Nielsen et al. 2001), which down-regulates Cl- channel function (Pedersen et al. 2005). Since it is not possible from these experiments to determine whether the effect of lactic acid is specifically related to the decreased intracellular pH (pHi) or extracellular pH (pHo), we here examine the effects of specific reductions in pHi and pHo on force and excitability in K+-depressed muscles.

Soleus muscles from Wistar rats were mounted on force transducers for isometric contractions in chambers containing Krebs-Ringer bicarbonate buffer. Two sec tetani were elicited every 10 min with 1 ms pulses at 30 Hz. Excitability and Cl- channel function was assessed from measurements of compound action potential area (M-waves) and membrane conductance (Gm), respectively. Intracellular pH was measured using fluorescence microscopy.

In the isolated muscles, an increase in [K+]o to 11 mM reduced tetanic force and M-wave to around 25% of control values determined at a [K+]o of 4 mM. Subsequent addition of 20 mM lactic acid, which reduced pHo and pHi from 7.4 to 6.8 and from 7.44±0.02 to 6.80±0.02, respectively, led to an almost complete recovery of force and M-waves. To examine the roles of pHi and pHo, two experiments were made in which either pHi or pHo were as reduced:

Reduced pHi: In these experiments, pCO_2 and buffer HCO_3^- were simultaneously increased from 5 to 15 % and from 25 to 70 mM, respectively. This reduced pHi from 7.16±0.07 to 6.95±0.04 (P=0.04, n=4) but had no effect on pHo (7.44±0.01 vs 7.44±0.01, n=3). At the same time, tetanic force was increased from 43±9 % to 70±7 % of the of control values at 4 mM K+ (n=8).

Reduced pHo: In these experiments 20 mM HCl was added. This led to a large reduction in pHo (from 7.40±0.01 to 6.72±0.01, n=2) but did not reduce pHi (7.17±0.05 vs 7.09±0.05, P=0.29, n=6). At the same time only a small and transient recovery of force and M-wave was seen (from 16±3 to 37 ± 9 %, P=0.06, n=5 and from 17±5 to 31±11 %, P=0.29, n=5, respectively). In concord with this, Gm did not change significantly (2136 ± 150 vs 2365 ± 119 mS/cm2, n=10/23 and 6/15 (muscles/fibres), respectively), indicating that HCl did not reduce Cl-channel function. However, a transient increase in resting membrane potential (from -51.7 ± 0.4 to -53.2 ± 0.4 mV, P = 0.04, n=10/23 and 6/15) was seen, which may explain the transient increase in force.

In conclusion, the protective effect of lactic acid on muscle excitability is specifically related to a decrease in pHi.

HEREDITY-INDEPENDENT EFFECTS OF LONG-TERM VOLITIONALLY INCREASED PHYSICAL ACTIVITY AND AEROBIC FITNESS ON HEPATIC FFA UPTAKE AND BODY ADIPOSITY

Hannukainen, J.C., Borra, R., Nuutila, P., Janatuinen, T., Heinonen, O.J., Kaprio, J., Kujala, U.M., Rönnemaa, T., Viljanen, T., Haaparanta, M., Parkkola, R., Knuuti, J., Kalliokoski, K.K.

University of Turku, Finland

Regular physical exercise decreases body adiposity and improves whole body lipid and glucose utilization. Effects of increased physical activity on hepatic free fatty acid (FFA) uptake are largely unknown, although exercise has been shown to decrease hepatic triglyceride accumulation and further enhance insulin resistance (5). Exercise training increases gluconeogenesis at rest (2) and decreases liver FFA uptake during hyperinsulinemia (4). In the present study we investigated heredity-independent effects of moderately increased physical activity and aerobic fitness on hepatic FFA uptake.

Based on the mailed questionnaires and a phone interview, 12 pairs of young healthy adult male monozygotic twins were recruited from a FinnTwin16 study (3). Subjects performed a VO_2max test with cycle ergometer and nine pairs with intra-pair difference of at least 9% in VO_2max were selected for further studies. Abdominal subcutaneous and visceral fat mass was measured using MRI and hepatic FFA uptake at fasting state with positron emission tomography and [18F]FTHA. The co-twins with higher VO_2max constituting the more active group (MAG) were compared to the less active brothers (LAG) with lower VO_2max.

Mean VO_2max was 18% higher in MAG than LAG (50.1±5.1 vs. 43.4±6.7 ml/kg/min, $p<0.001$). Both groups had similar BMI and similar lean body mass, but MAG had 10% lower whole-body fat percent. MAG had also 19% lower abdominal subcutaneous and 20% lower visceral fat mass compared to LAG. Plasma glucose and serum FFA concentrations were similar between the groups. Hepatic FFA uptake was 33% lower in MAG than LAG (5.5±4.3 vs. 9.0±6.1 µmol/100ml/min, p=0.04) and it was associated to whole-body fat percent in the whole study group (p=0.05). When the whole-body fat percent was used as the covariate in ANCOVA the difference in hepatic FFA uptake between the groups was no longer statistically significant (p=0.08).

Without the confounding effects of genetic factors, moderately increased physical activity and aerobic fitness decreases body adiposity even in normal-weighted humans. The lower hepatic FFA uptake in more active and fit subjects agrees with the suggestion that with decreased body adiposity, especially in intra-abdominal area, the rate of adipose tissue lipolysis is lower, thus decreasing the FFA load to the liver (1). As energy flux is the major determinant of energy utilisation it is also possible that increased gluconeogenesis (2) would lead to metabolic shunting of glucose to tissues. In conclusion, as liver is metabolically the most versatile organ and covers most of its energy demand by oxidizing FFAs, it is reasonable to presume that even small changes in the availability of substrates may have large effects on hepatic energy utilisation.

ENHANCEMENT OF CAPILLARY TORTUOSITY AFTER RESISTANCE TRAINING

Egeland, W., Kvamme, N.H., Rønnestad, B.R., Kadi, F., Raastad, T.

Norwegian College of Sports Sciences, Norway

Strength training has great impact on maximal strength and muscle hypertrophy, but results on capillarization are contradictory. Different training protocols and different measures of capillarization are possible reasons for conflicting results. A common method is to calculate the capillaries around each fibre (CAF), and in addition relate this to area of fibre (CAFA). By measuring the length of capillaries relative to the perimeter of fibre on cross-sections (LC/PF), it is possible to calculate the tortuosity of the capillaries. Charifi et al (2004) demonstrated that endurance training resulted in greater increase in LC/PF than CAF, however, no studies have been performed on strength training programs. In addition, training volume, given as the number of sets per exercise, may influence the effect on capillaries. Therefore, we hypothesized that 3-set strength training would, in addition to give greater changes in maximal strength, also have greater effect on muscular endurance and capillarization than 1-set strength training.

Sixteen untrained men (age 18-40) were randomly selected into two groups; a 3-set group (n=9) and a 1-set group (n=7). Both groups trained 3 days per week for 11 weeks, and workouts consisted of leg press, leg curl and leg extension performed with one or three 7-10 RM sets. Strength tests (1RM), relative muscular endurance (numbers of repetitions at 60% of 1RM until failure) and biopsies were conducted before and after the training period. Biopsies were taken from m. vastus lateralis, and stained for type I and IIa fibres and capillaries (CD31).

Both groups increased their maximal strength. The 3-set group demonstrated a significantly greater increase in leg strength than the 1-set group (41±3% vs. 25±2%, respectively, $p<0.01$), but there were no significant differences between groups in changes in muscular endurance or capillarization. Measured as changes in LC/PF both groups significantly increased capillarization for type I fibres (16±6%), and near significant for type IIa fibres (18±7)($p=0,058$). We found a significant reduction in CAFA for type IIa fibres (-8±4%), and the difference in change between LC/PF and CAFA was significant for type I fibres. No correlation between capillarization and muscular endurance was found.

The method of measuring capillarization has great impact on the results. This is indicated by the significant difference between LC/PF and CAFA. Thus, CAFA might not be a sensitive measure when hypertrophy is expected. Also, the addition of capillaries after training is usually described by greater CAF. Our findings demonstrate a greater increase in LC/PF than CAF after 11 weeks of resistance training, and this can indicate that the adaptation of the capillarization may be due to an enhancement of the capillary tortousity by increasing the capillary length rather than increasing the number of capillaries.

Charifi N, et al. (2004): Enhancement of microvessel tortuosity in the vastus lateralis muscle of oldmen in response to endurance training. J Physiol 554; 559-569

DECREASED SERUM BDNF REVEL IN ATHLETES

Kyushu University, Japan

Decreased serum BDNF level in athletes

Yu Nofuji1, Masataka Suwa2, Yoshihiko Moriyama1, Reiko nishichi3, Atsushi Ichimiya2, Zsolt Radak4, Shuzo Kumagai2,4

1: Graduate School of Human-Environment Studies, Kyushu University, Kasuga, Fukuoka, Japan

2: Institute of health Science, Kyushu University, Kasuga, Fukuoka, Japan

3: St.Mary's University, Kurume, Fukuoka, Japan

4: Faculty of Physical Education and sports Science, Semmelweis University, Budapest, Hungary

Brain-derived neurotrophic factor (BDNF) is a member of the neurotrophin family expressed in the nervous system and periphery. BDNF is known to play an important roles in the growth, development, maintenance and function of survival neuronal system. In rodents, it has been reported that voluntary exercise significantly increased the BDNF mRNA and protein levels in the hippocampus, lumbar spinal cord, cerebellum and cortex. The BDNF can cross the blood-brain barrier in both directions, suggesting that the serum BDNF level may reflect the brain BDNF level. Therefore, it is possible that exercise affect the serum BDNF level.

PURPOSE: The purpose of this study is to test the hypothesis that the serum BENF level associates with the exercise training.

SUBJECTS: Male 13 athletes (age: 21.62 ± 0.96 years) and 15 healthy volunteers with no sports activities (age: 22.33 ± 1.23 years) participated in this study. The athletes group includes distance runners (n = 8), a sprinter (n = 1), tennis players (n = 3), and a badminton player (n = 1). All athletes have participated in regular sports activities (over 16 hours per week for more than 3 years). Control subjects have not participated in any regular exercise (for more than 1 year).

METHODS: To evaluate physical activity, the participants attached the Lifecorder® (Suzuken, Nagoya, Japan), a small solid state recorder (62.5 × 46.5 × 26 mm, 40g), containing an acceleration sensor, for 1 week just before the day of blood collection. The self-ratable State-Trait Anxiety Inventory (STAI) and the 28 items version of the General Health Questionnaire (GHQ-28) were performed in all subjects. Serum BDNF levels were measured using the BFND Emax Immunoassay kit (Promega, Madison, WI, USA). The statistical analysis of the two groups was performed using Student's t test.

RESULTS: The serum BDNF level was significantly lower in athletes than in normal subjects (19.65 ± 4.35 vs. 23.80 ± 2.90 ng/ml, respectively; $p<0.01$). The mean daily calorie consumption and movement-related calorie consumption and stem numbers in the athletes group (2533 ± 270 kcal, 556 ± 174kcal, 15518 ± 4225 steps/day, respectively) were distinctly higher than in the control group (2200 ± 228 kcal, 262 ± 109 kcal, 9171 ± 2861 steps/day, respectively; $p<0.01$). On the other hand, there were no differences in age, sex, weight, body mass index, percentage of body fat between the two groups.

CONCLUSION: The serum BDNF level would associate with the physical activity.

RADIATION INDUCED THERMOREGULATORY FAILURE AND THE REDUCTION OF EXERCISE PERFORMANCE IN THE HOT

Suzuki, T., Kawabata, T., Fujimoto, S., Miyagawa, T.

Graduate School of Medicine, Osaka City University , Japan

It is well documented that exercise performance can be impaired in the hot environment. The solar radiation is especially important factor besides ambient temperature and relative humidity in the field. Infrared (IR) radiation increases skin temperature (1), and promotes sweating (2) and skin blood flow (3) for resting human. Therefore, we hypothesized that mechanisms of human physiological regulation at a high temperature environment with radiation were different from without one. In the present study, we investigated physiological changes by radiation during endurance exercise in the laboratory.

Nine healthy male subjects dressing shorts remained seated resting for at least more than 40 min, and then performed cycle ergometer at 60% peak oxygen uptake until exhaustion in the climatic chamber at 33°C ambient temperature (Ta), and 40% relative humidity (RH). The dorsal aspect of trunk was irradiated by IR heater with main emissivity intermediate-infrared (MIR; 1.5-5.8μm) regions (I-trial at 38°C globe temperature (Tg)) and compared without IR irradiation (C-trial at 33°C Tg). Esophageal temperature (Tes) and skin temperature (Tsk), sweat rate (SR), skin blood flow (SkBF), heat flax (HF), heart rate (HR), oxygen uptake (VO2), mean arterial blood pressure (MAP), and the ratings of perceived exertion (RPE) of dyspnea and leg were measured continually throughout the experiment. Body weight loss (BWL) was measured at the end of experiment immediately. And more we recorded the exercise performance time (EPT).

EPT was shorter in the I-trial (35.07±15.17 min) compared to the C-trial (43.81±14.04 min) and exhaustion during moderate exercise in a hot environment with or without IR irradiation occurred at the same Tes within an individual although both Ta were same in each trial. And significant differences in Tes, Tsk, SkBF, HR, and RPE by IR irradiation were observed. However, VO2, MAP were not affected.

Heat gain from the environment to skin must form part of the integrated responses which mediates the decreased central recruitment and power output in the heat, and a high skin temperature may inform the brain that the capacity for heat dissipation is reduced (4). Therefore, the increase in core and skin temperature with radiation influences on central thermoregulatory center and causes the reduction of exercise performance.

GENDER DIFFERENCES IN MUSCLE FATIGUE AND BRACHIAL ARTERIAL BLOOD FLOW DURING INTERMITTENT, MAXIMAL VOLITIONAL HANDGRIP

Saito, Y., Iemitsu, M., Otsuki, T., Maeda, S., Ajisaka, R.

University of Tsukuba, Japan

Introduction: Females have been reported to have greater resistance to skeletal muscle fatigue than males [1]. Russ et al. demonstrated that the gender difference disappeared during ischemic conditions[2]. It suggested the importance of muscle perfusion, which increases oxygen transport to the muscles and promotes removal of metabolic by-products, thereby may contribute to lessen muscle fatigue. Muscle blood flow may be greater in females than in males via some mechanisms such as vascular effects of estrogen [3], but gender differences in blood flow during exercise are unclear. We hypothesized greater blood flow contributes to smaller exercise-induced muscle fatigue in females. Purpose: The purpose of the present study is to investigate the relation between muscle force decline and increase in brachial arterial blood flow during intermittent, maximal volitional handgrip in young males and females. Methods: Healthy young (24.6± 0.5 years) males (n=8) and females (n=8) laid in a supine position and underwent a 4-min repeated (5 seconds contraction followed by 5 seconds rest) static maximal voluntary contraction(MVC)s handgrip. The MVC force during exercise was evaluated relative to their respective baseline values. Brachial arterial blood flow (BABF) was measured using Doppler ultrasonography. Results: A two-way ANOVA detected main effect of gender on MVC force decline during exercise ($p<0.05$). The MVC force decline was smaller in females than in males at the initial 1st min of exercise ($p<0.05$) and no significant differences were found at any other time points following the 1st min. A significant interaction between gender and time was detected in the BABF adjusted to forearm volume during exercise ($p<0.05$) and the BABF was greater in females than in males at the 1st min of exercise only ($p<0.05$). The area under the time-blood flow curve (AUC) analyses also supported this finding ($p<0.05$). There is a negative relationship between changes in the BABF and MVC from baseline to the 1st min of exercise only in females ($r=-0.69$, $p=0.058$). Conclusion: In conclusion, the gender differences in exercise-induced muscle force decline may be related to differences in the blood flow to their working muscles during the initial phase of exercise.

IS PEAK OXYGEN UPTAKE ASSOCIATED WITH MICROVASCULAR FUNCTION IN 9-10 YEAR OLD CHILDREN?

Farr, C., Shore, A., Armstrong, N., Mawson, D., Middlebrooke, A.

University of Exeter, United Kingdom

Risk factors for adult cardiovascular disease are present at a young age and are associated with the development of atherosclerotic disease (1). Changes in vascular function occur early in the development of cardiovascular disease (2) and microvascular dysfunction has been demonstrated in normal children with a clustering of cardiovascular risk factors (3). Microvascular dysfunction has been associated with maximal oxygen uptake in adults (4) and therefore the purpose of this study was to investigate whether subtle changes in microvascular function in normal healthy children were associated with peak oxygen uptake.

One hundred children, (53 boys and 47 girls) (age 9.9±0.4years, body mass 33.6±7.2kg, body mass index 17.3±2.6kg.m2), were recruited from local state schools. Each subject performed a continuous incremental exercise test to exhaustion on a cycle ergometer to determine peak oxygen uptake. Respiratory gas analysis was performed continuously throughout the test using an online breath-by-breath gas analyser. Microvascular function was assessed by the maximum skin hyperaemic response to local heating (42°C) on the dorsal aspect of the foot. The resultant red blood cell flux was measured using a single point laser Doppler probe at eight non-centric points on the heated site. Resting arterial blood pressure (systolic and diastolic) was determined as the mean of two readings with the subject in the supine position. The study was approved by the local Medical Research Ethics Committee and written informed consent was obtained from both the child and their parent(s) / guardian(s).

Peak oxygen uptake was significantly higher in the boys compared to the girls (boys: 194.6±30.0 v girls: 165.9±28.0mL.kg-0.58.min-1, p=0.0001). However, there was no significant difference in the maximum microvascular hyperaemia (boys: 1.78±0.32 v girls: 1.79±0.43V, p=0.880) although minimum microvascular resistance approached significance (boys: 39.7±7.4 v girls: 43.6±11.9mmHg.V, p=0.052). There was also no significant difference in maximum microvascular hyperaemia between the highest and lowest quartiles of peak oxygen uptake (highest quartile: 1.79±0.32 v lowest quartile: 1.75±0.36V, p=0.620). Sex-specific correlation analysis revealed no significant correlations between peak oxygen uptake and the maximum microvascular hyperaemia or minimum microvascular resistance.

These data demonstrate that despite a significantly higher peak oxygen uptake in boys this was not reflected in measures of microvascular function and that there is no association between microvascular function and peak oxygen uptake in 9-10 year old children.

AGE RELATED DIFFERENCES IN FIBER TYPE SPECIFIC SATELLITE CELL CONTENT

Verdijk, L.B., Koopman, R., Schaart, G., Meijer, K., Savelberg, H., van Loon, L.J.

Maastricht University, Netherlands

Introduction

Satellite cells (SC) play an important role in growth and repair of skeletal muscle fibers. The number of SC per muscle fiber has been reported to decline with aging (Kadi, 2004). However, this decline has not been reported consistently (Dreyer, 2006). A reduced number of SC could lead to impaired maintenance of muscle fiber structure and function. In healthy young adults, no differences seem to exist in the number of SC between type I and II skeletal muscle fibers (Kadi, 2005). Considering the specific loss and atrophy of type II muscle fibers with aging, we hypothesized that in elderly, SC content is specifically reduced in type II fibers.

Methods

Biopsies were taken from the vastus lateralis muscle of 8 elderly (E: 76±4 y) and 8 young (Y: 20±1 y) healthy male subjects. 5 µm thick serial cross sections were stained with ATPase for fiber typing, and with pax7 counterstained with DAPI to visualize SC and myonuclei. Differences between E and Y were evaluated by independent-samples T-tests; all values are expressed as means±SD. For SC counts, 291±83 and 287±74 fibers were analyzed in E and Y subjects, respectively.

Results

The proportion of type II fibers was smaller in E than in Y subjects (47.2±8.8 vs 56.8±8.5 %, respectively; P=0.043). For mean cross sectional area (csa) of type I fibers, no difference was observed between E and Y (5471±641vs 5589±794 µm², respectively). In contrast, mean csa of IIa and IIb fibers was smaller in E vs Y (4807±1328 vs 6260±1064, P=0.030; and 3970±959 vs 5890±1160 µm², P=0.003, respectively).

SC counts revealed no difference in the mean number of SC per muscle fiber (0.063±0.008 vs 0.076±0.017 in E and Y, respectively; P=0.067). However, fiber type specific analyses revealed a significantly lower number of SC per type II muscle fiber in E compared to Y subjects (0.044±0.010 vs 0.080±0.021, respectively; P=0.001). In addition, the number of SC per mm² of type II fiber was lower in E vs Y (9.7±2.8 vs 12.6±2.7, respectively; P=0.047). In type I fibers, no differences were observed between E and Y for either SC content (0.082±0.014 vs 0.071±0.016, respectively; P=0.151), nor for the number of SC per mm² (13.8±2.8 vs 12.7±3.1, respectively; P=0.468).

Discussion

This study is the first to show fiber type specific differences in SC content in skeletal muscle fibers between young and elderly men. The number of SC in type II muscle fibers is substantially reduced in elderly compared to young adults, even when correcting for fiber cross sectional area. As a consequence, the capacity to maintain structure and function of type II muscle fibers is likely to be impaired in elderly. This could represent an important factor in the development of sarcopenia and associated health problems.

KINETICS OF CARDIAC OUTPUT, SYSTEMIC O2 DELIVERY AND LUNG O2 UPTAKE IN NORMOXIA AND NORMOBARIC HYPOXIA IN MEN

Lador, F. 1, Azabji-Kenfack, M. 1, Moia, C. 1, Cautero, M. 2, Morel, D.R. 3, Capelli, C. 2, Ferretti, G. 1-4

1 Centre Mêdical Universitaire, Geneva, Switzerland, 2 Hôpital Cantonal Universitaire, Geneva, Switzerland, 3 Università di Udine, Italy 4 Università di Brescia, Italy, Switzerland

At the onset of light square wave exercise in normoxia, cardiac output (Q) and systemic O2 delivery (QaO2) is characterized by a first rapid phase (phase I) followed by a slower phase (phase II) up to steady state. The appearance of phase I was related, amongst others, to withdrawal of vagal tone upon exercise onset. Exposure to acute hypoxia implies reduced vagal activity and increased sympathetic activity. If this is so, the kinetics of Q and QaO2 ought to be slower in hypoxia than in normoxia, possibly for lack of phase I, this being a possible consequence of a lack of vagal activation in resting humans in hypoxia. In this study we tested the hypothesis that the kinetics of Q and QaO2 is slower in hypoxia than in normoxia, as would the associated kinetics of VO2. To test this hypothesis, simultaneous determinations of beat-by-beat (BBB) Q and QaO2, and breath-by-breath VO2 at the onset of constant load exercises at 50 and 100 W were obtained in normoxia and hypoxia on six men (age 24.3 + 3.1 years, maximal aerobic power 333 + 61 W in normoxia). VO2 was deter-

mined using Gronlund's algorithm. Q was computed from BBB stroke volume (Qst, from arterial pulse pressure profiles) and heart rate (fH, electrocardiograpy) and calibrated against a steady-state method. This, along with the time course of hemoglobin concentration and arterial O2 saturation (infrared oximetry) allowed computation of BBB QaO2. Lactataemia remained below the so-called lactate threshold during the experiments. The Q, QaO2 and VO2 kinetics were analysed with single and double exponential models. Q and VO2 increased upon exercise onset to reach a new steady state. The steady level of Q was significantly higher in hypoxia (Qrest 6.75 + 0.33 l/min, Q50W 12.18 + 0.25 l/min Q100W 17.81 + 0.64 l/min) than in normoxia (Qrest 6.58 + 0.22 l/min, Q50W 11.89 + 0.25 l/min Q100W 14.44+ 0.33 l/min) for each work load. The steady level of VO2 in hypoxia (VO2rest 0.57 + 0.08 l/min, VO250W 1.41 + 0.12 l/min, VO2100W 1.91 + 0.07 l/min) was not significantly different from that obtained in normoxia (VO2rest 0.61 + 0.08 l/min, VO250W 1.44 + 0.07 l/min, VO2100W 1.77 + 0.05 l/min) for each work load. The kinetics of Q and QaO2 at the whole body level was found slower in hypoxia than in normoxia (Time constants for phase I (T1) and II (T2): Qn50W T1 3.02 + 1.50 s, T2 2.10 + 1.04 s, QaO2n50W T1 2.69 + 1.31 s, T2 2.54 + 1.48 s; Qn100W T1 3.10 + 1.42 s, T2 8.53 + 3.28 s, QaO2n100W T1 2.47 + 1.64 s, T2 9.29 + 4.60 s; Qh50W T1 2.20 + 1.65 s, T2 20.59 + 8.63 s, QaO2h50W T1 2.38 + 1.08 s, T2 16.98 + 7.61 s; Qh100W T1 5.13 + 3.97 s, T2 37.23 + 7.41 s, QaO2h100W T1 5.54 + 5.59 s, T2 30.49 + 7.91 s). Moreover, the kinetics of QaO2 was not significantly different from that of VO2 (VO2h50W T1 1.36 + 0.73 s, T2 29.77 + 5.89 s, VO2h100W T1 2.67 + 0.63 s, T2 30.54 + 5.68 s). These results are compatible with the tested hypothesis, as well as with the notion of a lack of vagal activation in resting humans in hypoxia.

VARIABILITY OF MUSCLE ACTIVITY DURING PEAK POWER OUTPUT CYCLING

Albertus-Kajee, Y., Lambert, M.I., Noakes, T.D., St Clair Gibson, A.

University of Cape Town, MRC/UCT Research Unit for Exercise Science and Sports Medicine, South Africa

Variability is found in biological signals such as muscle activity patterns (EMG), however it is not known if this variability is due to biological control processes or testing artefacts. When analysing EMG, there is a need to reduce variability caused by testing artefact so as to highlight sensitive changes in muscle activity caused by the variability in biological control mechanisms. Thus normalisation methods play a significant role in reducing variability. The use of maximal voluntary contractions (MVC) as a normalisation method is standard, however using this method for dynamic exercise such as cycling; this method is questionable, because of the variability in maximal output in cycling. We have thus proposed two other methods for normalisation which may reduce variability, namely a 10 second maximal sprint and cycling at 70% of peak power output. This study aims to provide an appropriate method of EMG normalisation for cycling trials, while allowing assessment of minute stages of biological control mechanisms (muscle activity).

13 well trained cyclists performed the same experimental protocol on three separate occasions separated by 5-7 days of normal training. EMG activity was measured on 6 muscles on the right leg. Subjects firstly performed a maximum voluntary contraction (MVC) using the Biodex Dynamometer 3, followed by a 10 second maximal sprint on an electronically braked cycle ergometer starting at 200W. Following this, they performed the Peak Power Output (PPO) test until exhaustion, where work rates began at 3.33 W/kg body mass. After a resting period they performed a submaximal cycle at 70% of PPO for 5 minutes at 90rpm. The three EMG normalisation methods were the MVC, 10sec sprint and the 70% PPO for 5 min. The study showed that normalising EMG data to 70% PPO was more repeatable and thus less variable, where the intraclass correlation (ICC) of 0.87 (-0.48-1.00) was significantly higher than MVC ICC=0.66 (-0.55-1.00) (p=0.03) and 10s sprint ICC=0.65(-0.54-1.00) (p=0.04). Despite being more repeatable, greater changes in muscle activity were found in the muscle groups tested during PPO, where VMO, RF and BF muscle activity at exhaustion was significantly greater to activity at the start and middle of the trials. Whereas normalising to MVC, only RF and VL showed this significant difference. MG and LG were the only muscle showing no changes in muscle activity during PPO tests.

Normalizing EMG to 70% PPO appeared to reduce variability caused by testing artifact and elicit changes in muscle activity caused by variability of biological control mechanisms during PPO tests, which was not shown using the MVC or sprint method. The reason for the greater testing artefact variability in the MVC and 10 s sprint EMG (which are self-paced exercises) needs to be assessed in future research.

INDICES OF NEW FIBRE FORMATION AFTER STRENGTH TRAINING IN YOUNG, HEALTHY MEN

Kvamme, N.H., Egeland, W., Rønnestad, B.R., Hanssen, K.E., Kadi, F., Raastad, T.

Norwegian School of Sport Sciences, Norway

Kadi & Thornell (1999) observed fibres expressing embryonic and neonatal myosin heavy chain (MyHC) in the trapezius muscle of healthy women after ten weeks strength-training. Six out of nine subjects had small-sized muscle fibres expressing embryonic and neonatal MyHC, while the small-sized fibres were not detected in any of the biopsies taken before the strength training. The embryonic and neonatal MyHCs are considered as markers for the early stages of fibre development and positive fibres might therefore indicate formation of new muscle fibres in response to strength training. The purpose of this study was to further investigate the expression of developmental MyHC in vastus lateralis and trapezius in young men undergoing 11 weeks of heavy strength training.

Nineteen untrained men (18-40 years) took part in the study. The subjects performed 3 workouts per week for 11 weeks. Each workout consisted of eight exercises and subjects performed 1-3 sets of 7-10 repetitions (7-10 RM load) in each exercise. Biopsies were taken from trapezius and vastus lateralis before and after 11 weeks of training. Whole muscle cross sectional area (CSA) of thigh muscles and upper part of trapezius was measured by magnetic resonance imaging (MRI). Values are given as mean±SEM.

There was a significant increase in the number of fibres expressing embryonic MyHC (from 0.44±0.13 to 2.05±0.68%, $p<0.05$) and vimentin (from 0.12±0.05 to 1.92±0.60%, $p<0.01$) after training for vastus lateralis, while there was a significant increase in the number of fibres expressing neonatal MyHC (from 0.2±0.1 to 3.1±1.1%, $p<0.05$) for trapezius. We found a significant increase in the fibre area for type IIa in both vastus lateralis (19±5%, $p<0.01$) and trapezius (16±6%, $p<0.05$). We also found a significant negative correlation between the fibre area of type IIa at the start of the training and the relative change in fibre area during the training period for both vastus lateralis ($p<0.01$) and trapezius ($p<0.05$). In particular, subjects with fibre areas ≥8000 microns experienced no fibre hypertrophy but had the same increase in whole muscle CSA as the subjects with an increase in fibre area.

The increase in fibres expressing markers for formation of new fibres and the negative correlation between fibre area at the start of the training period and the change in fibre area during the training period may indicate a possible hyperplasia. It might be hypothesised that muscle fibres have a maximal size and when reaching this limit the fibres either split or there is a formation of new fibres An alternative hypothesis is that strength training induces local disruptions in myofibres and that the developmental MyHC indicates regenerating areas.

Kadi F & Thornell L-E (1999) Training affects myosin heavy chain phenotype in the trapezius muscle of women. Histochem Cell Biol 113, 99-103.

AN INVESTIGATION OF EXERCISE AND INSULIN-INDUCED OPENING OF MUSCLE CAPILLARIES USING NIRS

Shaw, C.S., Zijlstra, E.D., Wagenmakers, A.J.

University of Birmingham, United Kingdom

Muscle contraction and increases in plasma insulin following ingestion of a meal or drink can stimulate the recruitment of skeletal muscle capillaries and glucose uptake into the muscle cells. A growing amount of evidence suggests that the recruitment of muscle capillaries is vital in allowing access of glucose and insulin to the muscle bed and thus maintaining glucose homeostasis (Rattigan et al, 2005). We aimed to investigate whether the increase in muscle capillary volume could be detected using near infrared spectroscopy (NIRS) in the period of hyperaemia following isometric skeletal muscle contractions and in the 2 h period after consumption of a glucose+protein beverage, which is known to lead to a large increase in plasma insulin concentration (van Loon et al, 2000).

Our assumption is that total haemoglobin (HbT) and oxygen saturation (StO2) in muscle capillaries is measured using NIRS. HbT will increase when more red blood cells enter the muscle capillaries and the observed increase should be proportional to the increase in capillary volume; oxygen saturation is expected to decrease when blood supply does not meet oxygen demand and to increase when the increase in blood flow during hyperaemia exceeds the oxygen requirement of the muscle.

10 healthy lean subjects (aged 26.7±8.6 years, BMI 22.3±2.3) took part in one or both of the study protocols. 6 subjects completed 3 one-minute isometric contractions of the biceps brachii interspersed with 5 minute recovery periods. 6 subjects were measured for 2 hours after the consumption of a glucose+protein (75g+30g) beverage. The NIRS probe was attached to the centre of the biceps brachii and measures of StO2 and HbT content (relative to baseline) were recorded on a 4 wavelength continuous wave near-infrared spectrometer (InSpectraTM Tissue Spectrometer Model 325, Hutchinson Technology, Hutchinson, MN).

During the 1 min isometric contractions HbT decreased from 54.4±1.8 to 45.5±1.8 potentially due to the expulsion of blood from the muscle bed with the increased intramuscular pressure during contraction, while StO2 fell from the resting level of 78.4±2.0 % to 1.6±0.4 % ($P<0.05$). In the 5 minute period post-contraction, relative HbT content and StO2 increased on average 17.2±4.1% and 21.2±5.6% respectively ($P<0.05$) above resting values. During the 2 h period after consumption of the glucose+protein beverage, HbT remained unchanged throughout the 2 hour post-prandial period ($P>0.05$). StO2 fell from a baseline of 87.1±2.7% to 74.8±3.6 % during the 60-80 minute period ($P<0.05$).

We conclude that NIRS is suited to measure the increases in HbT levels indicating increases in capillary volume following a static contraction but is unable to identify the more subtle changes in capillary volume upon insulin-stimulation.

SPINAL AND CORTICOSPINAL CONTRIBUTION TO NEUROMUSCULAR CONTROL IN STRETCH-SHORTENING CYCLE

Taube, W., Leukel, C., Schubert, M., Rantalainen, T.J., Gollhofer, A.

University of Freiburg, Germany

Introduction

Muscular activation during drop-jump (DJ) is assumed to rely on spinal reflexes as well as on supraspinal participation (1). However, the relative importance of either activation sources could not be verified, so far. To identify spinal and corticospinal contributions to the muscular activation we applied peripheral nerve stimulation (H-reflex=HR) and transcranial magnetic stimulation (TMS) during different phases of DJ. The comparison of spinal and corticospinal effects was used to reveal modulations in cortical excitability.

Methods

In each subject 5 stimulation times were determined after averaging the background EMG of 10 DJs from 31cm. The first stimulus was applied in the pre-innervation phase (PRE), the second at the time of the short-latency response (SLR). Stimuli 3, 4 and 5 were timed to coincide with reflex peaks at approximately 70ms (medium-latency response=MLR), 90ms (long-latency response=LLR) and 120ms (later component of the LLR =LLR2). Subthreshold TMS and HR were triggered so that both, the motor evoked potential (MEP) and the H-reflex arrived in the soleus at the same time as the PRE, SLR, MLR, LLR or LLR2. HRs were recorded in two different ways to ensure constant stimulus intensity (methods are in accordance with (2) and will be described in the presentation). The underlying background EMG activity was subtracted from the HRs and MEPs evoked at PRE, SLR, MLR, LLR and LLR2. MEPs and HRs were expressed as a percentage of their maximal excitability during drop jump to compare the time course of spinal and corticospinal excitability.

Results

MEP- as well as HR-sizes were strongly dependent on the background EMG activity. However, differential excitability courses were obtained for electrical and magnetic stimulation when subtracting background EMGs from HRs and MEPs. MEPs were highest in PRE (100%) and of similar sizes at SLR (51%), MLR (46%), LLR (50%) and LLR2 (60%). HRs were also high at the beginning (PRE=82%); SLR=100%) but then progressively decreased with ongoing time from ground contact (MLR=46%; LLR=24%; LLR2=26%).

Discussion/Conclusion

Comparison of corticospinal and spinal excitability during stretch-shortening cycle indicates that cortical excitability is high during PRE, interestingly low at SLR and raised again approximately 90ms after touch down. In contrast, spinal excitability is most prominent at SLR followed by a progressive decline. Our results indicate that DJ is a centrally initiated activity with gating of spinal reflex pathways shortly after touch down. We assume the reflex gating to be caused by supraspinally induced reduction in presynaptic inhibition.

MATHEMATICAL MODELLING OF TRANSCAPILLARY INSULIN TRANSPORT

Zijlstra, E.D. 1, Sjöstrand, M. 2, Groenendaal, W. 3, van Riel, N. 3, Lönnroth, P. 2, Wagenmakers, A.J. 1

1 The University of Birmingham, United Kingdom, 2 University Hospital, Göteborg, Sweden, 3 Eindhoven University of Technology, The Netherlands, United Kingdom

BACKGROUND

Obesity and insulin resistance (IR) due to low physical activity levels and poor nutritional habits have developed into world-wide epidemics. Insight in the biological mechanisms leading to IR will define the targets for future interventions and can be enhanced by the use of mathematical models. It is well-known that insulin, when it binds to its receptor, promotes glucose uptake in skeletal muscle cells by means of GLUT-4 translocation. However, in recent years it has become evident that failure of insulin to recruit muscle fibre capillaries and limitations in transcapillary insulin transport may prevent the access of insulin to the interstitial fluid (ISF) surrounding the muscle cells especially in insulin resistant states.

AIM

The aim of this study was to investigate and quantify possible impairments in transcapillary insulin transport in obese, insulin resistant subjects after ingestion of a glucose drink (oral glucose tolerance test). This study helps to understand the role of insulin transport mechanisms in the development of IR. It will also provide a tool to assess the effect of exercise interventions on IR in future studies.

METHODS

A previously proposed mathematical model of insulin transcapillary transport (1) was used to quantify insulin transport rates in both a group of obese, insulin resistant subjects and a group of healthy lean volunteers. Parameter estimation was executed using Maximum Likelihood Estimation. Measured arterial plasma insulin concentrations serve as input signal and measured interstitial insulin concentrations as output signal for this model.

Experimental work was carried out in the Lundberg Laboratory for Diabetes Research. Subjects reported to the lab at 8:00 A.M. after an overnight fast and were instructed to drink a 250 ml solution containing 75g of glucose. Plasma and interstitial insulin concentration were sampled every 15 minutes for 105 minutes using respectively venous forearm cannulation and forearm muscle microdialysis.

RESULTS

The estimates from the measurements for the insulin transcapillary transport rate were 0.0172 ± 0.0066 vs. 0.0123 ± 0.0053 min-1(lean vs. obese); p = 0.03.

CONCLUSION

The transport of insulin from plasma to the ISF surrounding muscle cells is reduced during an oral glucose tolerance test in obese, insulin resistant subjects. This reduction, is either caused by defective insulin-induced capillary recruitment mechanisms and/or an obstructed transendothelial insulin transport, and is likely to contribute to the observed IR.

CARDIORESPIRATORY RESPONSES AT THE ONSET OF THE DOMINANT AND NON DOMINANT LIMBS EXERCISE

Hotta, N., Yamamoto, K., Katayama, K., Akima, H., Ishida, K.

Nagoya University, Japan

Our laboratory has found that cardiorespiratory responses at the onset of exercise in endurance runners and sprinters were lower than that of sedentary subjects. As cardiorespiratory responses at the initial phase after the start of exercise are mainly controlled by central command and mechanoreflex via thin-fiber muscle afferents, we have hypothesized that repeated exposure to muscle contraction or metabolic substances desensitizes thin-fiber muscle afferents. Generally, people give preference to their dominant arm or dominant leg in their day to day activities. Thus it can be assumed that dominant limbs are more often exposed to mechanical stimuli than non dominant limbs. Therefore, we compared the initial ventilatory and circulatory responses to light exercise of subjects using their dominant and non dominant limbs. Regarding the upper limbs, fifteen subjects performed a single-elbow flexion-extension exercise with a load of 5% MVC for 20 s during voluntary or passive exercise, attached to the wrist. In addition, passive exercise was performed on the subjects in the same way as the above-mentioned voluntary exercise to eliminate the effect of central command. We defined the difference between the resting value and mean value for 20 s as delta. It was found that delta ventilation during passive exercise of the dominant arm was significantly lower than that of the non dominant arm, whereas delta HR was unchanged between the dominant and non dominant arms. As for the lower limbs, all seventeen subjects performed a single-knee extension-flexion exercise and passive exercise in the same way as the experiment for the upper limbs. Delta ventilation during both voluntary and passive exercise by the dominant leg was lower than that of the non dominant one. Similar to the response of the upper limbs, delta HR showed no change between the dominant and non dominant legs. These results suggest that the sensitivity of thin-fiber muscle afferents to muscle contraction is dulled and that this can be attributed to the frequent exposure to mechanical stimuli such as muscle contraction.

THE EFFECTS OF HYPOXIA AND SHORT-TERM VIBRATION STIMULI DURING CYCLING ON ANGIOGENIC AND ANTI-ANGIOGENIC FACTORS

Suhr, F., de Marées, M., Achtzehn, S., Mester, J.

German Sport University Cologne, Germany

Introduction

Various stimuli are known to induce angiogenesis, e.g. mechanical forces, such as hydrodynamic induced shear forces, hypoxia and metabolites1. It is well-established that these factors induce the expression of matrix metalloproteinases (MMPs), the formation of endostatin, and an increased expression of VEGF. Hypoxia and mechanical forces normally are present in the vasculature by an increased cardiac output, lowered oxygen supply and deformations of muscle tissue during exercise. Therefore these factors are essential in the organ-specific expression of new capillaries. The aim of this study was to investigate the biological response in this area following highly intensified stimuli (vibration and artificial normobaric hypoxia).

Methods

Twelve cyclists participated in this study. Each subject completed four training sessions (90 minutes cycling for each) at weekly intervals in a randomised order. The four training sessions were: normoxia without vibration, normoxia with vibration, hypoxia without vibration and hypoxia with vibration. For each subject five blood samples were taken at each training session at the following terms: pre training, 0h, 0.5h, 1h and 4h post training. Hypoxia was induced by a normobaric hypoxic-chamber with an average altitude of 2500 m. The artificial mechanical forces (cycling with or without vibration) were induced by a cycling ergometer (a specially designed bicycle fixed on a vibration platform with a peak-to-peak amplitude of 4 mm and a frequency 30 Hz, where the vibration could be switched on or off). The parameters VEGF, endostatin and MMPs have been measured by ELISA kits (R&D Systems GmbH, Germany).

Results

VEGF showed a significant increase after the training sessions with artificially induced vibrations compared to the non-vibration sessions. Endostatin was significant increased after all training sessions.

Conclusions

These results show that the treatment with vibration can be an important stimulus for the increase in the expression of VEGF. The results induce the hypothesis that vibration can be a more efficient stimulus for the VEGF-release than hypoxia because an increase in VEGF after the sessions in hypoxia without vibration could not be proved. Endostatin has been discussed to inhibit as well as to facilitate the growth of new capillaries2 and was increased after all training sessions. This leads to the conclusion that the treatment with hypoxia as well as with vibration can be understood as an effective stimulus for the expression of endostatin. These findings may contribute to a broader understanding of angiogenesis and thus energy supply in the skeletal muscles.

TRAINING STRENGTH WITH HEART RATE: BENCH PRESS APPLICATION

Martín Caro, C., Benito, P.J., Díaz, V., Peinado, A.B., Calderón, F.J., Sillero, M.

Physical Education Faculty , Spain

Introduction: The relationship between heart rate (HR) and oxygen up-take remains lineal in strength exercises, there is a stronger slope toward HR, which indicates that, comparing strength exercises with resistance exercises, the HR increases more than oxygen uptake (1, 2). This work arises from the necessity of knowing if HR can be used as an intensity indicator for strenght exercises. Method: The sample was composed by 7 males in good physical fitness, skilled on strength training, aged 27 ± 4,7 years, weighted 72,1 ± 5 kg, and 169,8 ± 4,1 cm in height. They carried out 5 Bench Press trials, while HR was recorded by a Polar S710 HR monitor. In four of the them, the load was increased progressively along the sets from 20 to 90% of a single maximum repetition (1RM), performing 20 (2 times), 10 and 6 repetitions, and a previous maximum test to determine the 100% of 1RM. The 20 repetitions trials were performed at two different execution rates. It was carried out a lineal regression analysis with the variables and a Pearson's correlation. These variables were obtained from an ANOVA for each proposed model, and a Wilcoxon test for compared samples, the significance level was set at $p<0,01$.

Results: We found the highest correlations between percentage of 1RM and percentage of the corrected HR reserve: $r = 0,737$; $p <0,01$ (for 6 rep), $r = 0,738$; $p <0,01$ (for 10 rep), $r = 0,818$; $p <0,01$ (for 20 slow rep) and $r = 0,816$; $p <0,01$) (for 20 fast rep). We also found significant differences ($Z=-4,415$; $p<0,01$) between the maximum HR obtained in the fast and slow 20-repetitions sets. Four prediction formulas were obtained to estimate the % 1RM from the HR with a correlation of r=0,729 (6 rep) , r=0,796 (10 rep), r=0,830 (20 rep) and r=0,760 (general equation,, which is showed below).

%1RM= 34,148 – (1,771 • number of repetitions) + (0,704 • % reserve HRcorr)

Discusion: Supporting with Westcott's data (HR rest + 53 beats at 70%1RM versus HR rest + 50 beats at 85% 1RM) and with our data, we can assert that HR increase more with high repetitions sets (3). This is the only work that analyze the lineal relationship between HR and %1RM.

Conclusions: HR can be used as an easy method to control the execution intensity in bench press, assuming that the closer is the intensity to 1RM, the bigger is the error of the estimation.

PLASMA GHRELIN RESPONSES TO ACUTE EXERCISE IN BOYS AT DIFFERENT STAGES OF SEXUAL MATURATION

Pomerants, T., Tillmann, V., Karelson, K., Jürimäe, J., Jürimäe, T.

University of Tartu, Estonia

Ghrelin has recently been involved in the regulation of a large array of endocrine and non-endocrine functions, including the influence on growth hormone (GH) secretion, food intake and energy balance (Korbonits et al. 2004). The aim of the present study was to investigate changes in plasma ghrelin concentrations and pertinent components of the GH-insulin-like growth factor (IGF) axis during the 30 min cycle ergometer test in prepubertal (n=20), pubertal (n=20) and postpubertal (n=20) boys based on Tanner classification – group I was prepubertal, group II included stages 2 and 3, and group III stages 4 and 5. Subjects were also analyzed as a total group (n=60). Maximal oxygen consumption (VO2max) and individual ventilatory threshold (IVT) were measured directly using stepwise increasing loads on cycle ergometer. Second test consisted of a 30 min constant exercise on the same ergometer at the level of ~ 95% of their IVT. Venous blood samples were obtained before, immediately after and after 30 min of recovery for the measurement of ghrelin, leptin, insulin, testosterone, GH, IGF-I, IGFBP-3 and glucose. At baseline, prepubertal children had significantly different values for ghrelin, testosterone, GH, IGF-1 and IGFBP-3 levels compared to other groups. Testosterone and ghrelin were in significantly different between pubertal and postpubertal boys. Acute exercise altered GH significantly in all studied groups. The level of GH remained significantly higher after 30 minutes of recovery, with an exception of prepubertal group where the difference between GH pretest and recovery values was not

significant. Changes were also significant in levels of insulin in group II, III and total group and glucose in total group. Individual analysis indicated that ghrelin concentration increased more than 10% in 13 and decreased in 25 boys postexercise. Higher VO2max values were more related with increased ghrelin after exercise ($p<0.01$). VO2max correlated significantly with baseline ghrelin ($r=-0.61$), GH ($r=-0.50$), IGF-1 ($r=0.60$), IGFBP-3 ($r=0.46$), testosterone ($r=0.90$) and insulin ($r=0.52$) concentrations before cycle ergometer test in total group. The relationship of the same metabolic characteristics with VO2max/kg was significant, but lower ($r=-0.43$, $r=-0.30$, $r=0.49$, $r=0.31$, $r=0.60$ and $r=0.34$, with ghrelin, GH, IGF-1, IGFBP-3, testosterone and insulin, respectively). It was concluded that moderate intensity aerobic exercise did not change ghrelin concentration in blood, while the changes on GH levels were significant in all pubertal stages and insulin decreased in pubertal and postpubertal groups.

THE INFLUENCE OF CARBOHYDRATE INGESTION AND ENVIRONMENTAL TEMPERATURE ON PACING STRATEGY DURING A 16.1 KM TIME TRIAL IN WELL TRAINED CYCLISTS

Abbiss, C., Peiffer, J., Peake, J., Nosaka, K., Suzuki, K., Laursen, P.

Edith Cowan University, Australia

Introduction: Carbohydrate ingestion has been shown to reduce the overall time required to complete a given amount of work, especially in exercise durations greater than 1 h. Few studies however have examined the influence of environmental temperature and carbohydrate ingestion on the distribution of power during an exercise task. The purpose of this study therefore was to determine the effects of carbohydrate ingestion and heat stress on the pacing strategy employed during a 16.1 km time trial.

Methods: In a counterbalanced randomized crossover design, ten trained male cyclists (age = 27 ± 7 y; mass = 77.9 ± 6.1 kg; VO2max = 61.7 ± 5.0 ml/kg/min) performed a total of four 90 min constant pace experimental cycling trials at 80% of second ventilatory threshold (220 ± 12 W). Trials were conducted in either cool (18.1 ± 0.4 °C) or hot (32.2 ± 0.7 °C) conditions during which subjects ingested either carbohydrate (CHO; 0.96 g/kg/h) or placebo (PLA) gels; all trials were immediately followed by a 16.1 km time trial. Power output (Velotron, Racermate; WA), and rectal and skin temperatures (SquirrelView, Grant 2020; UK) were recorded every second and averaged over each 2 km of the trials. Venous blood was sampled through an antecubital vein for the determination of blood glucose concentration before exercise, following the 90 min trial and immediately post time trial.

Results: Time taken to complete the 16.1 km time trial was significantly greater in the PLA compared with the CHO condition during exercise in the heat (27.5 ± 1.9 vs. 26.6 ± 1.4 min, respectively; $P<0.05$) but not in the cool (25.4 ± 1.6 vs. 25.4 ± 1.7 min, respectively). In the cool, power output did not change significantly in the PLA condition, but significantly ($P<0.05$) increased for the final 2 km in the CHO condition. Compared with the initial 2 km in the heat, power output was significantly lower at and beyond 4 km, until the final 2 and 4 km under PLA and CHO conditions, respectively ($P<0.05$). Compared with trial means, power output tended to be greater during the first 2 km of the hot PLA trial (13.2 ± 16.4%; $P<0.07$) and in the final 2 km of both hot and cool CHO trials. The initial rate of heat storage (kJ/km) was significantly greater in the heat until the third km ($P<0.05$). Compared to the PLA trials blood glucose concentration following the 90 min constant pace cycling was significantly greater in both the hot (110 ± 10 vs. 91 ± 13 mg/dL) and cool CHO trials (100 ± 10 vs. 91 ± 7 mg/dL; $P<0.05$).

Conclusion: Compared to the mean power output subjects tended to commence the hot trials and finish the CHO trials at relatively high power outputs. These data suggest that the rate of heat storage and carbohydrate supply may independently influence not only the average absolute power output, but also the distribution of work during self-paced exercise.

RECOVERY-TIME CONSTANT AND AMPLITUDE CHARACTERISTICS TO REPEATED SHORT-TERM BREATH-HOLDING DURING DYNAMIC LEG-EXERCISE

Németh, H., Saito, H., Kimura, M., Maki, A., Ito, S., Takenaka, T.

Semmelweis University, Budapest, Hungary

Short-term breath-holding occurs in various water and outland sport activities. The purpose of the present study was to investigate breath by breath respiratory responses in the recovery after repeated short-term breath holding during dynamic leg-exercise in moderate-exercise intensity domain (2-102W). During the 45 minutes bicycle ergometer test the subjects performed 20-second breath-holding sessions starting at 20, 25, 30, 35 minutes of exercise. The short periods following the four sessions were analyzed. The end-tidal carbon dioxide concentration (ETCO2), the end-tidal oxygen concentration (ETO2), the expiratory tidal volume (TVe) and the respiratory rate were observed. Single exponential curves were fitted to ETCO2, ETO2 and TVe. Heart rate and arterial oxygen saturation have also been monitored. In case of ETCO2 and ETO2 bigger time constants and smaller amplitudes were found at lower intensity, and smaller time constants and bigger amplitudes at higher intensity. Amplitude-ETO2 was found to be bigger than amplitude-ETCO2. The respiratory rate seems to have bigger time constant. As for the cardiovascular response to breath-holding, a slightly delayed decrease of the heart rate was observed. The amount of this delay seems to increase proportionally with increase of exercise load intensity. A considerable decrease in arterial oxygen saturation was only observable at higher intensities.

We conclude that time constants and amplitudes of ETCO2 and ETO2 have intensity dependency, and that ETCO2 and ETO2 showed a somewhat different time course of recovery.

FOREARM VASCULAR RESPONSES TO COMBINED MUSCLE METABORECEPTOR ACTIVATION IN THE UPPER AND LOWER LIMBS

Tokizawa, K., Mizuno, M., Muraoka, I.

Waseda University, Japan

INTRODUCTION: Seals (1989) suggested that cardiovascular responses elicited during exercise of separate limbs exhibit an 'inhibitory interaction'. Our previous studies showed that venous occlusion or passive stretch of the lower limb, assuming a mechanical stimulus, attenuates the vasoconstriction in the nonexercised forearm during post-exercise muscle ischemia (PEMI) of the arm (Tokizawa et al. 2004a,b). In this study, we investigated whether a metabolic stimulus to the lower limb induces a similar response.

METHODS: Eight subjects performed a 2 min static handgrip exercise at 30% maximal voluntary contraction (MVC) followed by 3 min PEMI of the arm, concomitant with or without 2 min static ankle dorsiflexion at 30% MVC followed by 2 min PEMI of the calf. Mean arterial pressure, heart rate, forearm blood flow (FBF), and forearm vascular conductance (FVC) in the nonexercised arm were measured.

RESULTS: During PEMI of the arm alone, FBF and FVC decreased significantly, whereas during combined PEMI of the arm and calf, the forearm vasoconstriction produced by PEMI of the arm was attenuated. FBF and FVC were significantly greater during combined PEMI of the arm and calf than during PEMI of the arm alone. When PEMI of the calf was released after combined PEMI of the arm and calf (only PEMI of the arm was maintained continuously), the attenuated vasoconstriction observed during combined PEMI of the arm and calf was not observed.

CONCLUSION: These results indicate that a metabolic stimulus to the lower limb attenuates the vasoconstriction in the nonexercised forearm mediated by muscle metaboreceptor activation in the upper limb. It is suggested that the inhibitory integration of muscle afferent inputs from multiple limbs contribute to the attenuated vasoconstriction, irrespective of the mode of muscle afferent.

VARIATION IN LUNG VOLUMES WITH PSOITION

Álvarez, M., Díaz, V., Peinado, A.B., Benito, P.J., Martín, C., Calderón, F.J.

Politecnical University of Madrid, Spain

INTRODUCTION

In other studies there have been differences observed in the pulmonary volumes and capacities in relation to the position of the subject (1). The aim of this study was to observe the differences in the spirometric values in the three most common positions in sports and its possible application to the assessment of athletes. The observed variables were the habitual ones and the abbreviations of European Respiratoy Society were used (ERS).

MATERIALS AND METHODS

The study population consisted of 25 men and 7 women students of Physical Education that were healthy, nonsmokers. Each subject carried out a minimum of three manoeuvres of inspiration and forced espiration and three valid manoeuvres of maximal voluntary ventilation in 12 seconds in standing (S), sitting (ST) and supine position (SU) in a random order. The best attempt was chosen following the criteria of the ERS.

Spirometry was carried out using spirometer Jaeger Oxycon Pro ® (Erich Jaeger, Germany). The volume transducer is digital bidirectional (Triple V ®) of low dead space and resistance, fulfilling normative ATS (American Thoracic Society) (6) and ERS.

For the analysis of the data, a one-way ANOVA was used. If significant differences were found an analysis post-hoc of Scheffé was used. The signification level was set at $p<0.05$.

RESULTS

The analysis of the variance showed significant differences in the ERV in both genders, between the SU and S and between ST and SU, but no differences were found between the sitting and standing position. For both genders the ERV value in SU was lower than in the other two positions.

In the following variables no significant differences were found for men, but significant differences were found for women in FEV1, MVV, VCEX and FVC. The lowest value was in the SU.

DISCUSSION

In SU there is a reduced in ERV, decreasing FRC but remainding VC constant. This could be due to the elevation of the diaphragm about 40mm (2) that takes place in the SU (3). Therefore, in SU the IRV is larger. The greater number of differences found in women against men can be due to the size and heterogeneity of the sample.

The results suggest the evaluation of pulmonary volumes in the same position as the sport is practiced, for example in swimmers in supine position, since there is a redistribution of the pulmonary volumes varying the respiratory mechanics (4).

THE EFFECTS OF EXERCISE-INDUCED MUSCLE DAMAGE ON UNILATERAL BALANCE PERFORMANCE

Twist, C., Eston, R., Gleeson, N.P.

University of Chester, United Kingdom

Efficient movement execution requires an adequate postural stability, which is partly dependent upon afferent information directed from proprioceptors located within the contractile and non-contractile elements of the muscle-joint system. Exercise-induced muscle damage (EIMD) has been shown to impair proprioceptive function (Brockett et al., 1997). However, it is not known whether this phenomenon adversely affects balance performance. Therefore, the purpose of this study was to investigate the effects of EIMD on unilateral balance performance.

Six healthy adult participants (age 24.0 +/- 3.3 yr, stature 1.72 +/- 0.1 m, body mass 73.6 +/- 11.9 kg) who had not performed any systematic resistance training in the previous 6 months, participated in the study. Muscle damaging exercise consisted of 10 sets x 20 repetitions of double leg vertical jumps, interspersed with 1 minute recovery between each set. On landing, participants were instructed to

ensure minimal flexion at the knee, thus increasing the mechanical stress upon the triceps-surae muscle group. Stability was recorded as the variance between the tilted and reference position over a 20 s period (sampling rate 20 Hz) using an instrumented balance system (Biodex Balance System, Biodex Medical Systems, Shirley, NY) and expressed as a Stability Index (SI). Peak torque of the ankle extensors was measured at 30 and 180 deg/s to evaluate the effects of EIMD on muscle force generating capability (Biodex 3, Biodex Medical Systems, Shirley, NY). In addition, perceived muscle soreness was recorded on a 0–10 visual analogue scale. Measurements were taken before, immediately after and at 24, 48 and 72 hours following the muscle damaging exercise.

Perceived muscle soreness increased significantly following the plyometric exercise protocol, with values of 1.0 (0.5), 3.2 (0.5), 5.7 (0.9), 4.9 (0.9), 3.3 (0.9) at baseline, 30 min, 24, 48 and 72 h ($F_{2, 18} = 10.86$, $P<0.01$), respectively. Peak torque was significantly reduced from baseline after the plyometric exercise protocol ($F_{4, 20} = 3.40$, $P<0.05$), with similar decrements for slow (76.4 (4.6)%, 79.8 (8.8)%, 87.5 (5.7)%, 90.2 (8.4)%) and fast speeds (87.2 (7.2)%, 89.4 (7.5)%, 80.8 (12.0)%, 90.6 (11.6)%) at 30 min, 24, 48 and 72 h, respectively. The SI was significantly increased ($F_{1.5, 0.6} = 3.14$, $P<0.05$) with values increasing from baseline (2.05) to 2.60, 3.43 and 2.48 immediately after plyometric exercise, and at 30 min, 24 h and 48 h respectively.

These results indicate that neuromuscular control is reduced following a bout of muscle-damaging exercise. This has implications for both the use of skill-based activities and for increased injury risk following high intensity plyometric training.

FACTORS AFFECTING THE PREDICTION OF ENERGY EXPENDITURE FROM ACCELEROMETER DATA

Stone, M., Esliger, D., Tremblay, M.

University of Saskatchewan, Canada

Introduction: Some accelerometers employ frequency-dependent filters which may exacerbate reliability and validity problems when utilizing these devices for physical activity assessment. Differences in leg length (LL), stride length and stride frequency in a population could contribute to variations in activity data output and therefore prediction of EE. This study assessed whether age, weight and LL assist in the prediction of EE from three motion sensors (Actical, Actigraph, RT3) across various movement intensities during treadmill locomotion. Methods: Eighty six participants aged 8-40 yrs performed three 10-minute bouts of treadmill activity (speeds: walk, walk/jog, run) ranging in speed from 4-12 km/hr. Accelerometer-derived EE (predicted EE) was compared to measured EE from respiratory gas analysis across speed categories. Height quintiles were created in order to determine whether the capability of manufacturer-based, model-specific equations (MSE) to predict energy expenditure was affected by LL and whether the inclusion of LL as a predictor variable into our own research-derived regression equations (RDE) offered an improvement in the estimation of EE. Reliability coefficients (R2) from MSE and RDE for each model across each speed category were generated and compared. Results: All speeds considered, each model provided the most valid estimate of EE for height quintiles 3 and 4 (R2 = 0.54 to 0.86). For the tallest individuals, validity coefficients from all models were very weak during treadmill running (R2 = 0.14 to 0.39). The inclusion of weight, LL and age, in addition to accelerometer counts into regression equations explained 85-94% of the variance in EE. For all models, the inclusion of age and LL as predictor variables into RDE's helped to explain a larger amount of the variance in EE across all speeds. Age was a significant predictor of EE during treadmill walking, however it became non-significant during treadmill jogging and running for all models (except Actical for treadmill jogging). Conclusion: The validity of accelerometer-derived EE may be affected by changes in treadmill walking/running speed and individual differences in height. Accounting for age and LL may increase the accuracy and validity of EE data from accelerometers, however the predictive power of these variables (and others) may vary at different treadmill speeds.

This work was funded in part by Statistics Canada and the University of Saskatchewan.

EFFECT OF HYPERCAPNIA ON LACTATE AND AMMONIA ACCUMULATION DURING EXERCISE

Kato, T., Matsumoto, T., Tsukanaka, A., Nakano, M., Ito, R., Kosaka, M., Matsui, N.

Chukyo University, Japan

<Introduction> The application of hypercapnic gas inhalation may bring a novel impact on sports and/or health sciences. We have investigated physiological responses during exercise under hypercapnia (Kato et al, 2005). The purpose of this study was to determine the effects of hypercapnia on lactate and ammonia accumulation during exercise.

<Materials and methods> Six healthy males volunteered to participate in the present study. Each subject performed incremental exercise until exhaustion on three occasions; 1) breathing ambient air (MAX); 2) breathing hypercapnic (21% O2, 6% CO2, N2=balance) gas (6%CO2); 3) breathing mild hypercapnic (21% O2, 3% CO2, N2=balance) gas (3%CO2). Subjects breathed ambient air or hypercapnic gas from 10 min before the start of exercise until the end of exercise. Exercise tests were conducted using an electrically-braked cycle ergometer. The initial workload was 30 Watt (W), and thereafter the workload was increased by 30 W every 2 min until exhaustion. Arterialized blood was drawn from a superficial vein.

<Results> Before exercise, VE, respiratory rate (RR), and blood PCO2 were significantly higher in 6%CO2 than those in MAX and in 3%CO2 ($P < 0.05$). Blood pH was significantly lower in 6%CO2 than those in MAX and in 3%CO2 ($P < 0.05$). HR was significantly higher in 6%CO2 than that in MAX ($P < 0.05$). In comparison between MAX and 3%CO2, VE and RR were significantly higher in 3%CO2 than those in MAX ($P < 0.05$). At the exhaustion, plasma lactate concentration was significantly lower in 6%CO2 than that in MAX ($P < 0.05$). Plasma ammonia concentration was not significantly different among the three conditions (6%CO2 vs. MAX, $P = 0.095$). VE, RR, and HR were not significantly different among the three conditions. Blood pH was significantly lower in 6%CO2 than that in MAX ($P < 0.05$), blood PCO2 was significantly higher in 6%CO2 than those in MAX and in 3%CO2 ($P < 0.05$). Performance time and VO2max were not significantly different among the three conditions, but performance time tended to be lower in 6%CO2 than that in MAX ($P = 0.07$).

<Discussion> Our results showed that the higher hypercapnic gas inhaled, the lower plasma lactate and ammonia concentrations observed at the exhaustion. Lactate and ammonia are metabolites of anaerobic metabolism. Therefore, it is suggested that as hypercapnic level rises, anaerobic metabolism is limited. In comparison between 6%CO2 and 3%CO2, the responses in respiratory and circulatory system, and blood gas responses were more remarkable in 6%CO2 than that in 3%CO2. From these results, we recommend less than 3% of CO2 concentration, when hypercapnic gas inhalation is applied in sports and/or health sciences.

<Conclusion> The higher hypercapnic gas inhaled, the lower plasma lactate and ammonia accumulation occurred during exercise.

CARDIAC NERVE ACTIVITY DURING RECOVERY FROM EXERCISE CHANGES WITH AEROBIC TRAINING AND DETRAINING

Arduini, A. 1, López, Y.A. 2, Sala, S.P. 3, Guillen, S. 3, Romagnoli, M. 1+2

1 Dept.Physiolog,Univ.of Valencia, 2 Dept. of Sport Science, 3 ITACA University Polytechnics of Valencia , Spain

Introduction

Cardiodecelaration, during recovery from exercise, is governed by a rapid parasympathetic reactivation and by withdrawal of sympathetic stimuli (1). Cohort and training studies demonstrated that trained people have faster parasympathetic reactivation (2). HR-recovery kinetics allows a larger "window" of data to be analysed and avoid the technical inconvenient of non-linear sets of R-R intervals. So, the observation of the HR-kinetics could favour the understanding of the complex interaction between sympathetic and parasympathetic cooperation in the recovery process.

Aim of the study

1) To assess the sensitivity of HR-recovery kinetics for evaluation of cardiac nerve activity changes during a period of increased and decreased physical fitness; 2) To identify the significance of the parameters of the recovery kinetics.

Material and methods

Fourteen sedentary non-smokers subjects (30.16.1 yrs, 24.33.21 kg/m^2; underwent an exercise programme of 3d/wk for 8 wks on a static bike, followed by 8 wks of detraining. Intensity of training increased from 65 to 80% VO2max. VO2 was measured breath-by-breath and data were mediated during 30s of each 3-min step of the incremental exercise. HR kinetics was assessed in a 3-minute recovery by two exercises of 6 minute each, one at 65%HRmax and the other at 80%HRmax. Recovery data were fitted by an exponential function (y =A0+Amax(e-(x/τ))). Tau[30s], an index of parasympathetic reactivation was also calculated (3).

We applied a repeated measures design and significance ($p<0.05$) was evaluated by post-hoc Bonferroni comparisons.

Results

VO2max increased with training from 36.95.9 to 42.85.4 mLO2∙kg-1∙min-1 (week 8 vs. pre-training, $p<0.05$,). Amax increased during training from 46.08.7 to 53.79.6 and 58.59.0 bpm ($p<0.001$ after 8 wk vs. control) and decreased with detraining (48.112.2 bpm). A0 changed with training and detraining from 104.210.2, 96.911.8, 91.99.3 and 102.913.3 bpm ($p<0.001$ at 8 wk vs. control). Tau-3min showed only a trend toward a decrease (68.837.0, 67.534.2 and 55.321.3 s at 0, 4 and 8 wk, respectively, $p>0.05$), almost restored during de-training (61.624.6 s).

The variation of Amax and A0 with training was moderately associated with that of tau-30s ($r = 0.60$-$.63$). Tau-3min varied independently from any other parameter.

Conclusions

Vagal reactivation evidenced a time adaptation to increased physical activity. Amax and A0 also changed with training, so they can be used as valid markers to evaluate cardiac adaptations to changes in physical fitness. The 30% variation of A0 and Amax with tau-30s suggests that the former are reflecting mainly a non-parasympathetic component, possibly a sympathetic one. HR-recovery kinetics can effectively assess cardiac nerves adaptations to training and detraining.

EFFECT OF MANY DAYS LONG-LASTING HIGH ALTITUDE WORK UPON AEROBIC CAPACITY, STRENGTH AND SIZE OF MUSCLE

Popov, D.

Institute for Biomedical Problems Russian Academy of Since, Russia

Endurance training under normoxic conditions causes an increase of oxidative capacity of the organism. On the other hand many days long-lasting (6-8 hrs) moderate aerobic work under normal conditions (ski expeditions) do not lead to an increase of aerobic indices [1,2]. Moreover a decrease of oxidative capacity of working muscles and of muscle size is recorded after climbing 8000 m peaks in mountain-climbers [3].

The aim of the study was to evaluate the aerobic and force-velocity characteristics of human beings after long-lasting low-intensity exercise during high altitude expedition without aid of other men. The expedition took place at a height of 3000-6800 m above sea level (Pamir, Tadjikistan). The expedition route was 262 km long, included overcoming the mountain passes at high altitude (above 5000 m) and climb of the peak "Rossia" (6830 m).

4 male and 2 female athletes (age 25±1 yrs, weight 71±4 kg, height 1.77±0.03 m, VO2max 50±3 ml/min/kg) gave their written consent to participate in the experiment. The high altitude expedition lasted 33 days including 4 resting days, the mean height was 4243 m, total positive climb was 13800 m. Mean working time a day was 6-7 hours, starting rugsack weight – 30-35 kg. Before and 5-8 days after expedition testing took place at the sea level. Cross-sectional area (CSA) of m. quadriceps femoris was calculated using MRI section areas of the thigh. Force-velocity characteristics of knee extensor muscles were recorded in an isokinetic regime at angular velocities 300, 180 and 30 ˚/s. The aerobic and anaerobic thresholds (AeT and AnT), VO2max , maximal power (Wmax) and maximal blood lactate concentration were recorded on the cycle ergometer during incremental exercise till exhaustion.

After 33 days high altitude expedition decreases of body weight (8±2%), knee extensors force (10-11%), CSA of m. quadriceps femoris ((5±1%), VO2max (4±2%) and Wmax (4±2%) were demonstrated for all subjects. On the other hand the values of AeT and AnT did not change. When related to body weight force, CSA, VO2max and Wmax did not change and AeT and AnT had a tendency for an increase. The strong positive correlation between decreases of Wmax and of body weight was revealed ($r=0.89$; $p<0.05$).

Thus relative indices of working capacity tightly related to the work against gravity did not change after long-lasting high altitude expedition. The decrease of maximal aerobic capacity recorded under these conditions most probably was associated with a decrease of muscle mass, but not with a decrease of AeT and AnT.

A SINGLE LACTATE ASSESSMENT DOES NOT PREDICT ANAEROBIC THRESHOLD IN RUNNING

Romagnoli, M. 1+2, Yeste, A. 1, García Herreros, S. 1, Gómez-Cabrera, M.C. 3, Beorlegui, A.B. 1, Arduini, A. 2

1 Univers Polytechnics, 2 University of Valencia Dept Physiology, 3 Catholic University of Valencia, Spain

Introduction

Lactate anaerobic threshold (AT-lac) is a valuable parameter to determine the working load for a training programme and useful for the assessment of changes (either increases or decreases) in aerobic fitness. It is usually referred to as an intensity at which the human metabolism is able to keep equilibrium between lactate production and its removal. Sirtori et al. (1) proposed a method by a single lactate measurement (Mognoni-test) that predicts the AT-lac at 4mM (OBLA), with a r^2 of 91%. Later literature affirmed the uneven physiological response and time to exhaustion in different subjects at the intensity corresponding to OBLA.

Aim

To evaluate the relation between a single lactate determination and the AT-lac calculated (on an individual base) as the exponential increase of blood lactate relative to workload increase.

Material and methods

24 healthy subjects (30.4±7.2 yrs, 71.3±8.6 kg; BMI: 23.1±2.5 kg∙m^-2) underwent a running incremental exercise with a 3 min-step duration and at least one constant-load exercise of 6 min at a fixed velocity of 13.5 km∙h-1. Arterialized blood lactate concentration was used to calculate AT-lac with the method of Hagberg JM (2) with minor modifications (3). Test-retest was done with the Pearson's r and evaluating parameters of the equation. The same statistic was applied to evaluate the prediction of AT-lac by a single lactate determination and a $p<0.05$ was accepted as significant.

Results

The concentration of blood lactate at the AT-lac after the incremental exercise test was 3.0 ± 0.5 mM, and the corresponding velocity was 13.8 ± 0.8 km∙h-1. The lactate concentration after the 6 min constant pace exercise was 3.0 ± 1.4 mM. In the subgroup of 12 subjects who underwent the re/test procedure the lactate in the first trial was 3.4±1.7 and 3.3±1.8 mM in the second trial. The coefficient of correlation between the lactate measured in the two trials was r = 0.986 ($p<0.001$). The slope and the intercept of the regression were 1.06 and 0.32, respectively, both parameters non-statistically different from 1 and 0, respectively. Regression of lactate concentration at the end of the 6-min test to the velocity (km∙h-1) at AT-lac revealed association between the two parameters (r = 0.75), with a mean SE of 0.67 km∙h-1.

Discussion

A single assessment of lactate concentration after a constant load test is not enough to precisely determine the velocity corresponding to the AT-lac. By the way, lactate concentration was highly reproducible after a 6-min constant load running, independently of the relative intensity at the set velocity. So, conversely to heart rate measurement, the reliability of lactate concentration after a trial of such duration could benefit the design of new methods of AT-lac determination.

ECCENTRIC MUSCLE CONTRACTIONS INCREASE NEURONAL NITRIC OXIDE SYNTHASE MRNA EXPRESSION IN SKELETAL MUSCLE

Kon, M., Tanabe, K., Lee, H., Kimura, F., Akimoto, T., Kono, I.

University of Tsukuba, Japan

BACKGROUND: Nitric oxide (NO) is produced from L-arginine by the action of NO synthase (NOS) in skeletal muscle and plays an important role in activating of satellite cells. However, the effect of resistance exercise on the expression of NOS isoform gene in skeletal muscle remains unknown. Moreover, it is unclear that how contraction type muscle affects the expression of NOS isoform gene. The purpose of this study was to examine whether NOS isoform (nNOS and eNOS) mRNA expression in skeletal muscle changes after resistance exercise, and whether those expression is different depending on type of muscle contraction, such as eccentric and concentric muscle contraction.

METHODS: Eight-week male ICR mice (n=63) were divided into three groups: eccentric muscle contraction group (ECC, n=33), concentric muscle contraction group (CON, n=24), and control group (PRE, n=6). The muscle contraction was applied involuntary model, contraction of the tibialis anterior (TA) muscle was induced by electrical stimulation (frequency 100 Hz, duration 5 ms at 3V) of the peroneal nerve. Animals performed total 150 contractions grouped into 5 sets of 30 contractions. The TA muscle was isolated PRE and at 1, 6, 12, 24, 72, and 168 hours after muscle contractions. NOS isoform (nNOS and eNOS) and MyoD (index of satellite cell activation) mRNA expression were measured. Semiquantitative RT-PCR analysis was performed to measure each mRNA expression. The amounts of mRNA in each sample were normalized to that of GAPDH mRNA.

RESULTS: There was a significant difference between ECC and CON in the change of nNOS mRNA ($P<0.05$). In ECC, nNOS mRNA significantly increased at 12 h ($p<0.05$), returned to PRE levels at 24 h after exercise. On the other hand, nNOS mRNA did not change in CON. There was no significant difference between ECC and CON in the change of eNOS mRNA. Moreover, eNOS mRNA did not change after muscle contraction compared to PRE. There was a significant difference between ECC and CON in the change of MyoD mRNA ($p<0.05$). MyoD mRNA significantly increased at 12 h in ECC ($p<0.05$), returned to PRE levels at 24 h after exercise. In contrast, there were no significant changes in MyoD mRNA in CON.

CONCLUSIONS: These data suggest that eccentric muscle contractions increase the expression of nNOS mRNA and MyoD mRNA in skeletal muscle, concentric muscle contractions does not increase in the expression of those mRNA. However, the eNOS mRNA expression did not significantly change after both muscle contractions. From the above-mentioned, eccentric muscle contractions may increase nNOS expression. Therefore, there is also a possibility that nNOS-derived NO is associated with activation of satellite cell after eccentric muscle contraction.

CHANGES IN LUNG FUNCTION VALUES AFTER SHORT-TERM POWER OUTPUT IN ELITE JUDO PLAYERS

Radovanovic, D. 1, Bratic, M. 1, Vukovic, J. 2

1 Faculty of Physical Education Nis, 2 Public Health Center Sabac, Serbia and Montenegro

Judo is characterized as an explosive power sport, requiring tremendous reserves of anaerobic power and capacity operating within well developed aerobic system. The objective of this study was to examine the relations between the power expressed during short-term power output and the changes in lung function values (forced vital capacity-FVC, forced expiratory volume in 1 second- FEV1.0, and peak expiratory flow-PEF) in elite judo players (National, Balkan and Mediterranean Championship medalists). Eleven subjects (age 21.0yrs±2.41, height 176.63cm±7.43, weight 75.55kg±8.91, fat mass percentage 8.25±4.38, peak O2 uptake 54.99ml.kg-1.min-1±4.11), without history and clinically diagnosed exercise-induces bronchoconstriction, were subjected to the 30-s all-out test on a cycle ergometer for the recording of peak power (PP 11.95W.kg-1±0.79) and mean power (MP 8.18W.kg-1±0.48). Subjects were required to perform FVC maneuvers on computerized spirometer according to American Thoracic Standardization on Spirometry. The first measurement was done before the warm up procedure for the 30-s all-out test (FVC 6.52L±0.74, FEV1.0 5.1L±0.52, PEF 10.4L.s-1±0.96). The second measurement was done after the test, immediately after the heart rate frequency decreased bellow 120 beats.min-1 (FVC 4.85L±0.69, FEV1.0 4.02L±0.61, PEF 8.55L.s-1±1.01), the third measurement was done 1 min after the completion of the second, (FVC 5.54L±0.69, FEV1.0 4.48L±0.5, PEF 9.44L.s-1±0.87), and the fourth 2 min after completing the second measurement (FVC 6.09L±0.71, FEV1.0 4.84L±0.51, PEF 10.02L.s-1±0.9). The data were assessed for normality using the Shapiro-Wilk's test, and Levene's test was used to test the homogeneity of variance. A one-way ANOVA and Post Hoc (Tukey HSD) were used to analyze the data. Mean values of the lung function parameters were rapidly lowered right after the test, and afterwards their values gradually increased. There is a statistically significant difference in the mean values of FVC, FEV1 and PEF determined in different time periods in relation to the test (ANOVA – $p<0.001$). The correlation between FVC, FEV1 and PEF determined before the subjects underwent the all-out, and the same lung function parameters determined after the test was checked over using Pearson's coefficient of linear correlation and showed the following: a. the correlation is positive (the subjects with higher values of parameters before the test, exhibited higher values after the test as well) and statistically significant, b. the correlation strength between FVC and FEV1 (determined by the coefficient) was observed to be the lowest right after the test to increase over time during which there came to the recovery of lung function, c. the strongest correlation was observed between PEF before and after the test (r=0.935).

DELTA DESATURASE BLOCKADE AFTER CAFFEINE INGESTION

Olcina, G., Maynar, M., Caballero, M.J., Muñoz, D., Timón, R., Maynar, J.I.

Sport Science Faculty. University of Extremadura, Spain

Introduction: caffeine is a trimethylxantine with a great influence on fat metabolism. Many researches show that this alkaloid can enhance free fatty acid (FFA) mobilization from body fat tissues to mitochondria during physical activity. Does caffeine act equal over all FFA? or some FFA could be more affected by caffeine ingestion?.

Objectives: the aim of this study is to analyze the effect of caffeine ingestion on several FFA during exercise.

Material and Methods: A double blind randomized design with 5 mg/bw of caffeine (CAF) or placebo (PLA) was performed. Twenty non trained males were cycling until exhaustion on a cycle ergometer. Load started with 100 w and it was increased for 50 w every 2 minutes. Ergospirometric response was measured with a Medical Graphics gas analyzer. Before and after exercise vein blood was collected with the purpose of studying changes in plasma FFA composition (saturated C12:0, C14:0, C16:0, C18:0, C20:0; monounsaturated: C16:1, C18:1, C24:1; polyunsaturated: C18:2.6, C18:3.6, C18:3.3, C20:3, C20:4, C20:5.3, C20:5.4, C22:6) and desaturases enzymes activity (Delta 9.1: C 16:1 / C 16:0; Delta 9.2:C18:1 / C18:0 and Delta 5:C20:4 / C20:3) using gas chromatography. Statistical analysis was carried out using a statistical package for social sciences (SPSS 11.0 for windows). ANOVA for repeated measures was used to determine the significance of the differences, considering $P<0.05$ statistically significant.

Results: caffeine ingestion increase total time of exercise (PLA: 11'35" ± 1'45 vs. CAF: 12'08" ± 1'59) $p<0.05$, VO2 max in ml kg/ min (PLA: 38.47 ± 4.99 vs. CAF: 41.59 ± 6.50) $p<0.05$ and decrease maximum RER values (PLA: 1.46 ± 0.14 vs. CAF: 1.40 ± 0.13) $p<0.05$. In caffeine trials, percent of saturated fatty acids were increased after exercise (from 29.35 ± 5.79 to 33.83 ± 8.27) $p<0.05$, while monounsaturated fatty acids were decreased (from 25.62 ±5.70 to 23.69 ± 4.69). Polyunsaturated fatty acids didn't change significantly in caffeine trials as well as FFA in placebo test. Desaturases enzymes activity only changed in delta 9.2 after caffeine trials (from 2.75 ± 0.94 to 1.84 ± 0.36) $p<0.05$

Discussion: caffeine ingestion may enhance performance in ergometric incremental test until exhaustion in non trained men. A possible involved mechanism in addition to other should be FFA mobilization, concretely by blocking delta 9.2 activity, in this way stearic acid (C18:0) won't be converted into oleic acid (C18:1) and it could be use such as source of energy for exercise.

OXYGEN UPTAKE DURING SOCCER: A CASE STUDY

Gatterer, H.

University of Innsbruck, Austria

INTRODUCTION: So far no study has provided accurate and valid data of measured oxygen uptake (VO2) during soccer. The physiological demands have been determined mainly by monitoring heart rate (HR). Establishing the relationship between HR and VO2 in the laboratory subsequently allows calculating VO2 in a game. However, the validity of the HR-VO2 relationship in intermittent exercise may be questionable. Water loss, psychological stress etc. may influence HR by unaffected VO2.

According to Stolen et al., new gas analysers (~500g) should allow accurate measurement of VO2, but at present no such study has been performed (4). Therefore the aim of this study was to measure VO2 with a portable gas analyser during real match play.

METHOD: Two healthy amateur soccer players (24 and 25 years, 179 and 178 cm, 77 and 69 kg) participated in this study. During a friendly soccer match, VO2 of each of the two subjects was measured with a portable gas analyser (Cosmed K4, 800g) for one half. HR

(Polar) was continuously monitored over the whole time. VO2max was determined by an exhausting 600m-run performed directly after the halves.

RESULTS: Subjects obtained a VO2max of 65.8 and 56.2 ml/(min*kg). The average VO2's during match play were 37.4±6.8 and 34.3±6.4 ml/(min*kg), corresponding to 56.8 and 61.0% of VO2max. Average HR's were 167±9 and 176±11 b/min in the first half and 164±10 and 179±11 b/min in the second. Over the whole time average HR's were 166±9 and 177±11 b/min, corresponding to 87.4% and 87.7% of HRmax.

DISCUSSION: Monitoring HR showed that the gas analyser did not interfere or inhibit performance, because the HR values of each subject did not differ in the first and second halves. Data also show that the intensity of the play, given by % HRmax, was the same as reported by other studies (ca.87%Hfmax vs. 81.7-85.6%Hfmax)(3). Considering this the measured data of VO2 [37.4±6.8 and 34.3±6.4 ml/(min*kg)] should correctly reflect the true VO2 during match play.

It should be pointed out that the average relative intensity, given by % VO2max, with values of 56.8 and 61.0% is not high and differs from data reported in the literature (70-75% VO2max)(1). However data from literature were only estimates of VO2 from the HR. Thus it seems that HR is not a good predictor of VO2 in intermittent exercise such as soccer, as also other authors supposed (2).

It should be kept in mind that in this study data were only available for two players and that further work has to be carried out.

RELATIONSHIP BETWEEN MUSCLE OXYGENATION OF AN EXERCISING FOREARM AND INACTIVE LEG DURING AND AFTER STATIC HANDGRIP CONTRACTION

Ogata, H., Nakazawa, K., Akai, M.

Research Institute of National Rehabilitation Center for Persons with Disabilities, Japan

The purpose of this study was to determine whether a decrease in oxygen supply to inactive leg muscle is caused by an oxygen inadequacy in exercising forearm muscle during and after static handgrip exercise.

Eight healthy male subjects with a mean age of 26 ± 3 years, a mean weight of 68 ± 10 kg, and a mean height of 1.77 ± 0.06 m participated in this study. The subjects performed 2-min static handgrip exercise at intensities of 5, 25 and 45% of maximal voluntary contraction (SHG5, SHG25 and SHG45, respectively). Oxygen saturation (SmO2), determined by near-infrared spatially resolved spectroscopy (NIRO 300, Hamamatsu Photonics, Hamamatsu, Japan), was used to estimate the occurrence of oxygen inadequacy in exercising forearm muscle. SmO2 reflects a dynamic balance between oxygen supply and consumption. Thus, SmO2 was also used as an index of oxygen supply to inactive muscle, because oxygen consumption in an inactive leg muscle is almost constant. We measured SmO2 in the flexor digitorum superficialis muscle as a representative exercising forearm muscle and in the tibialis anterior muscle as a representative inactive muscle of the lower limb. SmO2 was measured continuously during rest, exercise and recovery periods.

In regard to change during exercise, SmO2 in the inactive leg (SmO2inact) decreased significantly from the pre-exercise value only during SHG45. The decrease in SmO2inact began about 60 sec after the onset of exercise. Thereafter, SmO2inact decreased gradually until the end of exercise. SmO2 in the exercising muscle (SmO2exerc), on the other hand, decreased significantly from the pre-exercise value during exercises at all intensities. The magnitude of decrease in SmO2exerc at the end of exercise tended to be larger with an increase in contraction force. The patterns of decrease in SmO2exerc during exercise were similar in the three trials. Briefly, SmO2exerc was close to the pre-exercise value for the initial 30 sec of exercise and then began to decrease. Thereafter, SmO2exerc decreased steeply until about 60 sec of exercise, and then the decrease became slower. In regard to change during recovery, SmO2inact after the end of SHG45 continued to decrease for about 30 sec. Thereafter, SmO2inact began to increase toward the pre-exercise level, but the value of SmO2inact was still significantly lower than the pre-exercise value at least until the 2nd min of recovery. SmO2exerc, on the other hand, began to increase rapidly after the end of exercise and then returned to the pre-exercise level within the 1st min of recovery in all of the three exercises.

We demonstrated that the decrease in SmO2inact after the end of SHG45 was not necessarily accompanied by the decrease in SmO2exerc. Thus, we concluded that the decrease in oxygen supply to the inactive leg muscle is dissociated from the oxygen inadequacy in the exercising forearm muscle during and after static arm exercise.

THE IMPACT OF HEART RATE UPON THE E/A QUOTIENT IN ATHLETIC AND NON ATHLETIC MALES

Kneffel, Z., Kispéter, Z., Horváth, P., Németh, H., Sidó, Z., Pavlik, G.

Department of Health Sciences and Sports Medicine, Faculty of Physical Education and Sports Science, Hungary

Purpose: To clarify whether an enhanced E/A of male athletes was independent of athletic bradycardia and thus an alteration in intrinsic relaxation properties of the left ventricle.

Methods: Echocardiograms were performed in 1238 males (940 athletic). Peak early (E) and atrial (late) blood flow velocities (A) were assessed by Doppler echocardiography at rest. Linear regression analysis determined the relationships between E/A and resting heart rate (HR), regression equations of athletes and non-athletes of different ages were compared.

Results: The E/A decreased with aging, decrease was less marked in the athletic subjects. Except the children, it was significantly higher in the athletes than in the non-athletes. Children (age<14 yr.): athletes 2.05 ± 0.45, non-athletes 2.03 ± 0.51, adolescent-young subjects (14-20): 2.13 ± 0.51 vs. 1.87 ± 0.46, young adults (21-30): 1.97 ± 0.44 vs. 1.80 ± 0.51, adults (31-44): 1.73 ± 0.42 vs. 1.38 ± 0.38, older males (age>44 yr.) 1.39 ± 0.42 vs. 1.11 ± 0.34. In the children, adolescent-young and young adult subjects E/A against HR equations of the athletic and non-athletic groups were similar, differences between the means were only due to the differences in the HR. In the 31-44 yr. old males, the athletes' regression curve showed a parallel upward shift. The oldest (>44 yr.) active subjects showed a significant regression while sedentary males did not.

Conclusions: Results indicate that a HR-independent beneficial effect of regular physical training on the diastolic function manifests itself only at an older age. The impact of resting HR should always be taken into consideration when assessing intergroup differences in the E/A ratio, especially when studying the effect of exercise training upon cardiac function.

METHODOLOGICAL APPROACH OF ARTERY DOPPLER BLOOD FLOW MEASUREMENT DURING DYNAMIC EXERCISE

Walther, G., Nottin, S., Perez-Martin, A., Dauzat, M., Obert, P.

Physiology Laboratory of Cardiovascular Adaptation to Exercise, UFR Sciences, University of Avignon, France

Purpose: Doppler ultrasound is a suitable method for non-invasive and continuous estimation of muscle blood flow during exercise. An appropriate methodology using this technology implies measuring simultaneously blood velocity and vessel diameter. Most of the literature studies have to date investigated lower limb vasculature (principally femoral artery) and used different methodological approaches. Few data are available on blood flow involving upper limb testing. Te present study addressed special methodological considerations by applying Doppler ultrasound to lower and upper limb vasculature. Accordingly, our aims were to assess the influence of exercise intensity on femoral and axillary artery diameter dilatation, 2) to determine whether volume blood flow (BF) measured during early recovery reflects accurately exercise BF, and 3) to evaluate the effect of artery calibre and/or site as well as exercise intensity on BF measurement reproducibility. Methods: Thirteen healthy subjects (25.9 ± 7.7 yr) performed a discontinuous (exercise : 150s, recovery : 30 s) incremental leg-extension (LE) and elbow-flexion (EF) exercise in supine position. At each step and maximal effort, arterial diameter and blood flow velocity were recorded simultaneously during the last 30 s of exercise and the first 30 s of recovery. Results: A significant increase in femoral and axillary artery diameter was noticed from workload #2 to peak (3.5% and 6.5%, respectively) exercise. Blood flow velocity during the recovery period was significantly different from end-exercise values, depending on time and workload. The coefficient of variation of BF measurement during exercise was 7.1 to 12.1% and 6.4 to 9.5% in LE and EF, respectively. Conclusion. The present study shows that BF measurement with Doppler ultrasound during exercise is reproducible but requires measuring arterial diameter at each workload. Measurements performed immediately after exercise cannot be used as a surrogate for exercise blood flow velocity.

PHYSIOLOGICAL EQUIVALENCE OF HORIZONTAL VS. UPHILL RUNNING: FINDINGS FROM JUNIOR AND ADULT WORLD CLASS ORIENTEERS

Zürcher, S., Tschopp, M., Clénin, C., Marti, B.

Swiss Federal Institute of Sport, Magglingen, Switzerland

When sport activities are taken outdoors, natural obstacles such as hill climbing becomes an issue. Yet, the question persists, to what extent does a horizontal detour to avoid climb still present the same effort in terms of physiological exertion or perceived fatigue? The additional horizontal distance required to achieve equivalent uphill work can be calculated by multiplying incline, uphill speed and an equivalence factor (EF). The literature has published a range of EF from 1.8, which from practical experience is too little, to the frequently used standard of 10, which in our opinion is inflated (1). Research question: To which additional horizontal distance does uphill running correspond to in endurance athletes with balanced abilities in both horizontal and uphill running? METHODS: Elite orienteers (18 Men, 14 Women, 21.8yrs+/-4.1) from the Swiss National team took part in this study. Two treadmill stage tests, with 3-4 hours rest between, were completed. The first a horizontal lactate threshold test and the second an uphill running test at a 22% incline. In pilot testing, a "physiological equivalence" of horizontal to uphill running was approximated using a EF 6.5; this thereafter determined the speed for each stage in the uphill running test. The initial speed in the horizontal test and uphill test were typically 9.0km/h and 10.8km/h, with a 1.8km/h increase and 3.6km/h and 4.3km/h with a 0.7km/h increase per 3 minute stage for women and men, respectively. Both tests were run to voluntary exhaustion. In data analysis, uphill speed was compared to horizontal speed at test termination (maximal speed, (MS)), at 90% of maximal heart rate (subHR), at 90% of maximal lactate (subLa), and at a rating of perceived exertion of 17 (RPE17). Different EF's based on MS, subHR, subLa, or RPE17, and an EFAll (mean of the four criteria) were calculated. RESULTS: The different EF's based only on one single criterion varied slightly. EFMS was 6.2+/-0.54, (range 5.4-7.6); EFsubHR 7.0+/-0.88 (5.8-8.6); EFsubLa 6.3+/-0.76 (5.4-8.0); EFRPE17 6.7+/-0.76 (5.6-8.8). The aggregate EFAll was 6.5+/-0.62, with a 95% confidence interval of 6.32-6.76. CONCLUSION: Within this sample of well trained male and female elite orienteers, we found a surprisingly consistent EF of about 6.5 at an incline of 22%, regardless of whether it was calculated from maximal speed or additional sub-maximal parameters. Individual variation in EF was broader, with values between 5.5 and 8.5, the former suggesting above average ability and the latter below average ability in uphill running for orienteers. This information provided individual feedback for the coach and athletes. The validity of the presently found EF of 6.5 should be checked with additional runners, specifically trained for horizontal or uphill running under conditions without preliminary maximal running test in the same day.

PHARMOKINETICS OF CAFFEINE FOLLOWING INGESTION IN CAPSULAR OR LIQUID FORMAT IN HEALTHY MALES

Beades, M., Donne, B., Warmington, S., Mahony, N.

Trinity College Dublin, Ireland

Sport drinks containing caffeine are increasingly used by athletes. However, scientific evidence regarding the ergogenic potential of caffeine, and particularly its role in influencing fat metabolism is highly variable (Graham and Spriet 1995, Armstrong 2002). Some of these differences in performance may be explained by differences in the absorption and/or metabolism of caffeine when ingested in either liquid or capsule format.Therefore, the aim of this study was to compare the effects of caffeine ingestion in capsule and liquid format on the serum concentration of non-esterified fatty acids (NEFA's) and the pharmokinetics of caffeine, at rest.

Following ethics approval, 9 healthy male non-habitual caffeine users underwent a medical examination and ECG screening prior to participation in the study (age 23±4yr, mass 84±12kg and height 1.80±6.4m). Each subject completed three different, randomised ingestion trials consuming either a placebo (PL: 300mg lactose capsule), caffeine (CAFF: water plus caffeine capsule), or Red Bull (isoRB: diluted 60:40 with water). Fluid volume ingested determined by body mass was the same in all trials. The caffeine dose was 3mg.kg-1 for isoRB and CAFF. Ingestion was completed over a 20 min period, and venous blood samples were collected both pre- and post-ingestion, and every 30 min for 2 hr following ingestion. A two-way repeated measures ANOVA with post-hoc Bonferroni tests were used to infer differences across treatments. $P<0.05$ was considered statistically significant.

No changes in serum glucose (mmol.L-1) were observed across time during PL and CAFF trials. IsoRB data were significantly lower at 90 (3.81±0.18) and 120 min (4.01±0.16) when compared to data immediately post-ingestion (5.36±0.37). In CAFF serum NEFA's increased steadily following ingestion, and were significantly higher at 90 and 120 min when compared to both pre-and post-ingestion. In contrast, in isoRB, NEFA's decreased compared to pre- ingestion, absolute changes relative to pre-ingestion were significantly different from CAFF ($P<0.01$) at 30, 60 and 90 min. A significant time effect was observed for serum caffeine concentration following ingestion ($P<0.05$). However, there was no significant treatment effect observed in serum caffeine concentration comparing isoRB and CAFF at any time point.

The decrease in serum NEFA's relative to pre-ingestion in isoRB possibly resulted from the carbohydrate contained in Red Bull inducing an increase in insulin and subsequent inhibition of lipolysis. However, the main findings of this study show that the serum pharmokinetics of caffeine are similar in response to caffeine ingestion from either a liquid or a capsule.

CYCLING POWER, PERFORMANCE AND PACING STRATEGIES AT SIMULATED 200, 1200, 2200, AND 3200 M

Clark, S., Bourdon, P., Aughey, R., Singh, B., Schmidt, W., Woolford, S., Onus, K., Cable, G., Gore, C.

Australian Institute of Sport, Australia

It is well established that altitude results in a decrease in VO2max (1) but the acute effect of altitude on performance in well-trained athletes has not been well documented. Wehrlin et al. (2) reported a decrease in run time to exhaustion of 14.5% per 1,000 m of altitude between 300 and 2,800 m. However, in most competitions athletes do not perform at a fixed workload until exhaustion. Instead, they usually produce the greatest power possible for a given distance or time, and this can be influenced by the athlete's pacing strategy. Therefore the aim of this study was to determine the performance decrement in an all-out 5 min cycling time trial (5TT) at 1200, 2200, and 3200 m simulated altitude compared with 200m. In addition, the pacing strategies adopted during the four trials for each individual were investigated. Ten well-trained male cyclists/triathletes (Mean±SD Age= 28.4±4.6 yr; Body mass= 73.0±8.6 kg; VO2max = 71.6 ±5.2 ml.kg-1.min-1) were recruited. Testing was performed in a hypobaric chamber at the Royal Australian Air Force (RAAF). Subjects completed a trial under each altitude condition in a random counterbalanced order. All trials were double blinded with only the RAAF personnel operating the chamber aware of the altitude. All subjects performed two habituation 5TT in the weeks prior to the study; the typical error for the mean power during these two trials was 3.5% (90% CI = 2.6-5.8%). All trials were conducted on one dynamically-calibrated, wind-braked cycle ergometer. After a standardised 25 min warm-up subjects performed an all-out 5TT, and during this time power, VO2, and HR were measured. Average power (W) during the 5TT was 367±42, 346±41, 329± 38, and 294± 37 and average VO2 (L.min-1) was 5.23± 0.64, 4.80± 0.58, 4.49± 0.45, and 4.03± 0.39 at 200, 1200, 2200, and 3200 m simulated altitude, respectively and the values at each altitude were significantly lower than at 200m. There was no difference in maximum HR during the 5TT at each of the simulated altitudes. Despite the mean power being lower at simulated altitude there was no difference in the pacing strategies adopted during each of the four trials. Interestingly, the decrease in mean power was apparent during the first 30 seconds of the 5TT at 3,200m without a reduction in VO2 at this time, which suggests a role of teleo-anticipation (3). However, the peripheral feedback from the warm-up in hypoxia may also have been a factor. In conclusion, acute exposure to low-moderate simulated altitude substantially reduced maximal cycling power, but despite the novelty of the altitude exposure, the pacing strategies were relatively consistent. How athletes determine the appropriate power to produce during the first 10% of a maximal 5-min effort at altitude requires further research.

MOTOR CORTICAL ACTIVITY DURING BILATERAL AND UNILATERAL REACTION TIME AND FORCE TASKS

Taniguchi, Y.

International Budo University, Japan

Introduction

When simultaneous bilateral movements are introduced in reaction time (RT) task or in strength exertion task, performances are reduced compared to that during single movement conditions. These phenomena, known as "bilateral deficit", have been studied separately in RT or force task. In many sports, however, quickness and strength are required simultaneously. In RT task, Taniguchi et al. (2001) reported that electroencephalograph (EEG) correlate of the bilateral deficit was not found during the preparatory period but during the execution period. Motor cortical activity in the simultaneous RT and strength task has not yet been clarified. This study determined, whether there was a bilateral deficit in RT and/or force, and whether there was a related bilateral deficit in EEG during the simultaneous RT and strength task.

Methods

Seven right-handed subjects, aged 18-34 years, performed simple RT tasks with isometric abduction of the index finger under three conditions; with the right hand, left hand, and both hands. Each response condition consisted of 2 blocks of 20 trials. The order of the blocks was randomized. EEG activity was recorded on 21 locations using the 10 - 20 system. During the preparatory period, EEG was averaged, time-locked to the preparatory signal, under the three task conditions. Electromyographs (EMGs) were recorded with surface electrodes on the right and left first dorsal interosseous muscles. EMG-RTs were measured from the response signal to the onset of EMG. Isometric abduction forces were recorded by force transducers.

Results and Discussion

A two-factor analysis of variance, with two tasks (unilateral and bilateral) x two sides (right and left) demonstrated that significant bilateral deficits in EMG-RTs were found in four of seven subjects. Regarding force, a significant bilateral deficit was observed in one subject, but significant bilateral facilitations were found on two other subjects. Amang the remaining four subjects, a significant bilateral deficit was observed on three right hands and significant bilateral facilitations were found on three left hands. During the simultaneous RT and strength task, it was concluded that bilateral deficit in RT was observed as shown in previous studies, but there was not consistent force. The amplitude of contingent negative variation (CNV) on motor cortical area (C3 and C4) just before the response signal, as an index of motor preparation, tended to show bilateral deficit but did not reach significance. More studies are needed to clarify whether motor cortical activity during the preparatory period causes the bilateral deficit in EMG-RT.

PHYSIOLOGICAL REACTIONS IN LISTENING TO THE MUSIC THROUGH THE RESPONSE OF THE AUTONOMIC NERVOUS SYSTEM

Naotaka, I.

Nagoya University of Arts, Japan

It is reported that the musical influence on the living body is admitted in the physiology under not only the psychological influence but also a certain situation. There is the possibility that listening to the music before or in the course of playing sports has an effect on the improvement of the game performance. However, the effect has not been clarified yet. This study is an examination about the response of autonomic nervous system as the clue of the influence of the music on the living body.

Using four kinds of music tones, awakening, sedative, bright and dark, the study examined a physiological change of the body when switching was instantaneously done.

Heart rate variability was used for the index of the change of the autonomic nervous system.

After measuring the R-R interval on an electrocardiogram and specifically performing FFT, two components, LF component and HF component, were extracted.

The precedent studies about that these components were reflecting activities of the sympathetic nervous system or the parasympathetic nervous system.

I examined the change in the activity of the autonomic nervous system by examining this transition of the above two components.

From the experiment, I find the tendency as follows； when listening to the awakening and bright music tone, the value of the HF component, the index of which showed the relaxation fell from 0.9 to 0.6, measured as relative value with rest. When listening to the bright and sedative music tone, the value of the HF component rise from 0.75 to 1.1, measured as relative value with rest. As a result, it was suggested that the activity of the sympathetic nervous system is controlled when listening to the awakening and bright music tone, and conversely, the activity of the sympathetic nervous system is activated when listening to the bright and sedative music tone, which suggests that the situation of the sympathetic nervous system become dominant.

HOW TO ESTIMATE THE RECOVERY FROM AN INCREMENTAL EXERCISE TEST BY CHECKING STEADY-STATE CONDITION FROM BEAT-TO-BEAT TIME SERIES

Merati, G., Veicsteinas, A., DiRienzo, M., Castiglioni, P.

University of Milan and Don C. Gnocchi Foundation, Milan, Italy, Italy

Heart rate (HR) and systolic blood pressure (SBP) recovery after an exercise test are currently accepted as predictors of mortality [Cole et al.] and considered of high prognostic value in patients at cardiovascular risk [Nishime et al.]. HR recovery is usually measured as the HR level reached after 1-1,5 minutes after exercise stop. In such conditions, HR is often a transient value, thus being scarcely informative about the process underlying cardiovascular recovery. Aim of this work was to assess whether recovery can be measured as the time needed by the cardiovascular variables to reach a steady state after the end of exercise, and whether this measure depends on the level of fitness, by applying a procedure for checking cardiovascular steady-state from blood pressure (BP) and HR values [Castiglioni et al]. Finger BP and ECG were continuously recorded in 5 healthy subjects (1 female, 4 males, 44 [14] (mean [SD]) yrs; 71 [13] kg) on a cycloergometer: 1) at rest (15 min); 2) cycling at progressive loads (25W/min) from 0 W to the maximal volitional load; and 3) during recovery. Beat-to-beat values of SBP, diastolic blood pressure (DBP) and R-R intervals (RRI) were derived from each recording to calculate a "steadiness profile". The algorithm was based on the "run-test", applied to SBP, DBP and RRI series to get a global index of steadiness, the total number of runs. Briefly, we split each series into consecutive non-overlapping windows of length T=20 s, and computed the mean in each window. A running segment of N=14 means was then considered. In the running segment, we computed the median of the N means; we associated the symbol "+" when the mean was greater than the local median and the symbol "-" otherwise. Finally, we calculated the number of runs as the number of sequences of consecutive "+" or "-" symbols in the running string of N symbols, separately for SBP, DBP and RRI. The global index of steadiness was obtained by summing the number of runs for SBP, DBP and RRI. The steady-state hypothesis was rejected when this global index was lower than a given threshold, derived from reference steady-state data. During exercise the level of steadiness decreased progressively with the workload, remaining however higher in the best trained subjects. Steady state was lost at the maximum workload (WLmax) in all subjects. Recovery time, measured as the period to reach a new steady state after exercise, was inversely related to WLmax, ranging from 254s in the subject with the best level of fitness (WLmax = 275W) to 350s in the subject with the worse level of fitness (WLmax = 175W)($r=-0.65$, $p<0.05$).

Assessment of this index of steadiness during and after incremental exercise tests may therefore provide an objective measure of the recovery time and give information on the cardiovascular fitness of the subjects.

THERAPEUTIC AND PREVENTIVE EXERCISE REDUCES BLOOD PRESSURE IN LDLR -/- MICE

Cardinot, T., Moretti, A., Koike, M., Souza, H.

State University of São Paulo, Brazil

Objective: To evaluate the effect of therapeutic and preventive exercise on resting blood pressure (BP) and weight (W) in LDL receptor deficiency mice (LDLr -/-) submitted to fat and cholesterol diet.

Methods: We studied 96 LDLr-/- male mice with 16 weeks of life they were randomly separated in 8 groups of 12 mice to start fat and cholesterol diet and/or exercise (see table below). Diet was added to 10% fat and 1.25% cholesterol. The exercised groups were submitted to 60 minutes of moderate intensity aerobic exercise (50% of VO2) in a treadmill, five days a week, for 14 weeks. The therapeutic groups started exercise protocol after 14 weeks of diet intake and preventive groups started diet and exercise simultaneously. Therapeutic groups were studied for 28 weeks and preventive groups for 14 weeks. At the end of the study therapeutic groups have 44 weeks of life and preventive groups 30 weeks of life. Weight was registered weekly and BP was verified at the beginning and at the end of the study.

TF: Therapeutic exercise and Fat and cholesterol diet group

TFC: TF's Sedentary Control group

TN:Therapeutic exercise and Normal diet group
TNC: TN's sedentary Control group
PF: Preventive exercise and Fat and cholesterol diet group
PFC: PF's sedentary Control group
PN: Preventive exercise and Normal diet group
PNC: PN's sedentary Control group
Results: Initial BP and W were not different among the groups. Final BP was significant different in TF, TN, PF and PN when compared with their respective sedentary control groups: TFC, TNC, PFC and PNC. Final W was significant different in PF and PN when compared with their respective sedentary control groups: PFC and PNC.

GROUP	WEIGHT	BP
TF	38,2 ± 4	90 ± 6
TFC	38,5 ± 3	102 ± 8
TN	28,5 ± 2	89 ± 4
TNC	29,0 ± 2	101 ± 8
PF	30,9 ± 5	95 ± 3
PFC	38,8 ± 7	112 ± 6
PN	28,4 ± 1	94 ± 8
PNC	30,2 ± 2	99 ± 6

Conclusion: Moderate intensity exercise reduced resting blood pressure independently of its therapeutic or preventive character and of the fat and cholesterol diet intake. However, only preventive exercise was able to reduce mice's weight.

EFFECTS OF CREATINE SUPPLEMENTATION ON PROLONGED INTERMITTENT EXERCISE IN THE HEAT

Ishizaki, S., Naito, H., Katamoto, S., Yasumatsu, M., Inagaki, M., Yoshimura, M., Aoki, J.,

Oyama National College of Technology, Japan

Creatine (Cr) supplementation has been demonstrated to increase concentration of Cr and phosphocreatine (PCr) in skeletal muscle (1), and to improve performance during high-intensity exercise (2). In addition, Cr supplementation has been consistently shown to increase total body water (TBW). Thus, it is expected that Cr supplementation could have beneficial effects on prolonged high-intensity exercise in a heat environment. We tested a hypothesis that Cr supplementation would enhance prolonged intermittent exercise performance in a hot environment.

Twelve male collegiate soccer players (age; 19.6 ± 0.9yr, height; 177.5 ± 6.0cm, body mass; 71.1 ± 7.3kg, VO2max; 62.9ml/kg/min.) volunteered to participate in this study. Subjects were randomly assigned to either a Cr supplementation group (CR; n=6) or a placebo supplementation group (PLA; n=6) using a double-blind design. The CR ingested four 5-g doses of Cr monohydrate (Kenko, Japan) per day for 5 days, whereas the PLA ingested the same dosage of lactose (Kenko, Japan). Before (pre-) and after (post-) the supplementation period, subjects underwent a prolonged intermittent exercise in a heat environment room (32.0 ± 0.2degrees, 58.5 ± 1.4%) for 45 minutes. This exercise consisted of forty-five 5-sec maximal pedaling (exercise load; 7.5% body weight kp) interspersed by 55-sec recovery (25-sec active recovery + 30-sec rest). Before the exercise, indices of body composition (%body fat, TBW, intracellular water; ICW, extracellular water; ECW) were estimated by a bioelectrical impedance analysis (InBody 3.2, Biospace, Japan). Mean power output, rectal temperature, heart rate, blood lactate concentration, rating of perceived exertion (RPE), and thirsty level were measured during exercise.

Body weight, %body fat, TBW, ICW, and ECW were not affected by Cr supplementation. And there were no differences in heart rate, blood lactate concentration, and RPE during exercise between pre- and post- supplementation periods. However, rectal temperature during the exercise in the CR group was significantly lowered (from 0.16 to 0.20degrees) at the set of 5, 10, 15, 20, 25, and thirsty level was lowered at the set of 25 in the post- supplementation. There was a significant increase of mean power output only in the CR group (pre; 741.5 ± 77.2watt VS post; 763.6 ± 78.8watt, $P<0.01$).

It was concluded that Cr supplementation could prevent the elevation of body temperature and improve mean power output during the prolonged intermittent exercise in the heat environment.

THE FREQUENCY CHARACTERISTICS OF RESPIRATORY RESPONSE DURING CONSTANT LOAD EXERCISE

Saito, H., Németh, H., Kimura, M., Watanabe, T., Kuboyama, I.

Kokushikan University, Japan

INTRODUCTION

Breathing has irregularities that produce breath-to-breath fluctuation in pulmonary gas exchange, but the mechanism of the fluctuation is not still clear now.

The purpose of present study was to analyze respiratory response during exercise through frequency analysis of respiratory response parameters.

METHODS

Two healthy female subjects used a bicycle ergometer, being instructed to keep cadence of the pedal around 60 rpm during exercise. The exercise protocol was seven-minute 2W pedaling and trapezoidal load which consisted of three-minute ascending ramp, 20-minute constant load and three-minute descending ramp. Intensities of the constant load were set at 2W, 22W, 42W, 62W, 82W, 102W, 122W, 142W and 0W (just sitting on the bicycle ergometer). Each load intensity exercise was repeated three times in different days. Sampled data of 15 minutes in constant load were adopted for subsequent analysis.

Expired gas was measured using respiratory gas analyzer (AE300S, Japan) with breath by breath method. Four analyzed respiratory response parameters were end tidal oxygen concentration (ETO2), end tidal carbon dioxide concentration (ETCO2), expiratory tidal volume (TVe), and respiratory rate (RR). Data sampling time was five seconds.

Power spectrum was obtained in each load through Kyplot 4.0 analysis software (Japan) using Continuous Wavelet Transformation with Gabor's Function.

RESULTS

Curves of power spectrum were much smoother and their power gradually declined as the frequency increased.

Power of RR in more than 62W load increased 10 times higher than one at rest in all frequency bands, and that of TVe was not changed from 0W to 42W load, but abruptly increased in more than 62W load in all frequency bands. Power of ETCO2 dropped in 22W and 42W, and recovered to 0W level in more than 62W load in all frequency bands, however, that of ETO2 increased in more than 82W load especially in middle frequency bands.

DISCUSSION and CONCLUSION

The frequency analysis showed that ETCO2 changed during mild exercise and ETO2 changed during hard exercise, which suggested exercise-induced respiratory response might contain frequency characteristics. Further study, however, would be required to clarify respiratory response during exercise in another method.

PROTECTOR EFFECT OF EXERCISE WEEKLY FREQUENCY ON BLOOD PRESSURE IN SPONTANEOUSLY HYPERTENSIVE RATS

Cardinot, T., Moniz-de-Aragão, A., Farintatti, P.

State University of Rio de Janeiro (UERJ), Brazil

Objective: To evaluate the effect of different exercise training weekly frequencies on resting blood pressure (BP) in spontaneously hypertensive rats (SHR).

Methods: Fifteen male rats had been studied in three groups of five rats: sedentary control (SG), trained with frequency of 3 days/week (G3) and 5 days/week (G5). The trained groups had been submitted to 60 minutes of low intensity aerobic exercise in a treadmill for 16 weeks. The trained groups started the adaptation exercise in the 5th week of life (WL). The following week they started the first week of exercise training (WT). BP and weight were verified weekly.

Results: The initial BP was not different among the groups: 117±3 mmHg (G5); 119±4 mmHg (G3); and 120±6 mmHg (SG) ($p>0.05$). G5 and G3 remained normotensive during all the studied period, but G5 BP was significant smaller since 13th WT. At the end of the study the difference between G5 and G3 was around 11 mmHg: 122±4 mmHg (G5) and 133±3 mmHg (G3) ($p<0.05$). The SG showed gradual increase of BP during all the studied period and its final BP was 184±10 mmHg. The BP difference between SG and trained groups was significant since 5th WT ($p<0.05$). No weight difference was observed among the groups during the studied period ($p>0.05$).

Conclusion: Low intensity exercise prevents hypertension in SHR with observed effects since 5th week of training independent of exercise weekly frequency, but the protector effect seems to be bigger in the 5 days/week training group.

EFFECTS OF BED REST AND POSTURE ON THE KINETICS OF O2 UPTAKE AND CARDIAC OUTPUT

Azabji-Kenfack, M. 1, Fagoni, N. 2, Tam, E. 1+3, Cautero, M. 3, Lador, F. 1, Moia, C. 1, Capelli, C. 3, Linnarsson, D. 4, Ferretti, G. 1+2

1 CMU, Genève, CH, 2 Uni Brescia, IT, 3 Uni Udine, IT, 4 Karolinska Institute, Stockholm, SE, Switzerland

The aim of this study was to evaluate the effects of prolonged bed rest on the kinetics of O2 uptake and cardiac output at the onset of square-wave exercise in upright and supine posture. To this aim, O2 uptake (V'O2) was determined breath-by-breath by Gronlund's algorithm and cardiac output (Q') was determined beat-by-beat by the Modelflow method on 18 male subjects (33.1 years ± 0.9; 71.1 kg ± 1.1; 1.75 m ± 0.01) at rest and during the rest-to-work transient of 50 W exercise in upright and supine posture, before (BB) and after (AB) 90 days of head-down tilt bed rest. In BB, the amplitude of the V'O2 change was lower supine (0.65+0.08 L/min) than upright (0.74+0.09 L/min) ($p<0.05$). In AB, the amplitude was the same supine (0,86±0,43 L/min) as upright (0,76±0,18 L/min). No effects of bed rest were observed. The time constant of the V'O2 increase was longer supine than upright, both in BB (52,49±10,77 s vs 28,42±6,19 s) and in AB (56,78±10,36 s vs 36,26±10,08 s). A significant effect of bed rest was found only in the upright posture. In BB, the amplitude of the Q' change supine (2,36±0,86 L/min) was not significantly different from upright (2,91±0,54 L/min). The same was the case in AB (3,72±1,55 L/min supine vs 2,92±0,59 L/min upright). A significant effect of bed rest was found supine. The time constant of the Q' increase was longer supine than upright, both in BB (24,95±15,10 s vs 4,12±2,32 s) and in AB (34,28±18,57 s vs 7,02±4,13 s). No significant effects of bed rest were found. The time constants of the Q' response were always faster than those of the V'O2 response. We conclude that the rapid Q' kinetics upright with respect to supine may be a consequence of reduced central blood volume in the former as compared to the latter posture. These results thus suggest a role for cardiopulmonary baroreceptors in determining the Q' response to exercise. The similar time constants before as after bed rest imply the regulation of circulation at exercise onset operates according to the same principles before as after bed rest, despite the development of cardiovascular deconditioning with bed rest.

RATE OF FORCE DEVELOPMENT: DIFFERENCE BETWEEN UPPER AND LOWER LIMBS IN HEALTHY OLDER WOMEN

Ditroilo, M., Fernández Peña, E., Benelli, P., Centonze, F., De Lillo, F., Giacomini, F., Grassi, E., Trisolino, G., Stocchi, V.

Istituto di Ricerca sull'Attività Motoria, Italy

In older people, the ability to exert a rapid increase in muscle force has important consequences with the successful performance of daily tasks like rising from a chair or climbing stairs, and may even reduce the incidence of falls related to the impaired control of postural balance with increasing age. The individual's ability to quickly generate muscle force is also known as the rate of force development (RFD). It was demonstrated that the lower limbs (LL) are more affected by strength loss than upper limbs (UL). Accordingly, the purpose of this study was to investigate whether the muscles of upper and lower extremities would show a difference in RFD. It was hypothesized that LL would have shown a reduced RFD compared to UL.

Twenty-five healthy women (age 68.4 ± 5.1 years; height 157.9 ± 7.4 cm; weight 63.5 ± 7.6 kg) volunteered and gave their written informed consent for participating in the study. Knee extension (keMVC) and hand grip (hgMVC) isometric maximal voluntary contraction were measured on both the right and the left limb with, respectively, a leg-extension machine (Panattasport, Apiro, Italy) and a hand

dynamometer (Lafayette Instrument Co., Lafayette, IN, USA) equipped with a strain gauge, sampling at 100 Hz and linked to a data collection unit (Muscle Lab Bosco System, Ergotest Technology a.s., Langesund, Norway). Subjects were instructed to push and squeeze as quickly and strongly as possible, trying to maintain the maximal force for about 3-4 seconds, while a vigorous verbal encouragement was given. A minimum of two maximal actions was recorded for each leg and hand, with at least 1 minute rest in between.

The keMVC and hgMVC were calculated by averaging the values of force registered during 600 ms which included the maximal peak force point. The slope of the first 0.25 s of the force time curve were considered for each subject to calculate the corresponding RFD.

The keMVC of the dominant side was significantly greater than hgMVC (302.8 ± 78.0 vs 260.0 ± 65.7 N). However no significant difference was found in RFD of LL and UL (slope 950.6 ± 323.9 and 939.6 ± 293.9 respectively). The force time curve showed that the subjects reached about the 50% of their MVC after 0.15 s, and about the 75% after 0.25 s, both in LL and in UL.

Opposing the hypothesis, it was found that the RFD is not significantly different in leg extensor and hand grip muscles of older women. However it should be stressed that i) the women participating in the study were physically active and involved in walks and housework; ii) the RFD data collected showed a large variance. Furthermore LL and UL RFD variables showed just a slight positive relationship unlike what would be expected.

COMPARISON OF THE VASTUS LATERALIS NEUROMUSCULAR ACTIVITY IN CYCLISTS AND LONG-DISTANCE RUNNERS

Oliveira Marques, F., Tavares, P., Rosado, M.F., Ribeiro, G., Anjos, I., Fontes Ribeiro, C.A.

Faculty of Sport Sciences and Physical Education, University of Coimbra, Portugal

There is agreement between exercise physiologists that the aerobic performance evaluation of a long-distance runner must be due in a treadmill whereas for cyclists that evaluation must be due on a cycloergometer due to biomechanic and physiological considerations. However, the leg muscle responsible for running and cycling is the same, namely the Vastus lateralis muscle. Thus, the aim of this study was to assess in both athlete type the Vastus lateralis neuroactivity in a cycloergometer aerobic maximal test.

Three groups of male volunteers participated in this study: cyclist athletes (CA), endurance athletes (EA) and seven sex-matched sedentary controls (SC), all matched in age (SA:22.0±1.5; EA:23.8±2.3; SC:24.1±0.5 years old). All the subjects performed an aerobic maximal graded exercise test in a cycloergometer (Monark 824E) in order to determine the specific VO2max. This test consists in a constant pedal frequency (60 rpm) starting with 50 W workload and increasing 25 W every two minutes until fatigue. Oxygen and carbon dioxide measurements were made with a Metamax Ergospirometry System. Before the exercise test, basal values of heart rate were determined as well as during and 30 minutes after the tests, by using a heart rate monitor (Polar®). During the exercise test the surface electromyographic parameters (RMS-EMG and MPF-mean power frequency) were evaluated in the Vastus lateralis muscle of each subject. The EMG recording was made with a MegaWin® ME3000 device. In order to compare individual results, the RMS-EMG values were normalized by dividing the obtained values for the crural perimeters of each subject. Results were analysed according to power and time.

Oxygen maximal consumption was higher in cyclists when compared with the other group. The maximal heart rate achieved was similar in both athlete groups. Concerning the EMG analysis, we verified that in both groups the MPF remained constant during the test and, therefore, is power - independent. The RMS-EMG values were positively correlated with power but show no significant differences between cyclists and long distance runners. Thus, both endurance athlete groups showed the same neuronal activation of the Vastus lateralis muscle during this aerobic maximal test in a cycloergometer.

Partial) and FCT (Fundação para a Ciência e Tecnologia), Portugal.

CHANGES IN CORTICOMOTOR EXCITABILITY OF ANTAGONIST MUSCLES DURING A SUBMAXIMAL FATIGUING CONTRACTION

Lévénez, M., Carpentier, A., Duchateau, J.

Université Libre de Bruxelles, Belgium

Introduction

The concurrent activation of agonist and antagonist muscles, which is commonly referred as coactivation (Nielsen & Kagamihara, 1993), must be continuously adjusted by the nervous system during a fatiguing contraction so that the performance of the agonist muscles is not impeded. The purpose of the present study was to improve our knowledge on the control mechanisms of coactivation by recording the changes in the corticomotor excitability of antagonist muscles during a submaximal fatiguing contraction.

Methods

Eleven subjects (24-40 yrs) participated in a fatigue study that consisted to sustain a submaximal isometric contraction with the dorsiflexor muscles at 50% of their maximal voluntary contraction until task failure. Surface EMG activities of the tibialis anterior (TA) and of two antagonist muscles, the soleus (Sol) and the lateral gastrocnemius (LG), were continuously recorded. Concurrently, motor evoked potential (MEP) induced by transcranial magnetic stimulation and compound action potential (M-wave) elicited by maximal electrical stimulation were recorded in these muscles, before, during (at 20s interval) and after the fatigue task. To exclude fatigue-related changes of the muscle fibre membrane in the interpretation of the data, the MEP area of the TA was normalized to its M-wave area.

Results

The average endurance time for all subjects was 340.2 ± 118.2s (mean ± SD). After the fatigue test, the maximal torque produced by the ankle dorsiflexors and the aEMG of the TA dropped by 35.8 ± 13.7% ($P<0.01$) and 30.3 ± 27.0% ($P<0.01$) of the pre-fatigue values, respectively. In the antagonist muscles, the aEMG increased by 119.9 ± 92.7% ($P<0.01$) and 65.5 ± 65.7% ($P<0.01$) in the Sol and LG, respectively. Compared with the pre-fatigue values, the normalized MEP area at task failure increased progressively to 156.6 ± 64.8% ($P<0.01$) in the TA and, to 139.0 ± 58.0% ($p<0.05$) and 146.5 ± 39.1% ($P<0.01$) in the Sol and LG, respectively.

Conclusion

The main finding of the current study was that the biphasic modulation of the spinal reflex excitability in the antagonist muscles during a sustained contraction at 50% MVC force (Lévénez et al., 2005) is accompanied by a progressive increase in the excitability of the corticospinal pathway. The latter observation indicate that the reduced spinal reflex excitability observed at task failure is not due to reduction in the excitability of the motoneurones pool but to an increased presynaptic inhibition. Collectively, these results indicate that the level of coactivation during fatigue is controlled by supraspinal rather than spinal mechanisms.

EFFECT OF POSTACTIVATION POTENTIATION ON THE LOADVELOCITY RELATION OF A HUMAN MUSCLE

Baudry, S., Duchateau, J.
Université Libre de Bruxelles, Belgium

Introduction
The torque and the rate of torque development of a muscle twitch is transiently increased after a maximal voluntary contraction (MVC; i.e. postactivation potentiation or PAP)1,3,4. However, it is not clear whether the maximal velocity of muscle shortening against different loads is also increased by a conditioning contraction. Hence, the purpose of this study was to compare the effect of PAP on the load-velocity relation and to investigate Sale's suggestion that intrinsic human muscle performance could be improved through this procedure 4.
Methods
The experiments were performed on ten subjects (24-40 years). The angular displacement of the thumb and its first derivative were recorded during contractions of the adductor pollicis muscle performed against various loads (10, 20, 30, 40 and 50% of MVC), before and after a conditioning isometric MVC of 6s. In a first series of experiments, the effect of PAP was tested by movements induced by tetanic contractions (15 pulses at 250 Hz) whereas, in a second series they were produced by voluntary contractions. The load-velocity relation was fitted by Hill's equation and the maximal shortening velocity at zero load (Vmax) was extrapolated from the relation. The maximal muscle power was also calculated.
Results
The load-velocity relations, tested by electrically-induced and voluntary contractions, were similarly modified after the conditioning MVC and showed an upward displacement. Vmax was significantly (P<0.01) increased by 14.9  5.4 % and 11.5  4.5% and maximal power was enhanced (P<0.01) by 16.8  4.1% and 12.3  3.1% during electrically-induced and voluntary contractions, respectively. Potentiation was maximal 1 min after the conditioning MVC and declined progressively over time to disappear completely after 5 min.
Conclusion
The main finding of the current work is that the velocity of muscle shortening against different loads is increased after a conditioning contraction. Furthermore, the similar effect of PAP on the load-velocity relation, maximal velocity of shortening and power when tested by a tetanic and voluntary contractions indicates that the mechanisms responsible for PAP are exclusively located in the muscle. This conclusion is in line with a previous work in mouse muscle showing that the increase in maximal shortening velocity after a conditioning contraction is induced by enhanced phosphorylation of myosin regulatory light chains2. In conclusion, our results indicate that PAP is acting during human voluntary movements and this mechanisms may be used to transiently increase speed and power in explosive sports.

ACUTE PASSIVE STRETCHING ALTERS THE MECHANICAL BUT NOT THE ELECTRICAL PROPERTIES OF CALF MUSCLES IN HUMANS

Esposito, F., Cè, E., Alfieri, P., Pizzini, G., Veicsteinas, A.
University of Milan, Italy

An acute bout of passive muscle stretching has been shown to diminish maximal force and power output. Two mechanisms have been suggested to explain these findings: a mechanical alterations in the stretched muscle and an impaired neural activation. Thus, the aim of this study was to evaluate i) the stretching-induced changes in the electrical and mechanical properties of the muscle fibres during maximal electrically elicited contractions of the calf muscles; and ii) the time to recovery of these changes within two hours after stretching procedures. Thirteen subjects (age 23±2 years, mean±s.e.m.; body mass 70±4 kg; stature 178±3 cm) underwent 3 tetanic electrical stimulation at maximal intensity, before and after (every 15 min for 2 hours) a bout of passive stretching. During contractions, the force, surface EMG and mechanomyogram (MMG) were simultaneously recorded from the medial gastrocnemius muscle. From the analysis of the 3 signals, after stretching it resulted that: i) the force peak, time to peak and the peak rate of force production significantly decreased by 34±6%, 5±2% and 34±6%, respectively; ii) the MMG amplitude (peak-to-peak) also decreased (-14±5%; p<0.05); iii) no differences were found in EMG parameters; and iv) maximum force production remained significantly lower even after 2 hours of recovery from the stretching procedures. In conclusion, acute passive stretching affected the mechanical but not the electrical properties of the maximally contracting muscles, suggesting a stretching-induced alteration of the musculotendinous stiffness, but not a depression of muscle activation. Moreover, force depression persisted steadfastly after 2 hours from passive stretching, indicating a maximum force recovery time longer than two hours.

MULTI-CHANNEL ANALYSIS OF HUMAN INTRA-MUSCULAR MYOELECTRIC SIGNALS

Mizumura, S., Ohtsuki, T., Maezawa, K.
Meiji University, Japan

Many researchers have reported on motor unit firing behaviors during human voluntary isometric muscular contractions. In most of their studies, the single channel intra-muscular myoelectric signals were analyzed into its constituent motor unit action potential trains at force production of the low or intermediate levels. In the present study, in order to verify whether multi-channel analysis is needed to precisely identify the motor unit action potentials during voluntary isometric muscular contractions, we compare the motor unit firing behaviors by the single channel analysis with those by the multi-channel analysis in the same trials of the same subject.

Subjects sat on an experimental chair with their right knee flexed at 90 degrees. Isometric knee extension forces were recorded using a force transducer positioned at the distal end of the right leg. We asked the subjects to produce isometric trapezoidal ramp and hold knee extension force as follows: to increase the isometric knee extension force up to 25 % maximal voluntary contraction in 2.5 seconds (10%MVC/sec), then to maintain the force level for 10 seconds, and to decrease the force to 0 % MVC in 2.5 seconds (-10%MVC/sec). Two differential intra-muscular myoelectric signals were simultaneously recorded from right vastus medialis muscle using a specially designed quadrifilar fine wire electrode (Mizumura, 1999). The two signals were decomposed into its constituent motor unit action potential trains by one channel analysis respectively, and the same signals were decomposed by two channel analysis.
As a result, the motor unit action potentials were more precisely decomposed by the two channel analysis than by the single channel analysis. We believe that multi-channel analysis is needed to precisely identify the motor unit action potentials during human voluntary isometric muscular contraction even when the human subject produce low level of isometric force.

THE ADDITION OF CAFFEINE TO A SPORTS DRINK INCREASES MAXIMAL CYCLING POWER BUT DOES NOT AFFECT FLUID BALANCE OR THERMOREGULATION

Mora-Rodriguez, R., Del Coso, J., Estevez, E., Baquero, R.

Universidad de Castilla La Mancha, Spain

Introduction

Fluid replacement prevents cardiovascular drift and hyperthermia during prolonged exercise in the heat (1). Carbohydrates improve endurance performance (2) and sprinting ability (3) during prolonged cycling in warm conditions. Caffeine ingestion enhances repeated high intensity bouts of team-sport performance (4). The purpose of this study was to investigate if the performance effects of fluid replacement, carbohydrates and caffeine are additive when they are co-ingested during exercise in the heat.

Methods

Seven heat-acclimated trained subjects pedaled for 120 min at 63% VO2max in a hot-dry environment (36ºC; 29% rh) in six different occasions; 1) no fluid ingested (DEH); 2) caffeine supplementation (CAFF; 6mg/kg BW); 3) rehydrating 90% sweat loss with water (WAT); 4) rehydrating with water+caffeine (WAT+CAFF) 5) rehydrating with a 6% carbohydrate-electrolyte solution (CES) and 6) rehydrating with CES+caffeine (CES+CAFF). After 30, 60, 90 and 120 min of continuous pedalling, maximal cycling power (Pmax) was measured during 3 all-out sprints of 4 s duration. Rectal and skin temperatures were collected during whole the trial. Sweat rate was estimated from changes in body weight. VO2, VCO2, cardiac output and blood volume changes were measured at 15, 60 and 120 min. Data from trials were pooled for caffeine (CAF, WAT+CAF and CES+CAF) vs no caffeine treatments (DEH, WAT, and CES). Significance level was set at $P<0.05$.

Results

In comparison to DEH, fluid replacement (WAT) lowered final rectal temperature ~0.7ºC, increased sweat rate (from 1.3 to 1.4 L/h) and maintained blood volume (5%) and cardiac output (1.3 L/min) during exercise in the heat. However, it did not enhance cycling power. The addition of CHO and caffeine to plain water (CES and WAT+CAF) had no further cardiovascular and thermoregulatory benefits. When pooling data in the caffeine trials Pmax was higher than in the no caffeine trials at 30, 60, 90 and 120 min of exercise.

Discussion

Our data suggests than when interested on preserving short-term sprint performance during prolonged exercise in the heat the choice of a rehydration drink that contains water carbohydrates and caffeine (6mg/kg body weight) is advisable. Water alone or a CES are not enough to improve short-sprint performance in our trained subjects. Caffeine co-ingestion during prolonged exercise in the heat does not impair the thermoregulatory benefits of fluid replacement.

ENERGY COST CHARACTERIZING FACTORS BY TERRAIN TYPES

Leonardi, A., Schena, F.

Ce.Bi.SM. - Center of Bioengineering and Motor Sciences, Italy

Winter and summery sports on mountain paths like snowshoeing, trekking and mountain biking are popular type of physical activities widely diffused and they can be consider useful resources to promote health and well-being.
These forms of exercise requires amount of energy highly variable, in relationship to different factors as slope and speed of locomotion as previously determined in laboratory controlled conditions by energy cost (CE) calculation. Modern technologies allow to conduct accurate measures of path characteristics and metabolic requirements even on the terrain, giving us the possibility to verify the existence of characterizing parameters also in natural environment
Topographical surveys were executed on mountain area in three different CE studies to detect recurrent types of terrain. Each units at different medium slopes and meaningful different length was clustered by macro categories: untouched snow US and packed snow by catsnow PS about snowshoeing study, layer of rock particles mixed with very little humus also called gravel GW and rock-wood steps SW about trekking study, smooth solid layer also called compact CM, gravel-disjointed DM and narrow highly disjointed path NM about mountain biking. Each units was digitalised by using cartographic imaging 3D with positioning satellite receiver GPS with barometric altitude correction.
Subjects were equipped with a portable gas analyzer (K4, Cosmed, Italy) and GPS integrated module and moved on slopes between ±30 [%] for snowshoeing trekking and between ±15 [%] by bike.
The speeds were self selected on the basis of personal physical capacity in order to have habitual sense of effort. Energy cost of walking was calculated for each test from the steady state V'O2 using heart rate and ventilation data to check the sub-threshold level of effort. In this condition CE ([J•kg-1•m-1]) in was set equal to the average value of oxygen net consumption per body mass ratio to average chronometric speed on covered path. Each activity is described by polynomial functions always different for CE value related terrain conditions. In comparison to GW, walking on SW causes a CE increase with range 0.5-1.9 [J•kg-1•m-1] in particular at medium slope between -15[%] to +5[%]. In snowshoeing the comparison between the two snow conditions shown a higher value of CE on US with

ranging 0.6-1.4 [J/(Kg*m)] around slope from -25 to 20[%]. In mountain biking DM function remain for all gradients 0.6 [J/(Kg*m)] higher than CM with a very similar behaviour however NM path confronted to DM requires an additional energy with rapid increase ranged from 0.4 to 2.2 [J•kg-1•m-1] around slope from -10 to 6[%]. Our data shown common CE characterizing factors depending from contact point on the surface which compactness grade, adhesion (gripping-sliding) and easy rolling progression continuity and support this possible method to estimate accurately the energy expenditure of these outdoor activity.

RELIABILITY OF MUSCLE VS NERVE ELECTRICAL STIMULATION TO DETERMINE MUSCLE FATIGUE

Del Coso, J., Estevez, E., Mora-Rodriguez, R.

Universidad de Castilla La Mancha, Spain

Introduction

Muscle contraction evoked by electrical stimulation (EL) has been used to determine the origin of fatigue during exercise. The ratio between the force in a maximal voluntary contraction (MVC) and that with superimposed electrical stimulation (to maximize recruitment) is regarded as central activation ratio (CAR; index of central nervous system drive). In addition, to evaluate if the origin of fatigue resides within the muscle, maximal contraction evoked by tetanic electrical stimulation (EL) is commonly used. These procedures to determine the origin of fatigue can be used stimulating percutaneously over the muscle belly (MS) or over nerve trunk (NS). The purpose of this study was to compare the reliability of these procedures when using MS in comparison to NS.

Methods

Five subjects familiarized with the procedures performed the reliability tests. After warm up, MVC of the right leg with superimposed EL to obtain CAR was performed in duplicate. Following electrical stimulation (EL 20 and EL 80 Hz) was used to assess muscle contraction function. In one occasion EL was applied percutaneously over the quadriceps (MS) and in another occasion over the femoral nerve (NS). Trials were performed randomly and separated by fifteen minutes of recovery. Subjects performed this protocol in three different days, twice a day separated 2 hours between them to study intra-and between-day reliability. To ensure that MS is a sensible method to detect fatigue 7 young cyclist pedalled (60% VO2max) during 120 min in a hot-dry environment inducing to hyperthermia (39.0ºC) and fatigue. Before and after the exercise the origin of fatigue was studied using MS electro stimulation.

Results

MVC was in average ~553±9 with high within and between-day reliability (R1=0.97 and 0.92). CAR was very similar using NS and MS (95±0.5% and 94±0.6%, respectively) and the intra-between day reliability was also similar. The ratio of force produced during the 20 Hz/80 Hz stimulation was similar using NS or MS (0.87 vs 0.85). However, response time at 20 Hz and at 80 Hz was slower for NS in comparison to MS (246±12 vs 213±4 ms and 260±9 vs 194±2 ms, respectively; $P<0.05$). 120 min of exercise-induced hyperthermia reduced MVC by 11% (from 759±65 to 683±73 N; $P<0.05$) and CAR by 5% while maximal contraction evoked by tetanic electrical stimulation was unchanged by exercise.

Discussion

Muscle stimulation (MS) results in similar values for the assessment of the origin of fatigue (MVC, CAR, EL 20 Hz / EL 80Hz) than when using NS. The faster time response (from stimulus to onset of force production) during NS in comparison to MS could be due to the proximity of the axon to the electrodes while the stimulus during NS needs to travel from the inguinal fold to the muscle. In conclusion, EL (directly positioning the electrodes on the muscle) seems to be a location as reliable as the typically used femoral nerve stimulation to assess the origin of fatigue.

BRAIN AND MUSCLE OXYGENATION AND NEUROMUSCULAR PROPERTIES RESPONSES TO AN INCREMENTAL MAXIMAL EXHAUSTIVE CYCLING EXERCISE

Rupp, T., Perrey, S.

Faculty of Sport Sciences, UFR STAPS, 700 avenue du Pic Saint Loup, 34090 Montpellier, France

Introduction: The physiological causes of fatigue have been classified as either peripheral (skeletal muscle contractility) or central (neural drive to muscle) in origin. To date, theory identifying central nervous system as the central governor of altered motor performance have received less attention (Noakes et al., 2004). This study integrates this last theory and attempt to explore the role of cerebral functional activation in the muscle fatigue etiology in humans during severe exercise. The purpose of this preliminary study was to examine the effects of fatigue resulting from progressive maximal exhaustive cycling exercise on brain cortical oxygenation, muscle oxygenation and neuromuscular properties. Methods : Twelve trained healthy subjects (age: 24.2 ± 5.1 years, training per week: 7.1 ± 2.3 hours) performed an incremental exercise to forced exhaustion on a cycling ergometer. Left frontal cortical oxygenation and muscle oxygenation (over the vastus lateralis) were measured simultaneously by near-infrared spectroscopy (NIRS) to give evidence of cerebral functional activation and oxygen delivery and uptake by the muscle. Maximal voluntary knee extension torque and neuromuscular properties (M-wave amplitude and duration, voluntary activation ratio) were measured on vastus lateralis just before and 6 minutes after exercise to examine the neural adaptation mechanisms induced by exhaustive fatigue. The electromyographic (EMG) activity of the vastus lateralis was recorded and analyzed to reflect modifications of the neuromuscular system throughout the incremental cycling test. Preliminary results and discussion: Up today a part of data is still in processing and supplementary subjects are planned. The mean maximal power output value of the exhaustive test was 384.5 ± 29.4 W and subjects' maximal oxygen consumption (VO2max) reached 74.3 ± 7.0 mL.min-1.kg-1. There was no significant difference between pre- and post-exhaustive exercise for both the voluntary activation ratio and the M-wave patterns. These findings suggest that 6 minutes are sufficient to restore neuromuscular function after a short progressive fatiguing exercise. EMG activity increased non-linearly from start to end of exercise. Further analysis are under-way to confirm correlation between ventilatrory thresholds, the global surface EMG energy and the marked reductions in muscle oxygenation measured by NIRS. Finally, brain cortical oxygenation increased during the first minutes of exercise but decreased markedly at severe exhaustion. This last finding is in full accordance with prior studies (Shibuya et al., 2006) and suggests that a short progressive fatiguing exercise induces a decrease of brain activity that leads to transient changes in muscular function at the end of exercise.

EFFECTS OF YOGA ON BONE MINERAL DENSITY AND BONE BIOCHEMICAL MARKERS IN ELDERLY

Bezerra, L.M., Oliveira, R.J., Abdhala, Lídia

Catholic University of Brasília, Brazil

ABSTRACT: The benefits of dynamic training for the bone mineral density (BMD) have been largely studied; however, the effects of static stimulus in bone physiology are not well-known. Thus, the practice of yoga may be a possible provider of static bone stimulus. Therefore, the aim of this study was to verify the effects of yoga in the bone mineral density and the bone biochemical markers (BBMs) of formation (osteocalcin) and reabsorption (CTx), as well as, the estradiol hormone. A total of fifty post-menopausal women (63,88 ± 5,66, years old) was randomly screened and divided in Yoga Group (YG, n = 25) and Control Group (GC, n =25). The BMD, the BBMs and the estradiol hormone were analyzed pre and post-test. Furthermore, the BMD of the femural neck, the trocanter, the Ward's area, the all hip region, the lumbar spinal (L2-L4), the total body region and the ultradistal forearm was performed by a Dual Energy X-ray Absorptiometry (DXA). The eletrochemioluminescence technique was performed to identify the BBMs and the estradiol hormone. The yoga intervention lasted six months (three time/week and one hour/session). The results were statistically analyzed by the SPLIT PLOT ANOVA and the significance level was p £ 0,05. The results showed a significant decrease between pre and post-test on BMD of spinal lumbar in both groups (0,984 ± 0,190 g/cm2 to 0,959 ± 0,175 g/cm2 and 1,021 ± 0,227 g/cm2 to 0,989 ± 0,230 g/cm2, to Yoga Group and Control Group, respectively). Besides, there was a significant decrease between pre and post-test in BMD of total hip region in control group (0,970 ± 0,161 g/cm2to 0,954 ± 0,164 g/cm2). The osteocalcin showed a significant increase between pre and post-test in Yoga Group (15,44 ± 6,16 to 20,89 ± 9,44 ng/ml). The CTx showed a significant decrease between pre and post-test in control group (0,453 ± 0,130 to 0,243 ± 0,206 nanog/ml). The values presented an increase of bone deposition in post menopausal women caused by the increase of osteocalcin. Therefore, the bone static stimulus, as result of the practice of yoga, can alter the bone metabolism.

VENTILATORY CONTROL AND PLASMA LEVELS OF ERYTHROPOIETIN AND OXIDIZED LDL IN ELITE APNEA DIVERS

Hildebrandt, W., Dröge, W., Bärtsch, P.

German Cancer Research Center , Germany

Elite apnea divers achieve extreme breath-hold (BH) times of >5 min that are indicative of a unique ventilatory control allowing to tolerate extreme hypoxia and/or hypercapnia. To what extent the BH training of today's competitive elite apnea divers affects their ventilatory control is largely unknown. Moreover, as BH training may impose a severe hypoxia-reoxygenation stress, it is of interest whether erythropoietin (EPO) and hemoglobin concentrations increase and whether apnea diver expose themselves to oxidative stress.

The present study therefore determined the isocapnic hypoxic as well as the hypercapnic ventilatory response (HVR and HCVR, respectively) in 8 elite apnea divers as compared to 25 age-matched non-diving controls. Moreover, apnea divers performed several maximal BH maneuvers for determination of their end-apnea levels of (minimal) peripheral O2-saturation and end-tidal gases as well as for arterial blood gas analysis around the BH breaking point. Pulmonary function parameter were also obtained in apnea divers. Furthermore, venous blood levels of hemoglobin, EPO, and oxidized LDL (oxLDL) were compared between 6 apnea divers and controls.

Maximal BH times of apnea divers ranged between 5:10 and 7:30 min and correlated best with vital capacity (VC) (r=0.93, p<0.001) which was 120+-17% of predicted values (mean+-SD). End-apnea O2-saturations were between 42% and 75% and expectedly related to maximal BH time. Isocapnic HVR was significantly lower in apnea divers compared to controls (0.36+-0.23 vs 0.69+-0.35 l min-1%-1, p<0.01) while HCVR was similar. End-apnea end-tidal and arterial PO2 were related to isocapnic HVR. There was a large interindividual variability in the pre-apnea hyperventilation maneuver leading to end-tidal PCO2 levels between 17.4 and 51.6 mmHg at last pre-apnea expiration and between 39.0 and 76.7 mmHg at end-apnea expiration. These normo- to extremely hypercapnic end-apnea levels of end-tidal PCO2 were inversely related to the apnea divers' HCVR (r=-0.79, p<0.05) indicating a very experienced use of hyperventilation. While no differences in hemoglobin were detected, plasma levels of EPO (14.2+-2.3 vs 8.5+-0.8 U/L) and of oxLDL (97.3+-8.6 vs 58.8+-4.6 U/L) were significantly increased.

These findings suggest that a high VC and a low HVR together with a HCVR-adjusted hyperventilation allow for extreme BH times and hypoxemia of apnea divers. BH training appears to impose a hypoxia-reoxygenation stress that is comparable to that occuring with sleeping apnea.

HEAT EXPOSURE ELEVATES MUSCULAR HEAT SHOCK PROTEIN 70 AND SUPPRESSES EXERCISE-INDUCED SKELETAL MUSCLE DAMAGE IN MICE

Mikami, T. 1, Yamauchi, H. 2, Ohota, S. 1

1 Nippon Medical School, 2 Jikei University School of Medicine, Japan

Heat shock proteins 70 (HSP70) is a super family of highly conserved protein, most of which are induced in response to a wide array of physiological and environmental stresses, including heat, cold, ischemia, hypoxia, and energy depletion. In cells, heat exposure induces cellular HSP70 and enhances a state of resistance to subsequent stress. In animal, exposing animals to hyperthermia also protects organs against stress-induced damage. Therefore, this study was designed to investigate whether heat exposure prior to exercise could elevate HSP70 in skeletal muscle and contribute to protect the muscle against exercise-induced muscle damage.

Male ICR mice were randomly divided into two groups, control and heat mice. The heat mice was anesthetized with pentobarbital sodium and placed in an environmental chamber at an ambient temperature of 42? for 30 min. Twenty-four hours after heat exposure, some of control mice and heat mice were killed to collect soleus, extensor digitorum longus (EDL) and plasma. The rest of mice were performed 60 min of downhill running on treadmill (decline 20 degrees, treadmill speed 25 m/min) because the downhill running are used as eccentric exercise model and the eccentric exercise induces more muscle damage than the concentric exercise. After downhill running, the exercised mice were killed at 12, 24 and 48 h after the end of downhill running. The amount of HSP70 in both muscles was determined using SDS-PAGE and western blot. Activities of plasma creatine kinase and muscle beta-glucuronidase were measured as the quantitative indicators of muscle damage. In addition, immunohistochemical analysis was performed to examine the change in HSP70 and dystrophin, a structural protein of the submembrane, in muscular cells.

Heat exposure significantly increased the amount of HSP70 in both soleus and EDL muscle compared with control mice. In non-heat/exercise mice, creatine kinase activity in plasma dramatically increased 12 h and 24h after downhill running, while beta-glucuronidase activity in soleus and EDL increased 48 h after downhill running; however, heat/exercise mice showed a lower level of both enzyme activities compared with non-heat/exercise mice. Histochemical analysis using Harris's hematoxylin-eosin staining showed that the degree of occurrence of muscle damage was less in heat/exercise mice than in non-heat/exercise mice. In double-

immunofluorescence staining using both anti-dystrophin and anti-HSP70 antibody, the soleus muscle of non-heat/exercise mice showed significant disappearance of dystrophin, while no disappearance of dystrophin was showed in the soleus muscle of heat/exercise mice.

These findings suggest that heat exposure prior to exercise may enhance skeletal muscle HSP70 and lead to a protective effect against skeletal muscle damage induced by exercise.

THE EFFECTS OF HIGH FAT FEEDING AND VOLUNTARY EXERCISE ON MITOCHONDRIAL RESPIRA-TION RATE IN SKELE-TAL MUSCLE OF MICE

Silvennoinen, M., Rinnankoski, R., Kivelä, R., Lehti, M., Vihko, V., Kainulainen, H.

University of Jyväskylä, Finland

Introduction

The prevalence of type 2 diabetes is increasing fast in the western countries. Increased resistance to insulin and impaired secretion of insulin characterizes this complex disorder. The main risk factors of type 2 diabetes are seden-tary lifestyle, overeating and obesity. It has been reported that type 2 patients have low oxidative capacity in their skeletal muscle. This may either be an important promoter of the disease or simply be the complication of disease. Regular exercise is recommended to diabetic patients because it increases the oxida-tive capacity and the insulin sensitivity of skeletal muscle. Our long-term aim is to study the significance of oxidative capacity in the aetiol-ogy of type 2 diabetes. In this pilot study, we tested the use of high fat fed mice as model for insulin resistance development.

Methods

Male C57BL/6J mice were fed with either normal low fat diet (LFD) or high fat diet (HFD). Mice were housed in indi-vidual cages. After 17 weeks, mice were divided to four groups: LFD sedentary (n=4), LFD running (n=4), HFD sed-entary (n=10) and HFD running (n=11). Running mice had running wheels in their gages. Glucose tolerance, fasting plasma glucose and insulin were measured three times during the experiment (after 9,16 and 30 weeks). When mice had been 34 weeks on the diet, they were killed and their mqf muscles were removed. Mitochondria were extracted from the muscle samples and the respiratory rates of mitochondria were measured with O2 electrode. Glutamate (5mM) + malate (2.5mM) and pyruvate (5mM) + malate (2.5mM) combinations were used as substrates. Maximal respiration rates of mitochondria were measured after ADP (0.125mM) addition.

Results

HFD mice had higher levels of glucose intolerance and fasting plasma insulin than LFD mice. Running didn't have effect on glucose intol-erance and fasting plasma insulin levels in either of the diet groups. There were no significant differences in maximal respiration rates between HFD and LFD sedentary groups with either of the substrate combi-nations. HFD running group had higher (15.8%, $p<0.05$) maximal respiration rate than corresponding sedentary group when glutamate and malate were used as substrate. With pyruvate and malate the difference (10.4%) was not statistically significant ($p=0.086$).

Discussion/Conclusion

High fat feeding induced glucose intolerance and insulin resistance as planned but didn't have an effect on oxidative capacity of mito-chondria. However, we can't exclude the possibility that the oxidative capacity has decreased by decreased number of mitochondria. The physical activity increased the oxidative capacity of mitochondria, but it didn't have significant effect on glucose tolerance or insulin resis-tance. Based on these result, the voluntary wheel exercise should be started earlier in the actual experiment in order to find more signifi-cant effects of physical activity.

SLEEP PATTERNS OF ADVENTURE RACERS ATHLETES

De Mello, M.T., Antunes, H.K., Andersen, M.L., Bittencourt, L.R., Silva, R.S., Tufik, S.

Federal University of Sao Paulo, UNIFESP, Brazil

The Ecomotion-PRO is a "non-stop" adventure race competition, where the athletes has to complete several km distributed in different sporty modalities, faced natural obstacles, weariness and sleep deprivation (SD). In October of 2004, Bahia (BA, Brazil) hosted Ecomotion-Pro, the most important "non-stop" and challenging adventure race on the Brazilian calendar that consisted in 6 nights and 7 days. The purpose of this study was to investigate the sleep patterns after an adventure race. Sixteen athletes of both genders were volunteers, standard polysomnographic recordings (Rechatscaffen & Kale, 1968), were carried out using an Embla Digital A10 Recording/ amplifier with Somnologica software (Flaga h.f., Reykjavík, Iceland), one week before the race and the first sleep after the race. in October of 2004, The results demonstrated an important decreased in sleep onset latency (min) (6.04 ± 4,79 to 1.08 ± 2.10), stage 2 of sleep (%) (62.08 ± 7.12 to 54.60 ± 5.01) and number of arousals (h) (8.77 ± 3.25 to 6.44 ± 2.96), increased was observed in total sleep time (min) (418.68 ± 50.59 to 573.04± 164.54), stage 4 of sleep (%) (13.21 ± 4.39 to 16.58 ± 5.01) and REM (%) (19.66 ± 5.29 to 23.77 ± 4.98). When the genders were observed separate, the females showed an increased in sleep efficiency and a decreased in stage 1 of sleep. The male's presented decreased in sleep onset latency, stage 2 and augmented in total sleep time, stage 4 and delta sleep (stage 3 +4). Sleep deprivation plus extenuated physical exercise promote modifications in sleep patterns of the adventures racers athletes. Ours results showed that after Ecomotion-Pro, these athletes increased REM sleep and delta sleep, possible because a necessity to promote physical recuperation. This is very interesting, once those innumerous researches presented that the relationship between REM sleep and delta sleep is inversely correlated. In this way, we can conclude that adventures racers need a time to restart cognitive and physical functions.

EFFECTS OF SINGLE AND MULTIPLE SET STRENGHT TRAINING ON THE NUMBER OF SATELLITE CELLS AND MYONUCLEI IN M. VASTUS LATERALIS AND M. TRAPEZIUS IN UNTRAINED MEN

Hanssen, K.E., Kvamme, N.H., Rønnestad, B.R. Egeland, W., Kadi, F., Raastad, T.

Ostfold Univeristy College, Norway

We have earlier observed that upper body muscles respond different from leg muscles on single vs. three set strength training (3). Leg muscles increased cross sectional area more with three sets than with one set strength training, while no differences between 1 and 3

sets was seen in upper body muscles. Satellite cells play an essential role in muscle mass enlargements by providing new nuclei to hypertrophying fibres (1). Therefore, the purpose of this study was to examine the effect of single and three set strength training on the number of satellite cells and myonuclei in a leg muscle (vastus lateralis) and an upper body muscle (trapezius). We hypothesised that 3 set strength training would lead to a greater number of satellite cells and myonuclei per fibre in leg muscles than 1 set training, but no differences in upper body muscles.

Twenty-five untrained men were randomly assigned into two groups. One group performed 3 sets in legs exercises and 1 set in upper body exercises (3L-1UB), while the other group performed 1 set in leg exercise and 3 sets in upper body exercise (1L-3UB). The subjects performed 3 workouts per week during 11 weeks. 1RM testing was done in all strength exercises pre- and post-intervention. Biopsis were obtained before and after training and cross sections from vastus lateralis (VL) and upper part of trapezius (T) were analysed by immunohistochemistry for satellite cells, myonuclei and fiber types.

3 L-1UB increased strength (1 RM) in leg exercise significantly more than 1L-3UB (41±3% vs. 25±2%, respectively, $p<0.01$), and correspondingly had a greater increase in thigh muscle CSA than the 1L-3UB group. In upper body there were no significant differences between groups neither in strength nor in muscle CSA. In VL fibre area in type IIA fibres increased in both groups (21±6% and 17±6% in 1L-3UB and 3L-1UB, respectively), while no significant changes in fibre area was observed in type I fibres. In T 1L-3UB got a significant higher increase in type IIA fibre area compared to 3L-1UB (35±7% vs. 7±6%, $p<0,05$). A significant higher number of satellite cells per fibre was observed in T compared to VL before training (0.15 vs. 0.13, respectively, $p<0.05$). The number of satellite cells in both VL (37%) and T (38%) was significantly increased after the intervention in both groups, but there were no significant difference between groups. The number of myonuclei per fibre did not change significantly during the training period in neither group.

The increase in number of satellite cells after strength training was similar to other studies (2). However, the greater increase in thigh muscle CSA in the 3L-1UB group was not preceded by a larger increase in satellite cells, myoneclei nor fibre are. Therefore, the mechanisms behind the greater muscle enlargement by 3 sets in thigh muscles could not be explained by differences in satellite cell activation.

THE IMPACT OF HIGHLY INTENSIVE INTERVAL LIKE TRAINING ON RESPIRATION

Maassen, N., Vardaxoglou, K., Frische, M.

Medical School Hannover, Germany

The present study compared the impact of 3 weeks highly intensive interval like training and continuous training with similar mean mechanical work on respiration (VO2, VCO2, Ventilation and RER) and their kinetics during and after exercise.

Male subjects (26.9 + 2.3 years), performing ball- and/or endurances sports were assigned to two groups (Interval Group (IG) n=11; Endurance Group (EG) n=10). The average performance in IG was 4.16 + 0.63 and in EG 4.17 + 0.71 Watt/kg. The range of the maximal oxygen consumption was in IG between 0.038 - 0.074 l*kg-1*min-1 and in EG between 0.039 - 0.071 l*kg-1*min-1. The average maximal oxygen consumption was in IG 0.048 l*kg-1*min-1 and in EG 0.047 l*kg-1*min-1. IG conducted a highly intensive interval like training (IT) of 1 hour and EG conducted an endurance training of 1 hour. The average training intensity was 50% of the maximal power reached in an incremental test (Powmax) in both groups. The training was added to their normal training and was performed 3 x per week for 3 weeks. Before and after the training an endurance test (EX) at 80% Powmax to exhaustion followed by a 10 min recovery phase (RP) was performed. Ventilatory parameters were determined breath by breath (Metalyzer IIIb). The values were fitted to a mono-exponential function with a linear term.

The improvement of endurance time in IG was significantly larger than in EG (50% vs. 21%, $p<0.05$). No significant differences were observed in the VO2 neither in the absolute values nor in the kinetics during EX and RP. However, during EX the amplitude of VE increased in both groups (IG: $p<0.02$; EG: $p<0.008$) whereas the linear term decreased (IG: $p<0.02$; DG: $p<0.05$). The linear term correlated highly with the performance times in both groups ($p<0.001$). During RP there was no difference in ventilation between the groups. VCO2 was reduced after both training regimen during EX and RP. The respiratory exchange ratio (RER) was significantly lower during exercise and RP after both types of training. The reduction was significantly larger in IG (EX: $p<0.001$; RP: $p<0.001$) especially during the first minutes of RP. The [Lac] was lower in both groups during EX, whereas there was no difference in [Lac] and total [CO2] in the blood between the training groups during RP.

The different behaviour of VE and VCO2 after training indicates that both are not tightly coupled. The decrease in VCO2 is partly due to a lower buffering of lactic acid. The lower [Lac] is also indicative for a lower carbohydrate combustion and thus for an increased fat metabolism. This is pronounced in IG in the beginning of the resting period when the RER drops rapidly whereas VE, [Lac] and TCO2 shows no difference between the training groups. The tight correlation between the linear term of the ventilation with the performance time shows that VE is a good indicator of endurance capacity.

THE EVALUATION OF THE MUSCLE OF MUSCLE FATIGUE BY SIMULTANEOUS ELECTROPHYSIOLOGICAL AND MECHANICAL RECORDING

Vasilescu, M., Rusu, L.

University of Craiova, Romania

Introduction. Our research propose a modern and complex exploration method of muscle performance by computerized acquisition and analysis of surface electromyography (SEMG) and mechanomyogram (MMG) during voluntary isometric maximal contraction of flexor hand fingers. The evolution of 12 classical (previously described in literature) SEMG and mechanographic parameters and new parameters and indices were analyzed with dedicated software. This modern exploration method allows precise, quantified, analysis of muscle performance and, by linear regressions and statistical analysis, permits to differentiate various groups of subjects.

Methods. Our study has included sixty healthy athletes, who received an medical – sportive confirmation to participate at the trainings and sport competitions. The total group was made of male subjects with age difference, right-handed, professional athletes belonging to a variety of sports.

There has been registered at the same time to these athletes an surface EMG and MMG during an maximal isometric contraction, hand grip type, undertaken till brake point. For the evaluation of the muscle fatigue during effort time we used 38 parameters EMG and MMG.

The program that has been elaborated by us allows the analyses of all the 38 parameters, either continue, or on portions of 410 ms with gaps of 4590 ms.
This way it results, from 5 to 5 seconds, values of all the EMGS and MMG parameters, with whom the program forms for each parameter a curve of time evolution during the entire contraction period.
Because the interpretation of the curves with evolution in time of the parameters previously presented (each having values from 5 to 5 seconds, on all the period of the contraction), it's pretty difficult, we have calculated the I order regression lines, noting for each regression line the values of the slope(ordinate value of a point where the regression line intersects the ordinate) and intercept (shows the brutal change of the parameter because of the fatigue).
For a better comparison, the amplitude of the intercept value modification , we have calculated the slope/intercept ratio. The percentage value of this report, indicates how many percentage of the intercept value (noted 100%) have decreased or increased after 5 seconds of maximal contraction.
Results and Conclusions. From all the results obtained it shows that based on some simultaneous electrophysiological and mechanical recording with the help certain highly evolved mathematical processes, obtaining a lot of parameters , indexes, reports, graphics , mapping etc. With the help of this modern technique, we have studied different athletes categories obtaining very interesting results for the performance and muscle fatigue evaluation.

VISCOUS-ELASTIC PROPERTIES OF PLANTARFLEXOR MUSCLES IN WHITE CAUCASIAN AND BLACK AFRICAN ATHLETES: A PRELIMINARY STUDY

Driss, T., Lambertz, D., Vandewalle, H., Badour, Y., Goubel, F.

Université Paris 10-Nanterre, France

UMR-CNRS 6600, Université de Technologie, 60205 Compiègne
INSEP de Paris

Driss et al. (2003) observed that for a given maximal anaerobic power on a cycle ergometer, vertical jump was 6.8 cm higher in black volleyball players than in Caucasian. A difference between Caucasian and African subjects regarding leg viscous-elastic properties was a possible explanation, as suggested a simulation study (Bobbert, 2001) and experimental data (Fukashiro et al., 2002). The present study investigated possible ethnic differences in elastic properties of ankle plantar flexor muscles in black (BS) and white (WS) male athletes.
Mechanical data were collected on 29 explosive force and sprint type college students (black = 17, white = 12) of regional and national level. Mechanical tests included (i) maximal voluntary contraction (MVC), (ii) musculotendinous (MT) stiffness and (iii) musculoarticular (MA) stiffness. A quick-release technique was used to determine MT stiffness, while subjects maintained different percentage of MVC. The ratio between variation in dynamic torque and displacement (i.e. stiffness) was related to torque and the slope of the linear relationship was defined as stiffness index (SIMT) (Lambertz et al., 2001). Furthermore, MT stiffness values calculated at the different torque levels were normalized with regard to MVC. Sinusoidal perturbations were imposed at different percentage of MVC. The elasticity K of the MA system was calculated by using Bode diagrams and related to torque. The slope of the linear relationship between K and torque was defined as a stiffness index (SIMA). Results were expressed in terms of differences (in %) between black and white subjects. A student t-test was used and statistical significance was set at $P<0.05$.
MVC was significantly lower in BS (-13.9%, $P<0.05$). SIMA was significantly higher in BS (+19.9%, $P<0.001$). Normalized MT stiffness values were significantly higher at low (+28.4%, $P<0.01$) and medium (+13.1%, $P<0.05$) torque levels for BS and showed no significant differences at the highest torque level (+7.1%, $P>0.05$). Consequently, SIMT was significantly lower in BS (-30.8%, $P<0.01$).
In the present study, significant higher SIMA values were found in BS. This result is in agreement with those of Fukashiro et al. (2002) who reported higher muscle stiffness in black athletes, by using the free oscillation method. When studied by the quick-release method, musculotendinous stiffness, expressed by SIMT, was lower in BS of the present study, which was in contrast to Fukashiro et al. (2002) who reported no significant differences in tendon stiffness. However, there was no significant difference between BS and WS for MT stiffness values at the highest torque levels, i.e. for stiffness values probably similar to the tendinous stiffness in the study by Fukashiro.

CARDIOVASCULAR ANALYSIS IN AN AEROBIC CYCLING TEST IN SPRINTERS AND LONG-DISTANCE RUNNERS

Tavares, P., Anjos, I., Parada, J., Ribeiro, G., Rosado, M.F., Santos, A., Fontes Ribeiro, C.A.

Faculty of Sport Science and Physical Education, university of Coimbra, Portugal

The cardiovascular risk with exercise is associated to sympathetic nervous system activation and vagal activity. Some recent studies indicate heart rate recovery in the first minute as a predictor of sudden death and mortality. Thus, the aim of this work is to study the cardiovascular risk by the evaluation of the heart rate and substances responsible for the vascular tone (nitric oxide and catecholamines) in different trained and untrained subjects.
Male volunteers participated in this study: sprint athletes (SA), endurance athletes (EA) and age and sex-matched sedentary controls (SC). All the subjects performed an aerobic maximal graded exercise test in cycle ergometer (Monark 824E), consisting in a constant pedal frequency (60 rpm) starting with 50 W workload and increasing 25W every 2 minutes until fatigue. Before, during and after exercise (for 30 min) heart rate was continuously assessed by using a heart rate monitor (Polar®). Before the exercise test a 10 ml blood sample was collected to analyse plasma nitrates/nitrites (NOx, as measure of nitric oxide) and catecholamines. After exercise, blood was collected again and the referred measures repeated (5 and 30 minutes during recovery). The NOx was measured using a commercial kit (R&D Systems; DE1500). Plasma catecholamine levels were measured by HPLC-ED.
As far as specific VO2max is concerned, there was an increase in both athlete groups but more significantly in EA than SA group, as expected. Heart rate rest values were lower in EA. The maximal heart rate achieved was under the theoretical maximum, except for the control group that reached equal values (calculated and measured). Thus, all subjects used more than 80% of the heart rate reserve, meaning a good chronotropic response and a correct sympathetic nervous system activation. Values under 80% are a predictor of mortality. Nevertheless, the EA maintained a lower heart rate during the test when compared to SC (the highest one). Heart rate recovery after

one minute was above 12 bpm, which means a reduced cardiovascular risk (vagal activity increases properly), since a first minute recovery less than 12 bpm is another risk factor for sudden death and mortality. EA had the highest level for first minute recovery and the lowest heart rate after 30 minutes. Catecholamine levels are in agreement with the degree of sympathetic activation and heart rate values for each group. Concerning vascular relaxation, the EA group showed a higher basal level and a high NOx production after the exercise test when compared to control. Thus, none of the studied subjects present cardiovascular risk. However, the EA group has more exercise benefits that the SA one.

This work was supported by a PAFID programme from the Portuguese Sport Institute and by FCT (Fundação para a Ciência e Tecnologia), Portugal.

ELECTROMYOGRAPHIC ANALYSIS OF AN ABDOMINAL EXERCISE PERFORMED IN TRAINED (BODY-BUILDERS) AND UNTRAINED SUBJECTS

Ribeiro, E., Tavares, P., Ribeiro, G., Rosado, M.F., Fontes Ribeiro, C.A.

Faculty of Sport Science and Physical Education, university of Coimbra, Portugal

Endurance of the abdominal musculature is an essential component of fitness for health and sports performance. A wide variety of different exercises are currently used. However, the effectiveness of neuromuscular training is typically based on anatomical evaluation, empiric measurements or subjective perception. Nowadays, the general public is very interested in abdominal exercises for their body image and in some cases by health reasons, since a good abdominal musculature is essential for trunk support. The important question is to choose the right exercise and how to evaluate its effectiveness. Despite the large number of exercises, literature about its evaluation is lacking. Thus, it was our aim to compare the neuromuscular efficacy of a classic exercise in body builders and in active subjects.

Ten male body builders and ten untrained subjects were recruited and volunteered to participate in the study. The training frequency of the body builders was 5.3 ± 1.5 days/week. Using surface electromyography (SEMG) we measured the Rectus abdominis and Rectus femoris muscles activity in a traditional trunk curl. The feet were placed on the ground with the knees flexed to 140º (start position) and the arms along the body. Subjects elevated the trunk by sliding the hands 12 cm along the body. The feet slide also increased the knees angle. The cadence of the exercise was constant and commanded by a sound repetition. Each subject performed only one exercise until fatigue. During the exercise test the surface electromyographic parameters (RMS-EMG and MPF-mean power frequency) were evaluated in each subject. The EMG recording was made with a MegaWin® ME3000 device. In order to compare individual results the RMS-EMG values were normalized by dividing the obtained values by the maximal contraction of the muscle.

We verified that in the Rectus abdominis the RMS-EMG values were higher and the MPF (Hz) lower than in the Rectus femoris. Nevertheless, the neuromuscular behaviour of these muscles in the both studied groups were different. Thus, concerning the Rectus abdominis there was an increase of the amplitude (RMS-EMG) in the untrained subjects and a decrease (in the last repetitions) in body builders. In the untrained subjects the MPF decrease with the repetitions increase, whereas in body builders the MPF values slight decrease in the first repetitions and then stabilized. In the Rectus femoris muscle the MPF showed no differences between groups and maintained an almost constant value along repetitions. On the contrary, the RMS-EMG values were higher in body builders than in untrained subjects, with a tendency to decrease with repetitions. In the untrained subjects the opposite occurred, since there was a tendency to increase RMS values.

SEASONAL CHANGES IN BODY COMPOSITION OF ELITE SOCCER PLAYERS

Tofas, T., Theodorou, A., Stavrakoudi, A., Nikolaidis, M.G., Jamurtas, A.Z.

University of Thessaly, Greece

Body composition comprises one of the many factors that affect performance in soccer. The effects of post season on body composition are detrimental in a way that players put on weight and increase their percentage body fat. Therefore, one of the many aspects that the coaching team needs to monitor during the training year is body composition. The purpose of this study was to examine the seasonal changes that occur in body composition of elite soccer players. Twenty-two elite professional soccer players playing in the first Division of the Greek League volunteered. Their mean age and height was 26.6 ± 3.7 yrs and 1.76 ± 3.8 m, respectively. Body mass was measured to the nearest 0.2 kg with the players lightly dressed and barefooted. Percentage body fat was calculated according to published guidelines (ACSM Guidelines, 2000), from seven skinfold measures (average of two measurements of each site) using a Harpenden calliper. Measurements were made at the beginning of preseason (beginning of July), mid-preseason (three weeks into training), at the end of preseason (Mid-August), in September, and every two months thereafter (November, January, March, May) until the end of the season. One way ANOVA for repeated measurements was used to assess differences between pre-season and the following measurements. Data are presented as means ± SEM. Body weight decreased ($p<0.01$) at the mid-Preseason and End-PreSeason measurements. Following those two measurements body weight was not significantly different compared to Pre-Season. Percentage body fat decreased ($p<0.001$) at the mid-PreSeason and remained significantly lower compared to Pre-Season. Body composition seems to rapidly change at the beginning of pre-season. Coaches should not look at the body weight of the players only but pay closer attention to percentage body fat also.

THE ANTHROPOMETRIC, PHYSIOLOGICAL AND MOTOR FITNESS FEATURES PROFILES THAT PARTICIPATING KARATE AT NATIONAL TEAM OF IRAN

Hojjat, S., Tarverdizadeh, B. ,Rasooli, S.A., Behpour, N.

Islamic Azad University, Branch of Karaj, Iran

The main purpose of this project is to search about anthropometric, physical and motor fitness features profiles that participating karate at national team of Iran.

Among those who invited to national team in 2005 year ten people participated in the test voluntary. This project way is descriptive.

Project variable include anthropometric , physical and motor fitness (weight, age height, biacromial breadth , trunk length , hand length , arm length , forearm length , palm length , thigh length , calf length , head circumference , chest circumference , abdominal circumference , proximal thigh circumference , calf circumference , arm circumference , forearm circumference, wrist circumference, wrist breadth,

elbow , knee width , ankle width , five part of body fat and the percent of fat , agility , reaction , balance , speed , power, muscular endurance , muscular power , vo2 max , resting heart rate and exercise heart rate).

The project result shows that:

1. Anthropometric features distance is high performance of karate matches in different weights one of the reasons for changes.
2. Motor fitness variable record distance is high; this shows with participants in some variable low (less) and in some other variable level.
3. Most of the participants in physical variable have high level fitness.

EXPLORING PHASE II HEAR RATE KINETICS DURING SUB MAXIMAL RUNNING TEST IN PROFESSIONAL FOOTBALL PLAYERS

Jemni, M., Mitchell, A., Sands, W.A., McNeal, J.R.

Sport Science Department. Anglia Ruskin University, Cambridge. UK, United Kingdom

Purpose: This study examined sub maximal heart rate (HR) kinetics in outfield professional football players. It attempted to calculate the amplitude of the transition from a walking steady state to jogging steady state HRs.

Method: Eight professional football players (25 ± 5.3 yrs; 180 ± 5 cm; 76.5 ± 4.7 kg) from the English Championship volunteered to participate in this study. They performed six trials of a square-wave transition from 5 min walking at 5.5 km/h to 5 min running at 11 km/h on a treadmill. Thirty minutes of rest was initiated between each 10 min trial. Trials were performed at the same time of day and took place through 15 weeks.

Beat by beat HR was monitored using a Polar S810i HR monitor. HR data were calculated in accordance with a similar experimental designed by Fukuoka et al. (2002). The average of the last 30 sec of the 5th minute was calculated to get HR value for the walking steady state. The average HR of the last 30 sec of the third minute of the jogging was also calculated.

HR amplitude was calculated by subtracting the average HR of the walking steady state from the average HR of the jogging steady state. Fifty percent of this amplitude was considered for all comparisons (phase II HR kinetics). The time required to reach 50% of the Heart Rate Reserve (HRR) was also calculated for further analysis and comparisons.

One way analysis of covariance ANCOVA with repeated measures was performed due to the repeated testing.

Results: Average HR increased from 90 + 10 b/min to 137 + 11 b/min during the transition from walking to jogging. Average HR at 50% of the phase II HR kinetics was 114 + 13 b/min. The athletes reached phase II within an average of 40 + 5 b/min which represented 34 ± 7% of the HRR. The time required to reach phase II kinetics was 328 + 6 sec (28 + 6 sec after the transition). The athletes reached the HR steady states after 465 + 15 sec.

Statistical differences between the trials did not reach statistical significance when comparing absolute HR amplitudes or HRR data ($p>0.05$).

Conclusion: These findings suggest that HR kinetics responses to a sub maximal test do not change through 15 weeks of training time in high level outfield football players. This would suggest that aerobic components of fitness, as measured by HR, are not affected by training sessions and competitions through this period. Further investigations to explore HR kinetics responses to a maximal test are required; these would give an insight on the anaerobic components of fitness during such period.

MUSCLE MAXIMAL CO-CONTRACTIONS OF THE ELBOW EXTENSORS AND FLEXORS DURING ISOMETRIC CONTRACTIONS

Driss, T., Serrau, V., Vandewalle, H., Lesne-Chabran, E., Lepellec-Muller, A.

Université Paris X, 200 avenue de la république, 92000 Nanterre, France. , France

Muscle maximal co-contractions of the elbow extensors and flexors during isometric contractions.

T. Driss 1, V. Serrau 1, H. Vandewalle 2, E . Lesne-chabran 1, A. Lepellec-Muller 1

1 E.A. 2931, UFR STAPS, Université Paris X, 200 avenue de la république, 92000 Nanterre, France. E-mail : tarak.driss@u-paris10.fr

2 INSEP de Paris, 11 avenue du Tremblay, 75012 Paris, France.

The purpose of this study was to investigate the magnitude of integrated electromyography (iEMG) during maximal isometric co-contractions of the agonist and antagonist elbow muscles in order to estimate the force levels during this kind of exercise.

Eight male subjects were instructed to perform maximal unilateral co-contraction exercise which consisted in exerting a maximal co-activation of the agonist and antagonist muscles of the right arm (i.e. a maximal rigidity of the right elbow without external resistance). In addition, they performed bilateral isometric exercises: 1) maximal flexion of the right elbow against the resistance of the elbow extensors of the left arm, 2) maximal extension of the right elbow against the resistance of the elbow flexors of the left arm. iEMG were measured with a MA-300 electromyograph during maximal unilateral and bilateral co-contraction exercises and compared with iEMG collected during isometric elbow flexion and isometric elbow extension against a force transducer at 30, 60 and 100% maximal voluntary force (MVF). All the exercises were performed with the same body and elbow positions (90° flexion of the elbow and a 45° external rotation of the shoulder). We estimated the force level during unilateral and bilateral co-contraction from iEMG data collected during these exercises, with the assumption that there was the same iEMG – force relationship for exercises against external resistance and co-contraction exercises.

iEMG during maximal unilateral co-contractions were equivalent to the iEMG value corresponding to force levels around 55% MVF for the elbow flexors and extensors. The maximal levels of iEMG during maximal bilateral co-contractions were slightly (but not significantly) higher than iEMG during maximal unilateral co-contractions.

The results of the present study suggest that maximal isometric co-contraction exercises could be used to maintain muscle strength in rehabilitation programs.

Keywords: Isometric contraction and co-contraction, Surface electromyography, Biceps brachii and Triceps brachii muscles.

TIME SERIES OF ENDOCRINE PARAMETERS INDICATE DESYNCHRONIZATION OF BIOLOGICAL RESPONSE IN HIGH TRAINING LOAD SITUATIONS

Suhr, F., Yue, Z., de Marées, M., Achtzehn, S., Mester, J.

German Sport University Cologne, Germany

Introduction

The biological responses following high trainings loads are not fully understood. In endurance sports the monitoring of an overreaching and the understanding of the mechanisms inducing overreaching are very important to avoid an overload, a decrease in performance and healthy risks. The aim of this study was to determine the responses of two vascular growth factors (VEGF and endostatin) and muscular growth factors (IGF-1 and HGF), respectively, during a long-term high-intensity cycling intervention.

Methods

Two endurance cyclists were trained with high training loads for about eight weeks. The following measurements were carried out: daily data such as heart rate, body temperature/weight, weekly the anaerobic threshold and oxygen uptake, and three and five blood samples in the morning, respectively, were drawn. The subjects performed 14.1 ± 0.5 hr per week on a cycling ergometer. Time series analyses such as LAMP-fitting, cross-correlation, spectrum- and wavelet-analyses were used to get a better understanding about the biological response regarding high training loads.

Results

The two subjects showed a highly individual biological response with regard to VEGF, endostatin, IGF-1 and HGF. After training input for subject I there was a HGF-increase right before a release of IGF-1. The two vascular growth factors showed a similar pattern. In subject II the mentioned parameters did not react that clear. For HGF there seems to be pre-release compared to IGF-1. VEGF and endostatin were expressed consecutively as well, but the effects for all parameters were not that clear compared to subject I. On the other hand in time-series clear synchronized and desychronized between the training load and the response could be identified. The desychronization indicated a time-lagged response in endocrine parameters especially when it came to an accumulation of the previous loads.

Conclusion

HGF has been shown to initiate and stimulate the activation and proliferation of satellite cells in the skeletal muscle tissue for muscle-repair after damage1. Therefore it is reasonable for subjects I that HGF responses previously to IGF-1, what is able to modulate and stabilize the activated satellite cells. VEGF is a potent mitogen for endothelial cells and endostatin possesses the ability to inhibit the VEGF-induced migration and proliferation2. Because of biological activities of the parameters the detected patterns for subject I seem to logic and subject I obviously was able to tolerate the high training input. Subject II was not in a position to abide the high training load during the whole intervention, and therefore subject II did not show that clear patterns.

THE EFFECT OF ACUTE GARLIC INTAKE ON BLOOD PRESSURE AND WATER CONSUMPTION IN YOUNG NORMOTENSIVE HUMANS

Botonis, P., Herouvim, E., Stampouloglou, A., Koskolou, M.D., Nassis, G., Geladas, N.D.

Faculty of Physical Education and Sport Science, University of Athens, Greece

Reduction in blood pressure results in high circulating plasma angiotensin-II, which is a stimulus for thirst (Stocker et al., 2000). Garlic is a compound that may lower blood pressure at least after long term use of it (Steiner et al., 1996). The purpose of this study was to examine the effect of acute garlic intake on blood pressure and water consumption. Thirteen healthy normotensive subjects (6 men and 7 women, age: 23 ± 3 years, height: 171.5 ± 9.8 cm) underwent the same protocol on two separate experimental days within a week, in a counterbalanced order. One day before each experiment, preliminary baseline measurements were taken. In the experimental day, the subjects reported to the laboratory after an overnight fast (~ 12 h) and were administered either an aged garlic extract (Kyolic 600 mg; G) or a placebo (C) pill. After a 60-min rest in supine position, they cycled in sitting position for 30 min at 60% of heart rate reserve and, afterwards, they recovered for 90 min lying supine. They were allowed to drink as much water as they liked from the 10th min of recovery onwards. Body mass (BW), mean, systolic, diastolic blood pressure (MAP, SBP, DBP), cardiac output (Q), haematocrit (Hct), haemoglobin concentration ([Hb]) and the subjective feeling of thirst were evaluated at baseline, following the fasting, as well as at certain time points throughout the experimental day. The level of recorded dehydration at the end of exercise was the same in the two experimental conditions (C: 0.9 % BW vs. G: 1% BW, $p > 0.05$). At the 60th min of recovery, MAP (C: 84 ± 7 vs. G: 75 ± 9 mmHg, $p < 0.05$) and DBP (C: 68 ± 6 vs. P: 59 ± 8 mmHg, $p < 0.05$) were lower in G than in C, respectively. Δ values (certain time point value – initial resting value) were also lower in G than in C for MAP at the 60th min (C: 4 ± 5 vs. G: -7 ± 10 mmHg, $p < 0.05$) as well as the 80th min (C: 5 ± 7 vs. G: -2 ± 10 mmHg, $p < 0.05$) of recovery and for DBP only at the 60th min (C: 4 ± 6 vs. G: -6 ± 9 mmHg, $p < 0.05$) of recovery. There were no significant differences between the two treatments in the total water consumption (C: 539 ± 314 vs. G: 603 ± 364 ml, $p > 0.05$), as well as in SBP, Q, Hct, [Hb], plasma volume and the subjective feeling of thirst, at any time point of measurement. In conclusion, although a reduction of MAP associated with a decrease in DBP was observed after G intake, confirming previous results (Steiner et al., 1996), this had no influence on water consumption and the subjective feeling of thirst in young normotensive humans.

PHASE III V'O2 INCREASE DOES NOT LEAD TO V'O2 VALUES HIGHER THAN V'O2 MAX DURING PROLONGED INTENSE EXERCISES IN HUMANS

Alfieri, P. 1, Schena, F. 2, Ferretti, G. 3, Esposito, F. 1

1 University of Milan, 2 CeBiSM, 3 University of Geneva, Italy

The aim of this study was to test the hypothesis that maximum O2 uptake (V'O2 max) sets the uppermost limit to O2 flow. If this is so, the V'O2 increase with time during high intensity prolonged exercises (slow component) can not reach V'O2 levels higher than V'O2 max. To

this aim, on 15 amateur cyclists (age, 24±4 yrs; mean ± S.E.M.) V'O2 max was measured during graded cycloergometric exercise. On different days, the subjects performed exercises at 80% and 90% of the previously determined V'O2 max up to exhaustion (W80 and W90, respectively). Measured variables included time to exhaustion (Tlim), power output, V'O2, CO2 production (V'CO2), ventilation (V'E) and blood lactate concentration ([La]). V'O2 max was 4.05±0.08 L•min-1. At the end of W80 (Tlim 1649±145 s) and W90 (Tlim 733±65 s) V'O2 was 3.77±0.13 and 4.08±0.12 L•min-1. V'O2 at the end of W90 was similar to V'O2 max, while at the end of W80 was significantly lower. [La] was increased at the end of prolonged exercises not only with respect to rest, but also compared to values at exercise min 5, indicating anaerobic lactic metabolism contribution to energy production. Compensation of lactic acidosis led to significant increases in V'E and V'CO2 at the end of W80 and W90. In conclusion, the present results support the hypothesis that V'O2 max really reflects the individual maximum aerobic power, without being limited by factors intrinsic with the experimental procedures.

ACUTE EFFECTS OF PASSIVE STATIC STRETCHING ON LEG EXTENSOR MUSCLES: DIFFERENCES BETWEEN SQUAT AND COUNTERMOVEMENT JUMP

Merati, G., Silvaggi, N., Limonta, E., Rampichini, S., Alberti, G.

University of Milan and Federazione Italiana di Atletica Leggera (FIDAL), Italy, Italy

The acute effects of stretching on muscular performance are currently ascribed to mechanical and neuro-muscular mechanisms. Aim of this study was to compare the effects of static stretching on leg extensor muscles during squat jumps (SJ) and countermovement jumps (CMJ). Seven healthy male subjects (age [mean (SD)] 29 (7) yrs; height 177 (5) cm; body mass 81.9 (10.4) kg] participated in this study. After a 10 min warm-up, each subject performed 2 consecutive series of 5 SJ and 5 CMJ in 2 separate sessions on different days in randomized order: in the control (C) session the first SJ and CMJ series were followed by 10 min rest, whereas in the stretching (S) session the first SJ and CMJ series were followed by a passive static stretching bout (10 min), applied bilaterally on quadriceps and gastrocnemius muscles (4 stretches/muscle, 30 s stretch/30 sec rest). Each jump series was executed on a force platform (4 Jump, Kistler, USA). During the whole SJ and CMJ series of either session the EMG signal was simultaneously acquired (Muscle-Lab, Bosco System) from 6 leg muscles (vastus medialis and lateralis, gastrocnemius, gluteus maximus, tibialis anterior, biceps femori). The average, the Root Mean Square (RMS) and the time to EMG signal peak were calculated from the rectified EMG signal. Maximal power, force and velocity did not significantly differ between the first and second jump series, both during C and during S session. However, in the eccentric phase of CMJ, both velocity (+ 0.02 m/s during C session, p=ns; + 0.10 m/s during S session, p<0.05) and power (+26 (52) W during C session, p=ns; +83 (63) W during S session, p<0.05) were significantly increased in the S session only. Average and RMS of the EMG signal did not significantly differ between the first and the second SJ and CMJ series, both during C and during S session. Time to the maximal EMG activation for each muscle did not differ in S and C conditions between the first and the second SJ series; however, a significant delay in the activation of vastus lateralis (+28 (27) ms and tibialis anterior +66 (64) ms (p<0,05)) was observed during CMJ execution in S session only. In our experimental protocol stretching did not significantly reduce the force and power output of the investigated muscles. However, since as previously reported the mechanical effect of stretching is likely to be influenced by knee starting angle, our results may have been affected by the choice of 90° knee starting angle of SJ. Concerning EMG, the observed delay of the maximal activation of EMG signals in vastus lateralis and tibialis anterior muscles suggests the occurrence of a neuromuscular inhibition on the stretched muscles, which is apparent for CMJ only. Thus, CMJ more than SJ, especially during the eccentric rather than the concentric phase, may help to better understand the effects of acute stretching on leg muscles performance.

RATE OF PERCEIVED EXERTION AT A GIVEN EXERCISE-INDUCED DECLINE IN STROKE VOLUME IS HIGHER IN SPINAL CORD INJURED THAN IN ABLE-BODIED INDIVIDUALS

Geladas, N.D., Zacharakis, M., Nassis, G., Kounalakis, S.N., Anastasiadis, M.

National and Kapodistrian University of Athens, Greece

Cardiovascular drift, a phenomenon characterized by progressive increase in heart rate and decline in stroke volume during constant load prolonged exercise, has not been extensively investigated in spinal cord injured athletes on those such data exceed in able-bodied individuals (Bhambhani, 2002; Coyle and Gonzalez–Alonzo, 2001). In a previous study in our laboratory we have shown that exercise-induced stroke volume decline is similar in spinal cord injured (SCI) and able-bodied (AB) athletes (Zacharakis et, 2005). The aim of this study was to compare the rate of perceived exertion (RPE) at a given stroke volume decline in SCI and AB athletes. Eight SCI with high-level spinal cord injury (C7-T6; aged: 32.3±8.4 yrs, mean±sd) and 9 AB (aged: 20.6±1.0 yrs) performed 60-min exercise at 50% of maximum oxygen uptake on a wheelchair roller ergometer in a thermo-neutral environment. Throughout exercise, the following parameters were determined: oxygen uptake (VO2) with a metabolic cart, cardiac output (Q) with the exponential CO2 rebreathing method, heart rate with telemetry, oral temperature (Tor) with an electronic thermistor, and RPE with the 6-20 Borg scale. Rate of perceived exertion (RPE10) at a stroke volume decline equal to 10 ml/beat (SV10) was calculated for each individual by curve fitting. RPE10 was compared between groups with a t-test for independent samples after adjusting for potential covariates. Time for SV10 was estimated at 73.5±51.8 min in SCI and 32.4±13.9 min in AB (P< 0.05). RPE10 was higher in SCI than in AB (16.3±3.0 vs. 11.9±1.8, respectively, P< 0.01). This difference persisted after adjusting for percent of maximum heart rate achieved (80.0±4.6 for SCI and 81.0±4.9 % for AB, P> 0.05) and Tor (37.6±1.1 for SCI and 37.2±0.3 oC for AB, P> 0.05) recorded at SV10. These results show that rate of perceived exertion at a given exercise-induced stroke volume decline is higher in spinal cord injured than in able-bodied athletes. This was independent of heart rate and oral temperature responses. It seems therefore, that spinal cord injured athletes experience greater discomfort for the same magnitude of cardiovascular drift than able-bodied athletes.

THE EFFECT OF PROLONGED EXERCISE AND BLOOD SAMPLING ON SERUM ERYTHROPOIETIN CONCENTRATION

Szygula, Z., Pilch, W., Wnorowski, J., Wiecek, M., Zembron-Lacny, A.

University School of Physical Education, Krakow, and University of Physical Education Poznan, Faculty of Physical Culture, Gorzow Wlkp., Poland

Introduction/Purpose: The effect of physical exercise on regulation of EPO synthesis has not been fully elucidated. Some authors have found an increase of erythropoietin concentration [EPO]s after an exercise (Roberts et al. 2000; Schmidt et al. 1991) whereas others were unable to demonstrate any significant changes in [EPO]s (Bodary et al. 1999; Duda et al. 2003). There is also no agreement as to diurnal variation of EPO synthesis (Klausen et al. 1993; Roberts & Smith 1996). Therefore the aim of the study was to compare changes in [EPO]s and PV induced by prolonged exercise and by controlled blood sampling.

Methods

Seven healthy men (20-24 yr) exercised at 55% VO2max till exhaustion on the cycloergometer. Venous blood samples were taken before, immediately, 3 h, 9 h after exercise, on the 2nd and on the 3rd day of the experiment. On the other occasion at the same time schedule venous blood samples were taken at resting conditions. Hemoglobin and hematocrit were determined and relative changes of PV were calculated. [EPO]s was determined by a commercially available radioimmunoassay and corrected for changes in PV. The Fridman's ANOVA with repeated measures was applied to analyze the overall changes. Post-hoc comparison was conducted with Tukey's test. A value of $P < 0.05$ was accepted as significant.

Results

PV decreased by 8.8% ($P < 0.05$) just after exercise whereas a significant increase of PV was observed 3 h later (+3%) and 9 h after exercise (+7.8%). The most pronounced increase of PV was noted the next day (+9%). PV remained elevated 48 h later (+5.6%). [EPO]s increased from 8.0 ± 4.5) mU/l to 8.8±3.5 mU/l 3 h after exercise but the elevation was not statistically significant. A significantly elevated [EPO]s was observed 9 h after exercise (13.7±4.2 mU/l; 71%) as well as the next morning (13.1±5.2 mU/l; 64%) and 48 h later (12.2±4.8 mU/l; 52.5%). In the controlled samples of blood statistically significant increase of [EPO]s was observed in the evening (+38%).

Discussion/Conclusions

The most pronounced elevation of PV observed the next day after prolonged exercise could be the effect of fluid conservation by the kidneys. The elevation of [EPO]s 9 hrs after exercise could be partly result of enhanced EPO synthesis due to the increased oxygen consumption in the kidneys as an effect of intensified sodium reabsorption in renal tubules. Diurnal variations of EPO biosynthesis have to be also taken into consideration. However, an elevation of [EPO]s the next days may be the result of hemodilution due to expansion of PV.

CARDIOVASCULAR EFFECTS OF 9 DAYS OF DRY-HEAT ACCLIMATIZATION IN TRAINED MEN

Estevez, E., Del Coso, J., Mora-Rodriguez, R.

Universidad de Castilla-La Mancha, Spain

INTRODUCTION

Dry-heat acclimatization is characterized by a lower heart rate and core temperature during exercise in the heat. Nielsen et al (1991) has also described an expansion of plasma volume and increases in cardiac output directed to non-exercising tissues (i.e., skin blood flow). However, in that classical acclimatization study the subjects were stressed to exhaustion in each session. Our purpose is to investigate if the acclimatization responses are present when exposure time is kept constant and thus strain gradually declines due to the acclimatization process.

METHODS

During 9 consecutive days, seven endurance trained cyclists (VO2max of 61±8 mL·kg-1·min-1) pedalled for 90 min at 63% VO2 max in a hot-dry environment (35ºC; 29% rh; 2.5 m·s-1 wind speed). Plasma volume changes were measured from hematocrit and hemoglobin concentrations (Dill and Costill, 1974). Heart rate (HR), rectal temperature (Tre), arterial blood pressure and forearm skin blood flow were monitored. Cardiac output (Q) was measured at 15 and 90 min of exercise by using a computerized version of the CO2-rebreathing technique of Collier. All the measures were taken on days 1, 3, 6 and 9 of exercise. Two-way ANOVA was used to detect differences among days.

RESULTS

After 90 min of exercise HR was lower in day 9 than in day 1 (142±5 lat·min-1 vs 156±5 lat·min-1; $P<0.05$). Final Tre also decreased in day 9 in comparison to day 1 (39.3±0.2 ºC vs 38.9±0.1 ºC; $P < 0.05$). However, whole body sweat rate (measured by changes in mass loss) was unchanged with acclimatization (~1.2±0.05 L·h-1). In addition, there were no reductions in basal hemoglobin concentrations that remained at 14.3±0.2 g·dL-1. The initial reductions in BV after 15 min of exercise in day 1 were lessened after 6 days of acclimatization (-4.90±-0.6%; -2.49±0.55%; -1.25±1.11% in days 1, 6 and 9 respectively). This allowed a better maintenance of Q and a tendency to increase the skin blood flow ($P<0.05$).

DISCUSSION

In comparison to the traditional results from Nielsen´s group we observed that our well-trained subjects need 9 days of acclimatization to reduce final rectal temperatures. However, heart rate (index of cardiovascular stress) is lower after only 3 days of acclimatization. The improved heat dissipation in day 9 is not accompanied by increased sweat rate. Acclimatization did not expand plasma volume (similar basal haemoglobin) but reduced the exercise induced hemoconcentration (measured at min 15 of exercise). This allowed a better maintenance of Q which may have permitted the increases in skin blood flow (NS). Likely more strenuous exercise (to exhaustion) or exposure time (more than 9 days) are required to increase plasma volume and sweat rate in well-trained unacclimated subjects.

CHILDREN HAVE A HIGHER HYPOXIC VENTILATORY RESPONSE THAN THEIR FATHERS

Kriemler, S., Zehnder, M., Kohler, M., Bloch, K.E., Brunner, H.P., Boutellier, U.

ETH-University of Zurich, Switzerland

Introduction: Chemoreceptor sensitivity plays an important role in the short-term adaptation to high altitude (HA). Decreased ventilatory response to hypoxia (HVR) is a risk factor for the development of high altitude pulmonary edema and possibly of acute mountain sickness (AMS). It is not clear, however, whether HVR is different in prepubertal children and adults nor whether there is a hereditary influence. Isocapnic HVR was therefore measured in 20 fathers (mean age 44.0±4.2y) and their prepubertal children (mean age 10.7±1.1y) at low altitude (LA, 450m) and on day 1 and 2 of HA (3450m) using the partial rebreathing technique. After 15 min of resting ventilation, three levels of hypoxia (PETO2 60, 55, 50 Torr) were randomly induced and kept stable (±2 Torr) for 2 min with 5 min of recovery in between. PCO2 was kept constant at ±2 Torr of values while breathing room air. HVR is expressed as increase in minute ventilation per decrease in saturation corrected for body weight. AMS was measured by Lake Louise Questionnaire. Clustering of HVR within families was tested by correlation analysis of slope differences (deltaHVR) from LA to HA. Results: AMS occurred in 8 children and 7 adults. HVR (corrected for body weight) was significantly higher in children than in adults irrespective of altitude (0.020±0.010, 0.020±0.011, 0.024±0.012 vs. 0.012±0.007, 0.014±0.011, 0.018±0.012 ml*kg-1*min-1*%-1 at 450m, day 1 and 2 of 3450m, respectively, all $p<0.0005$). Only adults significantly increased their HVR on day 2 of HA ($p<0.05$). There was a significant correlation of deltaHVR from LA to day 2 of HA within families ($r=0.59$, $p<0.01$). Individuals with AMS did not show a lower HVR than those without AMS. Conclusion: Children generally have a higher HVR than their fathers which does not protect them from AMS. HVR seems to be genetically influenced.

EFFECTS OF PHYSICAL ACTIVITY ON DIABESITY IN MICE

Rinnankoski, R., Silvennoinen, M., Kivelä, R., Lehti, M., Vihko, V., Kainulainen, H.

LIKES research center for sport and health sciences and Neuromuscular research center, Finland

In the modern world the prevalence of type 2 diabetes is ever increasing, above all because of sedentary lifestyle, overly rich nutrition and obesity. This metabolic disorder results from insulin resistance accompanied by pancreatic islet dysfunction. Exercise training and regular physical activity have been shown to increase fat metabolism, thus potentially reducing the symptoms of this metabolic disease. However, there is a need for more knowledge of the molecular mechanisms underlying the basic defects inducing type 2 diabetes.

The ultimate goal of this pilot study was to collect valuable information for the actual experiment planned to conduct shortly after. The aim of this study was to generate a conveniently designed mouse model, which combines overfeeding and voluntary exercise. With this model the mechanisms and pathways affecting the emergence of glucose intolerance in type 2 diabetes would be investigated.

Male C57BL/6J mice were fed with either normal low fat diet or high fat diet, containing 60 % fat. In order to obtain the weight gain, food consumption and energy intake, the animals and food were weighed once a fortnight. Mice were kept in individual cages and after 17 weeks on the diets, half of the animals had access to voluntary wheel exercise. Customized computer program collected the running data. During the experiment intraperitoneal glucose tolerance tests were also made and fasting plasma glucose and insulin levels were measured. After 34 weeks on the diet, the mice were killed and their lower limb muscles, heart and epididymal adipose tissue were removed, the wet mass weighed and stored for further purpose.

Normal diet and high fat diet mice, both without exercise were compared. High fat fed mice showed significant increases in energy intake, body weight and insulin levels, whereas significant decreases were seen in muscle weight and glucose tolerance in contrast to low fat fed mice. When exercised and sedentary mice on normal diet were compared, there were no significant changes. This indicates that the exercise itself has no remarkable ameliorating effects on body composition in lean mice. In contrast, when high fat diet mice were compared together, exercised mice showed significant decrease in their body weight gain.

As the energy intake and body weight increases in high fat fed mice, the physical activity seems to decrease accordingly. Once the mice have gained weight substantially, the physical activity seems to have only delaying effects on body composition. Based on these results, the voluntary wheel exercise should be started at an earlier stage in the consequent actual experiment in order to find more beneficial effects of exercise on obesity and type 2 diabetes.

EFFECT OF INTERMITTENT HIGH-INTENSITY EXERCISE COMPARED TO MODERATE CONTINUOUS EXERCISE ON GLUCOSE PRODUCTION AND UTILISATION IN INDIVIDUALS WITH TYPE 1 DIABETES

Guelfi, K., Ratnam, N., Smythe, G., Jones, T., Fournier, P.A.

University of Western Australia, Australia

Recently, the glucoregulatory response to intermittent high-intensity exercise (IHE) has been compared to continuous moderate-intensity exercise (MOD) in individuals with type 1 diabetes (Guelfi et al., 2005). The results of this study demonstrated that the decline in blood glucose was less with IHE both during exercise and throughout the first hour of recovery. To determine whether this lesser decline in glycaemia was the result of a greater increment in hepatic glucose production or attenuated glucose utilisation, the present study compared the effect of IHE and MOD on the rate of glucose production (Ra) and utilisation (Rd) during and after exercise in individuals with type 1 diabetes. Nine healthy individuals with type 1 diabetes were tested on two separate occasions during which either a 30-minute MOD or IHE protocol was performed under conditions of a euglycaemic clamp in combination with the infusion of [6,6-2H]glucose and indirect calorimetry. MOD consisted of continuous exercise at 40% VO2peak, while IHE involved a combination of continuous exercise at 40% VO2peak interspersed with 4-second sprints repeated every 2 minutes to simulate the activity patterns of common field sports. The participants were monitored for up to 2 hours of recovery. The exercise-induced rise in glucose Ra commenced sooner with IHE, and was of a greater magnitude compared to MOD. Similarly, glucose Rd rose sooner during IHE, but the increase by the end of exercise was to a similar extent as that elicited by MOD. During early recovery from exercise, Rd rapidly declined following IHE, while remaining elevated after MOD. During the second hour of recovery, Ra and Rd returned to baseline following MOD, but remained elevated after IHE. These changes in Ra and Rd were consistent with a lower glucose infusion rate (GIR) during early recovery from IHE and a higher GIR after 2 hours of recovery compared to MOD ($p < 0.05$). In conclusion, the repeated bouts of high-intensity exercise associated with IHE stimulate a more rapid and greater increment in Ra during exercise and attenuate glucose Rd during early recovery. These findings assist in ex-

plaining, in part, the previous observation that the risk of hypoglycaemia might be lower during and for the first hour after IHE and compared to MOD.

Guelfi et al., 2005. Diabetes 28(6):1289-1294.

INFLUENCE OF CLIMBING STYLE ON PHYSIOLOGICAL RESPONSES DURING INDOOR ROCK CLIMBING ON ROUTES WITH THE SAME DIFFICULTY

de Geus, B., Villanueva O'Driscoll, S., Meeusen, R.

Vrije Universiteit Brussel, Belgium

Introduction: Rock climbing is a sport with a rapid growth in popularity both as a recreational and as an international competitive sport. Previous studies [1,2] investigated the effect of an increasing difficulty on physiological responses. Heart rate and oxygen consumption were significantly higher during harder climbing, compared to easier climbing [1]. While the heart rate increases with climbing angle (increasing difficulty), VO2 does not significantly vary, and causes a disproportional rise in heart rate compared with oxygen consumption [2].

Objectives: 1) to continuously assess oxygen uptake and heart rate and 2) to quantify the extent to which maximal cardiorespiratory capacity, obtained during a graded exercise test on a treadmill, is utilised during difficult rock climbing on four routes with the same difficulty but different in steepness and/or displacement.

Design: Fifteen expert climbers underwent a graded maximal exercise test (GMT) on a treadmill in order to asses their maximal heart rate (HRmax), oxygen uptake capacity (VO2max), respiratory exchange ration (RERmax), lactate concentration (Lct) and ratings of perceived exertion (RPE). At least one week after GMT four routes were climbed, carried out on two separate occasions on an artificial wall in a climbing gym. The four testing routes were equal in difficulty rating (7c, French grading system) but different in steepness and/or displacement. The first route (OR) had a vertical displacement on an overhanging wall. Route VR had a vertical displacement on a vertical wall. Route OT was an almost horizontal overhanging roof with horizontal displacement (roof). Route VT had a vertical displacement on a vertical wall (traverse). VO2 and HR were continuously measured during climbing. Absolute and relative energy expenditure (EE) and RER were calculated. Lct and RPE were taken before and directly after the climbing. Data were expressed as peak values (HRpeak, VO2peak and RERpeak) and as averages over the entire climb (HRavg, VO2avg and RERavg).

Results: During climbing, higher HRpeak and HRavg were found in routes with a vertical upward displacement (OR and VR) in comparison to traversing routes with a horizontal displacement (OT and VT). VO2avg, VO2/kgavg, EE/d, EE/kg/d and lactate concentration were significantly lower in the traversing route (VT) in comparison with the three other routes. No significant differences for VO2peak and VO2/kgpeak were found between the four routes. Climbing seems to cause a disproportionate rise in heart rate compared with VO2. The traverse is done at a lower percent of the running maximum.

Conclusions: Comparing four routes with the same difficulty but different in steepness and/or displacement shows that: 1) routes with an upward displacement causes the highest peak and mean heart rate; 2) the route with a vertical displacement on overhanging wall is physiologically the most demanding; 3) the traverse is physiologically the less demanding.

HIGH ABILITY AND TALENT IDENTIFICATION IN SWIMMING, WRESTLING, AND GYMNASTICS

Révész, L., Trzaskoma-Bicsérdy, G., Bognár, J., Géczi, G.

Semmelweis University Faculty of Physical Education and Sport Sciences (TF), Hungary

Introduction

Elite sport demand sportsmen with different anthropological, psychological, mental, social skills, and coordination-conditioning ability complexes. For sport experts examining high ability and talent issues, it can be important to unambiguously assess the contribution of genes and training to individual differences in performance. Sport scientists have been divided over the respective importance of biological and environmental contribution to expertise. The nature and nurture question has been long discussed, theories have been developed but coaches and managers have yet to wait for sport specific practices with their talent developmental work.

Hungarian swimmers, wrestlers, and gymnasts are among the best elite athletes in the world. We have long been proud of their ongoing successes and Olympic, World and European championship medals. Still, there are no identified or documented talent identification and management models for their practices.

Hence, the aim of our study was to examine the specificity of high ability and talent identification in swimming, wrestling, and gymnastics.

Methods

This qualitative study was based on the experiences and viewpoints of well-known coaches (N=12) and one Olympic medalist from the sports swimming, wrestling, and gymnastics. All the coaches have successes as sport specialists at the international level, and most of them participated in the Olympic Games as national coaches or team leaders. Among their competitors there are a lot of Olympic, World- and European Championship medalists. Structured interviews with each participant lasted for an hour, they were taped and transcribed. The answers were analyzed and then were grouped into themes.

Results

Swimmers highly emphasized inherited abilities, such as anthropometrical parameters, flexibility, endurance, coordination, love for sport, monotony bearing, parental support, and sport specific appearance. Wrestling coaches do not consider success as talent in childhood years, but more like a skillful competitor. Besides through systematic training programs, talent unfolds due to genetically determined physical ability complexes and specific psychological factors. In wrestling talent can be easily lost due to social factors, such as financial or family problems, or studies. Gymnasts emphasized flexibility, balance, rhythm, love for sport, overcoming long-time psychological and physical load, parental support, overcoming fear, and aesthetic skills.

Conclusions

Competitive sport is highly specialized. Physical and physiological abilities are very important conditions of sport results in these sports, but they are other factors as well determining high expertise. Preparation in swimming, wresting, and gymnastics tends to be a long and demanding process in which physical abilities, psychological, mental and social factors, and also the time spent with training seem to have of high importance. Based upon this study we cannot support Ericsson's deliberate practice theory.

PREDICTION OF RESTING HEART RATE VARIABILITY FROM TRAINING LOAD TIME SERIES

Di Michele, R., Merni, F.

Faculty of Exercise and Sports Science, Italy

INTRODUCTION

HRV monitoring, economic and non-invasive, allows the detection of possible symptoms of autonomic imbalance and has been suggested as potential tool to prevent overtraining in competitive sport [2]. Previous studies showed that resting heart rate variability (HRV) measures, indices of autonomic function, are influenced by exercise, both after a single bout [1] and training cycles [2]. To date however specific short- and long-term effects of training on HRV parameters are not completely clear. Our aim is to check the predictability of daily HRV measures time series on the basis of training volume and intensity series.

METHODS

HRV was recorded in a middle-distance runner (VO2max = 65 ml*Kg-1*min-1; Age:23,2; height: 175 cm; bm:64,5 Kg), at the awakening, for 90 consecutive days, with a telemeter (Polar S810; Polar Electro Oy, Finland), for 5 min in supine and 5 min in upright position. Data were processed through the HRV Analysis Software 1.1 for windows (developed by The Biomedical Signal Analysis Group, Department of Applied Physics, University of Kuopio, Finland, and free available at the website http://venda.uku.fi/research/biosignal). All the commonly used time and frequency domain HRV measures [3] were computed. The athlete trained once a day, in the evening. Volume (min) and intensity (speed %AT) were recorded. For each of HRV indexes a forecasting model was computed treating training volume and intensity separately as independent variables (predictors). Stationary R-squared (R2) was considered to determine the goodness of the model. The bivariate time series analysis was performed through the software SPSS® 14.0 (SPSS Inc, USA)

RESULTS

Considering training volume as the predictor variable, the upright HR is the better predictable measure (R2=0,505), while for other parameters models are not good (R2<0,3). 4 HRV variables are better foreseeable from the training intensity time series: supine HR (R2=0,581), triangular index in the supine position (R2=0,535), the minimum RR interval after standing up (R2=0,518), and upright HR (R2=0,552).

CONCLUSIONS

Bivariate time series analysis shows that some HRV measures are more influenced by training than others, and may be forecasted with a sufficient accuracy from training load series data. Training intensity seems a better HRV predictor than volume and it should be considered for the predictions by coaches using HRV as a tool for the detection and prevention of overtraining.

HEART RATE RESPONSE TO STEADY STATE RUNNING REFLECTS AEROBIC FITNESS AND RUNNING ECONOMY

Niva, A. 1, Nissilä, J. 1, Pullinen, T. 2, Juuti, R. 2, Kinnunen, H. 1

1 Polar Electro Oy, Kempele, 2 Department of Biology of Physical Activity, University of Jyväskylä, Jyväskylä, Finland

Purpose: Novel technology provides tools to monitor heart rate (HR) and running speed freely in outdoors as well as on treadmill. This study was conducted to test if a minute by minute HR response to submaximal running speed can be used to estimate runner's maximal workload (Wmax), VO2max and running economy. Our goal was to develop a reliable running performance index which could be measured at all running speeds.

Methods: A group of 4 male (mean ± SD, 25 ± 4 y, 180 ± 4 cm, 73 ± 8 kg, 48 ± 2 ml/kg/min) and 9 female subjects (25 ± 3 y, 166 ± 7 cm, 62 ± 9 kg, 39 ± 6 ml/kg/min) took part in a training intervention. The training lasted 12 weeks, starting with 2 to 3 and ending with 4 to 5 weekly running sessions. Intensity was controlled with personal HR monitors, and training sessions were targeted to light (45-60%), moderate (60-70%) and hard (70-87.5%HRR) intensity areas.

VO2max, Wmax and running ECO were measured at weeks 0, 6 and 12. A graded maximal treadmill protocol was used to measure VO2max and Wmax. Two separate constant workload treadmill running sessions, 30 minutes at 60% of initial Wmax and 25 minutes at 75% of initial Wmax, were organized to evaluate running economy. Economy was determined from the difference between theoretical and measured VO2 during final five minutes of the tests. HR response was measured with Polar HR monitors. The three performance tests were always conducted in the same order and separated by at least 48 hours from each other.

A running performance parameter, Running Index (RI), was calculated from minute by minute %HRR and treadmill speed measured during the constant workload tests. The calculation was based on the estimated linear relation between theoretical %VO2 reserve and %HRR. HR drift was compensated so that each minute by minute HR contributed equally in the calculation and corresponded to HR at 12 minutes of running. RI was presented in the same numeric scale as theoretic VO2max.

Results: The subjects trained a weekly average of 158 min (93% of target). Intensity varied between 40 and 90 %HRR and median was at 60-70 %HRR). RI evaluated both at 60 %Wmax (39 ± 6, 41 ± 6, 42 ± 7) and 75 %Wmax (41 ± 7, 41 ± 5, 42 ± 6) showed similar results with VO2max (42 ± 6, 44 ± 7, 43 ± 7 ml/kg/min) at weeks 0, 6 and 12, respectively. RI correlated strongly with Wmax (r = 0.87, 0.68, 0.74 at 60% and 0.84, 0.87, 0.87 at 75% Wmax) and VO2max (r = 0.85, 0.66, 0.67 at 60% and 0.85, 0.86, 0.83 at 75% Wmax). Importantly, the deviation between RI and measured VO2max correlated positively with running economy, and the correlation was the strongest at moderate aerobic speed after 12 weeks of training (r = 0.76 at 60 %Wmax).

Conclusion: The novel performance parameter, Running Index is a reliable indicator of running performance. Along with maximal performance, RI gives information on running economy. Running economy seems to be a strong determinant of HR response at submaximal workloads, especially after running training.

EFFECT OF WEARING AMERICAN FOOTBALL HELMETS ON NECK FUNCTION IN EXTENSION AND FLEXION

Hume, P.J., McCarthy, P.W., Lark, S.D., Heusch, A.I.

University of Glamorgan, United Kingdom

Introduction: Players in contact sports such as American football and Rugby have a higher risk of suffering cervical spine trauma. However, there have been few investigations into the effect of American football equipment upon the cervical spine and no studies using British Collegiate American football players (BCAFs).

Methodology: BCAFs (n=15) volunteered and were matched to non-American football playing university students (controls; n=11). The tests took place in the afternoon and followed a standardized protocol. A cervical range of motion (CROM) device (Youdas et al., 1991) had been modified by adding lasers which could be aimed at targets mounted on the wall to assess repositioning accuracy. An American football helmet was similarly modified. Both were used to measure the subject's CROM and their repositioning error returning to a set point from full flexion or extension. ANOVA, Paired and unpaired comparisons were performed on the data using SPSS software for PC.

Results: BCAFs had significantly better repositioning in flexion ($p<0.005$) compared with controls. The helmet was found to significantly reduce the CROM in extension ($p<0.05$) in both groups.

Discussion: The results show that there is no significant difference between players and non-players in all forms of repositioning when they are not wearing the helmet and when returning to neutral from an extended position wearing the helmet. However, BCAFs appear to have an increased accuracy when returning from flexed posture to neutral when wearing the helmet. The relative specificity of this change (i.e. no change in accuracy from an extended posture) might relate to the reduction of CROM into extension imposed by wearing the helmet (seen in both groups).The improvement in accuracy in the BCAFs suggests that the players have adapted to some as yet unknown additional sensory information that they receive whilst wearing the helmet, which the untrained (controls) were not aware of.

Conclusions: British Collegiate American football players who have had at least 3 years experience have a greater accuracy in repositioning their head (a potential indicator of enhanced proprioception) from a flexed posture which is only apparent when they are wearing an American football helmet. American football helmets appear to significantly reduce the CROM in extension in all parties.

ANALYSIS OF COGNITIVE ACTION VELOCITY OF FEMALE HANDBALL GOALKEEPERS AS A BASIS FOR EFFECTIVE TRAINING IMPROVEMENT

Speicher, U., Kleinöder, H., Klein, G., Mester, J.

Institute for Training Science and Sport Informatics, Germany

Introduction: The position of the goalkeeper (GK) is of decisive importance for the success of the team. Nevertheless, there are only few leads for a detailed training improvement. In many cases training units are planned simply intuitively. Therefore it is the intention of the investigation to provide a scientific analysis of actual demands on handball GKs. Cognitive action velocity poses a general demand in handball specific situations such as the start and defence of the counterthrust by the GK. These have been verified as the decisive requirements according to recent match analysis. On this basis appropriate suggestions for training practice shall be provided.

Methods: Cognitive action velocity was tested with 28 female GKs from 1st to 5th league. For this purpose a videographic and a structure dimensional test have been combined. The videographic analysis was used to elucidate the decision process of the GKs. Both the individual solution of handball specific situations itself and the required time budget for decision making were measured. For this purpose a computer program was developed. The video sequences were filmed from the GK´s perspective during different game situations of the counterthrust. The analysis of mental representation clarifies the fundamental perception for each decision. This was realized by adapting the Structure Dimensional Analysis-Motorics (SDA-M; Schack, 2004) to GK specific demands. Thus GKs judged the context of perception by using terms which represented the game situation in question.

Results: All divisions showed significant differences in the situation start of counterthrust with respect to hits and decision time (ONEWAY ANOVA). Moreover, the different levels could clearly be identified by regression, too. The functionality of perceived situation decreases from higher to lower levels. The SDA-M by means of Lambda matrix also confirms the division in different leagues. In the situation defense of counterthrust the best division specific mental structures can be defined. The video analysis allows comparisons with top level and clarifies the drop in performance for each level.

Conclusion: Both tests helped to analyse the gap between the real situation and the perceived impression of the GK. This allows a better training improvement because the training considers the specific aspects of the situation and a better time management as parameters of cognitive action velocity. Typical hierarchy of division can be identified which allows a formulation of specific (start of counterthrust) and general (defense of counterthrust) training aims. This means that the training will become more effective even without the practical experience of goalkeeping. The adequate parameter for training improvement will be provided so that the appropriate exercises for each individual can easily be chosen from existing literature.

RELIABILITY AND SENSITIVITY OF SPRINT PERFORMANCE THROUGHOUT 3H CYCLING

Currell, K., Kirk, T., Jentjens, R., Jeukendrup, A.E.

University of Birmingham, United Kingdom

When measuring performance or fatigue the protocol used must be reliable, valid and sensitive enough to detect small changes that are relevant to athletes. The aim of this study was to investigate the reliability and sensitivity of power output during a 25s sprint throughout 3h of cycling as a measure of fatigue.

Thirteen male subjects were recruited (Age 27 ± 2 years, VO2max 64.3 ± 0.9 ml.kg-1.min-1, Wmax 367 ± 9 W). The subjects underwent four trials to determine the reliability and sensitivity of the protocol. Three of these trials were placebo trials with the final two trials being randomised and counterbalanced with a carbohydrate beverage (6.67% Maltodextrin solution). Subjects reported to the laboratory between 7 – 9am in a fasted state. The protocol involved cycling at 55% Wmax for 3 h. Every 20 min the subjects performed an all out 25s sprint. Following the sprint the power output dropped to 45% Wmax for 95s to allow the subjects to recover. Subjects were given 60, 30, and 10s warnings that the sprint was about to occur, followed by start and stop. In the five minutes prior to the sprint expired air was collected as well as blood, heart rate and RPE. A 600ml bolus of a placebo drink was given prior to the onset of exercise with a 230ml

bolus given 8min prior to each sprint. Each sprint was analysed for mean and peak power. Measurements of mean power and fatigue index (peak-lowest/peak %) of the mean powers of the nine sprints were also calculated. The placebo trials were analysed for reliability of mean power output over the nine sprints and fatigue index using a coefficient of variation (CV), with 95% confidence intervals. The CV of the mean and peak power of each sprint was also calculated.
There was no significant difference in mean power, peak power and fatigue index between these trials ($P > 0.05$). There was no significant correlation ($P > 0.05$) between the measurement error and any of the power variables. The mean power over the nine sprints had a CV of 9.4% (95% CI 6.9 – 17.3%), peak power had a mean CV of 15.4 % (95% CI 11.3 – 31.0%), and fatigue index 53% (95% CI 45 – 144). There was no significant effect of carbohydrate on mean or peak power and fatigue index ($P > 0.05$). It appears that sprint performance during prolonged exercise is not dependent on exogenous CHO delivery.
Therefore the test did not prove sensitive to carbohydrate feeding, probably because carbohydrate feeding does not fuel the very high intensity sprints. The protocol appears to have a lower variation than other measures of fatigue such as a time to exhaustion protocol (CV ~ 25%) and can therefore be used to describe the fatigue pattern over time.

THE EFFECTS OF PRELOADING USING HEAVY RESISTANCE EXERCISE ON ACUTE POWER OUTPUT DURING LOWER-BODY COMPLEX TRAINING

Schneiker, K.T., Billaut, F., Bishop, D.

The University of Western Australia, Australia

Complex training involves the use of alternating sets of biomechanically similar heavy resistance exercises and explosive exercises. It has been demonstrated that a set of heavy resistance exercise can result in greater acute power output during subsequent low-load power movements (Young et al., 1998). The phenomenon by which the explosive capability of muscle is enhanced after it has been subjected to maximal or near-maximal contractions is referred to as post-activation potentiation (PAP). Complex training has been advocated based on the assertion that acute increases in power output, as a result of PAP, may result in greater chronic adaptations in power development. Based on this premise, complex training may be superior to more traditional methods of training only if the specific training protocol used results in PAP. The purpose of this study was to determine whether preloading using half squats results in PAP and an increase in acute power output during subsequent sets of high-load squat jumps. To do this, nine male team-sport athletes were recruited from a state-level Australian Rules Football club. Participants had prior experience with performance of the half-squat exercise and were familiarized with performance of loaded squat jumps prior to testing. To determine baseline values, participants performed two sets of loaded squat jumps involving six repetitions with the bar loaded to 30% of 1RM. The PAP testing protocol was designed to simulate a complex training session and involved performance of alternating sets of six repetitions of heavy half squats (6RM), and six repetitions of loaded squat jumps (30% 1RM). During all testing sessions, participants performed a standardized warm-up, cadence for squat jumps was kept constant and rest period length between sets was four minutes. Results were recorded as peak power output and mean power output for each set of jumps. Data revealed a trend for increased peak power and mean power for the first set of jumps (3.2% and 2.6%) and the second set of jumps (1.7% and 1.9%). While these results are similar to the 2.8% increase in explosive jump height reported by Young et al., increases in power output failed to achieve statistical significance ($P > 0.05$). While these results may be partially attributed to the large variability in individual responses, it is also possible that PAP improves subsequent low-load, but not high-load, power. In conclusion, it was found that preloading using half squats had no significant effect on peak power or mean power output during subsequent sets of loaded squat jumps. Based on these results, performing alternating sets of 6RM half squats and high-load squat jumps with four minutes of rest between sets may not be an effective protocol for use during complex training.
Young, W. B., et al.. JSCR. 12:82-84, 1998.

WHOLE-BODY VIBRATION-INDUCED IMPROVEMENTS IN STATIC BALANCE CONTROL AND KNEE EXTENSORS AND FLEXORS ISOKINETIC STRENGTH OF MIDDLE-AGED WOMEN

Spilipoulou, S.I., Amiridis, I.G., Oikonomidis, D.

Laboratory of Neuromuscular Control and Therapeutic Exercise, Geriatric Unit, Pathology Clinic, Ippokrateio Hospital, Greece

Spiliopoulou I Stiliani1, Amiridis G Ioannis1, and Oikonomidis Demetrios2

Numerous findings provide evidence in support that mechanical vibration could positively influence many risk factors of falling and enhance muscle strength of the lower extremities (Runge et al. 2000). To add further conclusive evidence on the efficacy of whole-body vibration thirty (58.5+5.3years, 156+6cm, 69+6.2kg) middle-aged women, all free from any neurological, musculoskeletal disease or impairment, voluntarily participated in the study and classified into one of two groups, either the Training Group (TG, n=15) or Control Group (CG, n=15). The TG performed 36 training sessions (40min/session, 3s/week) divided into 3 phases, warm-up, principal phase (30min, mainly isometric exercises such as, standing in a half-squat position with or without handstand to the support) and recovery. An interval protocol was applied alternating muscular contraction and rest time (1:3 to 1:1) progressively increasing training volume and intensity (from 15Hz, 2mm, 10sec to 30Hz, 8mm, 45sec). During training, participants were encouraged to strongly contract their muscles especially knee extensors and flexors, taking into account their level and session number. Three postural tasks (5 sec) of increasing difficulty were performed: a. Normal Quiet Stance, Sharpened or tandem Romberg Stance and One-Legged Stance. Peak-to-peak amplitude (CοPmax) and standard deviation (CoPsd) of Center of Pressure (CoP) oscillations along the Anterior/Posterior (A/P) and Medio/Lateral (M/L) axis were calculated from ground reaction forces (Kistler 9281C, 1000Hz). All tests were performed with Eyes Open (EO) and Eyes Closed (EC). To evaluate isokinetically the knee extensors and flexors moment, participants performed 3 maximal concentric actions in 5 angular velocities (600, 1200, 1800, 2400 and 3000.s-1) as well as 3 maximal eccentric actions in 2 angular velocities (600, 1200.s-1), randomly presented in an isokinetic dynamometer (Cybex Norm, NY). Statistical analysis revealed that after training, TG had significantly lower ($p<0.001$) and less variable ($p<0.001$) CοP excursions than the CG in both A/P and M/L direction. Increased postural requirements induced greater ($p<0.01$) CoPmax and CoPsd values for both groups. Post hoc analysis of a significant STANCExGROUPxVISION interaction ($p<0.01$) revealed that TG demonstrated a greater restriction of CoPmax and CoPsd under EC than under EO conditions, across all balance tasks. Constant Angular Moments developed during concentric (60, 120, 1800.s-1) and eccentric (1200.s-1) actions by knee extensors and eccentric (60, 1200.s-1) actions by knee flexors were significantly ($p<0.05$) increased after training, for the TG. In conclusion, this study revealed that the vibration intervention had direct influence on static balance control especially with eyes closed and knee extensors isokinetic strength of middle-aged women.

HEART RATE AND LACTATE PROFILE IN BEACH SOCCER

Lederhilger, B., Trauner, T., Schwameder, H.

University of Salzburg, Austria

Beach soccer is a young and growing sport with 20 national teams currently in Europe. It is played barefoot on a sand-pitch (38x28m) with 4 players and a goalkeeper in each team. The specific format (three periods of 12 min each, free substitutions, free kicks without barrier, 'always a winner' and high goal average) make the sport dynamic and attractive for the spectators (www.beachsoccer.com). A game lasts about 1 hour with an average playing time of 36±8 min per player.

Only little is known so far about the physiological demand in beach soccer and about the specific game activities. Beach soccer is often compared with soccer and therefore it is important to know whether or not the specific demands and training programs for soccer can be transferred to beach soccer.

The purpose of the present study was to analyse heart rate and blood lactate of the Austrian and Swiss beach soccer national teams (17 players total) during two games and to perform diagnostic tests prior to the game. Specific game activities were simultaneously documented (Trauner 2006). The results were compared with studies in soccer (Reilly & Craig 2005, Sassi 2005) and basketball (McInnes 1995).

Heart rate was measured (Polar S810) with a 5 s interval before, during and after game one, game two and a 20-m shuttle run on sand. The shuttle run was used as a performance diagnostics test. Lactate samples were taken from the earlobe: prior to the games and the shuttle run, before and after each activity, 3, 6, 9 and 12 min after the games and the shuttle run. The samples were analysed using a Biosen 5040. The data from the two games and teams were averaged. Data from the two games were correlated with the data of the shuttle run.

The players showed maximal heart rate (HRmax) and maximal lactate (Lmax) during the shuttle run. The average HRmax during the shuttle run was 188±9 bpm. The average maximal heart rate during the games was 98% of HRmax. The mean heart rate during the games was 167±13 bpm (89% of HRmax). On average the players were 56% (20 min) of the active time between 90-100% of HRmax, 34% (12 min) between 80-90% of HR max and 10% (4min) below 80% of HRmax. On average Lmax was 11.1±2.7 (6.9-15.0) mmol/l in the shuttle run and 8.1±3.6 (4.7-14.9) mmol/l during the games.

The different involvement of a player in the games and the time of sampling cause a wide range of blood lactate accumulation. Regarding heart rate and lactate profiles in beach soccer were found to be very similar to small-sided games in soccer (Reilly & Craig 2005, Sassi et al, 2005) and in basketball (McInnes et al 1995). Training programs of soccer need to be adjusted to the high energy demands of beach soccer players. The demands in beach soccer differ from soccer due to the specific characteristics. In particular, the influence of the sand and the small pitch needs further investigations.

MUSCLE DE-OXYGENATION AND NEUROMUSCULAR FATIGUE DURING REPEATED SUPRA-MAXIMAL EXERCISE

Racinais, S., Bishop, D., Denis, R., Lattier, G., Mendez-Villaneuva, A., Perrey, S.

University of Montpellier, France

Purpose and Methods: Central fatigue has been suggested to "protect" the muscle from further peripheral fatigue (and damage), but at the expense of a truly maximal performance. In order to investigate if the decline in power output across sprint repetitions is associated with evidence of a central fatigue concomitantly with changes in peripheral metabolic parameters, nine healthy male subjects performed a repeated-sprint test (consisting of ten, 6-s, maximal sprints every 36 s). Oxygen uptake was measured breath-by-breath, vastus lateralis muscle de-oxygenation was assessed continuously using near infrared spectroscopy and surface electromyograms (EMGs) of both agonist (vastus lateralis) and antagonist (biceps femoris) muscles were recorded. Prior to and following the fatiguing cycling exercise, maximal voluntary force, neuromuscular efficiency (NME = force / RMS activity) and the percentage of muscle activation by voluntary drive (twitch-interpolated method) were measured.

Results and discussion: Consistent with previous research, our data showed a significant power decrement during the repeated-sprint test ($P < 0.05$). For the first time however, our data indicate that there is an increase in muscle de-oxygenation during this kind of exercise which seems to be the result of an inability to restore pre-sprint levels of oxygen saturation during the 30 s of recovery following each sprint. Indeed, our results showed that the increase in [HHb] engendered by each sprint remained fairly constant throughout each sprint repetition (+21.34 ± 1.56 ?mol.L-1), suggesting that the ability of the subjects to utilize available O2 was well preserved. However, at the end of each recovery period, [HHb] failed to return to the end-recovery value of the previous sprint ($P < 0.002$) leading to a progressive muscle de-oxygenation. Consistent with the hypothesis of a central fatigue concomitant to peripheral change, the progressive muscle de-oxygenation during repeated bouts of short-term exercise was coupled with a significant decrease in EMG activity ($P < 0.05$).

Our results also showed a significant decrease in maximal voluntary force (-16.5%, $P < 0.05$) after the cycling test which can be explained by both a significant impairment in NME (-11.4%, $P < 0.05$) and a significant decrement of the percentage of voluntary activation (-3.0%, $P < 0.05$). In consequence, our hypothesis that there is a central limitation to the performance of repeated-sprint exercise was also supported by a significant decrease in voluntary activation from rest to post exercise MVC. This decrement has previously been observed after prolonged running, but this is the first time that a reduced maximum voluntary activation has been reported following repeated-sprint cycling exercise.

PHYSIOLOGICAL PROFILES OF JUDO ATHLETES AND CLIMBERS: A COMPARISON

Pocecco, E., Holztrattner, E.

Institute of Sports Science, Austria

Introduction. Judo and climbing both use the whole body, but in different ways. In the literature there is apparently neither a comparison between spiroergometric parameters of athletes of these two sports nor research focusing its attention on the development of a laboratory test lasting the duration of a judo/climbing competition (about 5 minutes), regarding maximum arm and leg performance.

Purpose. The aim of this study was to describe and to compare maximum arm and leg performance attributes of male adult judo athletes (n=6) and climbers (n=7) of different rank, derived from laboratory tests, which are similar in duration to a competition (5 minutes).

Material and Methods. Anthropometric measurements included height, body weight, Body Mass Index (BMI) and body composition (BIA). The tests consisted of a continuous incremental load test with the arm crank ergometer (Pstart=25W, power increment units body weight dependant, intending to peak at about 5 min) and in a 5 min test on the cycle ergometer with a constant maximum sustainable work load (torque factor=0.5). Recorded parameters during the tests were: maximum power (Pmax) during arm cranking and mean power (Pmean) during cycling; heart rate, VO2peak, ventilation and respiratory exchange ratio.

Results and Discussion. The only anthropometric parameter that differed markedly between the two groups of athletes was the BMI (significantly lower among climbers) reflecting probably different constitutional types.

Climbers had nearly the same arm and leg relative power values (upper body: Pmax=2.73±0.28W/kg, lower body: Pmean=4.41±0.29W/kg) as judokas (upper body: Pmax=2.75±0.33W/kg, lower body: Pmean=3.95±0.46W/kg), but their VO2 values for reaching those performances were significantly higher (climbers – upper body: 39.4±2.7ml/min/kg, lower body: 58.0±3.6ml/min/kg vs. judokas – upper body: 30.0±3.5ml/min/kg, lower body: 50.2±6.4ml/min/kg; t-test – upper body: $p<0.001$, lower body: $p<0.05$). In contrast, performance of judo athletes may depend more on anaerobic capacity. The reason of these differences could probably be explained by the different focus in the additional conditioning training: endurance (climbers) vs. strength (judokas).

The correlations between upper and lower body physiological parameters of both groups (climbers – power: $r=0.759$, $p<0.048$; VO2 peak: $r=0.918$, $p<0.004$; judokas – power: $r=0.812$, $p<0.001$; VO2peak: $r=0.574$, $p<0.013$; arm Pmax vs. legs' VO2peak: $r=0.637$, $p<0.004$) reflected the general state of training of the whole body, since in judo as well as in climbing both upper and lower body are involved in determining the performance. A similar result was that of the athletes of the 1987 Canadian National Judo Team, among whom the physical work capacity with the arms (PWC170) was significantly correlated with the VO2max as determined from the treadmill aerobic test (1).

MOTORCYCLING COMPETITION: IS CARDIAC LOAD DEPENDENT TO TRACK? A CASE STUDY

D'Artibale, E. 1, Tessitore, A.1+2 , Tiberi, M.1+3, Capranica, L. 1

1 Iusm of Rome, 2 Vrije University of Brussels, 3 Asur Marche, Italy

Introduction

The high accelerations and the speed of the motorcycling road races require a relevant physical effort, which might depend on characteristics of the track (Ceccarelli, 1999; Gobbi et al, 2005; Jacobs et al, 2002). However, there is a lack of scientific information regarding the rider's physical load depending on different tracks. Thus, the aim of this study was to evaluate the cardiac load of a rider during the competitive season of the European Motorcycling Road Race Championship.

Methods

A male rider (age 21 yrs, height 167.5 cm; body mass 69.8 kg; BMI 24.9; percentage of body fat 12.9 %; VO2max 67.2 ml/min/kg), competing in the 2005 European Road Race Championship (600SuperSport class), gave his written consent to participate in this study. Data were collected during the seven grand prix of the Championship (track length: 3854±472 m; right curves: n = 6.7±1.6; left curves: n = 6.3±1.3). Each competition was organized during three consecutive days, which included two 25-minutes free practice trials, two 25-minutes qualifying trials and an official race (total length 79.4±8 Km; track condition: dry; ambient temperature: 25.6±4 °C; humidity: 53±15%). The rider's heart rate (HR) was recorded during competitions (Team System, Polar, Finland) and the intensity of performance was calculated as percentage of his HRmax. Furthermore, a questionnaire was used to assess the level of difficulty of the tracks. Significant differences ($P<.05$) between competitions were tested by means of the analysis of variance and chi-square test. The Pearson correlation was used for correlation analysis between the HR data, the performance score variables, the questionnaire scale variables.

Results

During the race, the mean speed of the participant was 143.7±12.7 Km/h, mean time was 32'51"± 4'28" and his ranking was always within the first four positions. Significantly ($P<.05$) higher HR values were found during the official race (occurrence of HR ≥90% HRmax: 97±5%) with respect to the qualifying trials (occurrence of HR ≥90% HRmax: 68±15%) and free practices (occurrence of HR ≥90% HRmax: 53±20%). A significant positive correlation ($r=.76$; $P<.05$) was found between the frequency of occurrence ≥90% HRmax and mean speed of the race. No correlation between frequency of occurrence of %HRmax and score of the track difficulty questionnaire.

Conclusion

The present study shows that motorcycling performance requires a high cardiac load, which is correlated with the high mean speed of the races. Instead, the cardiac load does not reflect the subjective perception of track's difficulty. The results indicate that to ride the motorcycle at high speed, riders might benefit from a specific training aiming at improving their cardiovascular fitness level.

RELATIONSHIP BETWEEN PLANTAR PRESSURE AND SUBJECTIVE PERCEPTION PROPERTIES DURING LANDING ON MATS

Pérez, P., Llana, P., Alcantara, E.

University of Valencia (Spain), Spain

INTRODUCTION: Landings suppose a great stress for the muscle-skeletal system and a great challenge for the gymnasts. There are several studies whose analysed kinetic and kinematic foot variables during landings on different mats or surfaces (1), but magnitudes or plantar pressure pattern on foot zones are not study yet to identify injuries or mats properties. The objectives of this study were: a) analyse the maximum plantar pressure in different anatomical foot zones, and b) describe the plantar pressure pattern and its relation with gymnast stability and properties perception on different mats. METHODOLOGY: Five male gymnast with national and international sports level performed 5 valid drop jumps, from a height of 0.8 m, on 6 different mats. Plantar pressures in right foot were evaluated by system

instrumented insoles Biofoot/IBV 2001®. After 5 valid landings on each mat, the gymnast valued with a survey the properties perception in mats. The statistical analysis was made by statistical package SPSS.10. RESULTS: A similar pattern in a plantar pressure was observed in all mats. ANOVA identified several statistically significant differences ($p<0.05$) in different zones by mat. Factorial analysis identified the relations between foot zones, and identified 4 factors that are represented with a 83.80% of the total explained variance. Results about properties perception in non-parametric analysis of variance did not show any statistically significant differences ($p< 0.05$). Significant correlation ($p<0.01$) were identified in a nonparametric correlations analysis on perception and pedobarography variables. DISCUSSION: Results showed great pressure in CH (785 ± 231.9 Kpa), followed of H5M (352.6 ± 124.3 Kpa) and rest zones had similar magnitudes (near 200Kp).

A THEORETICAL ANALYSIS OF THE TAPER IN COMPETITIVE SWIMMERS

Thomas, L., Mujika, I., Busso, T.

University of Saint-Etienne, Athletic Club Bilbao, France

The mathematical model of training responses proposed by Busso (2003) allowed simulations to analyse the factors affecting the efficiency of the period of reduced training before a competition, termed taper (Thomas and Busso 2005). That study showed that greater solicitations before the taper would allow reaching better performances, but would demand a greater reduction of the training loads over a longer period. Nevertheless, the characteristics of the optimal taper in that report did not match very well the data of the literature, which suggests that the reduction of training volume should reach 60 to 90% over a period ranging from 4 to 28 days (Mujika and Padilla 2003). These discrepancies could arise from the data used to derive the model, which came from 6 non-athletic subjects enrolled in a controlled experiment on a cycle ergometer. The aim of the current study was thus to examine the factors which could affect taper efficiency in an athletic population.

The model of Busso (2003) was applied to 8 elite swimmers over two entire seasons in real training conditions. The model parameters were individually determined by fitting the modeled performances to the actual ones. Afterwards, the model parameters were used to estimate for each subject the characteristics of the step taper which would maximize performance for two simulated situations before the taper: (1) a regular training corresponding to the average training done by the subject (without OT) and (2) with an overload training corresponding to an increase of 20% of the training amounts over the 4 weeks before the taper (with OT).

The fit between modeled and actual performances was statistically significant for the 8 swimmers (r^2 ranged from 0.45 to 0.63, $P<0.005$). The optimal taper yielded to a higher gain in performance with than without OT (3.6 ± 2.6% vs 2.0 ± 1.6%, $P<0.005$) for an optimal duration longer with than without OT (22.4 ± 13.4 d vs 16.4 d ± 10.3, $p<0.05$). However, there was no statistical difference in the optimal rate of training reduction (67.4 ± 27.0% with OT and 65.3 ± 30.5% without OT).

These findings confirmed that the pre-taper training would influence the characteristics of the optimal taper. A greater overload before the taper would require a longer taper duration. However, contrary to our previous report, the greater overload would not require a greater relative reduction of training during the taper. The theoretical characteristics of the optimal taper in this study were better in line with the data from the literature. This showed that a highly trained athlete would need a greater reduction of training over a slightly shorter period than a less trained subject. The large observed inter-individual differences also pointed out the importance of the individualization of the taper programme.

HEAT TRANSFER CHARACTERISTICS OF ROWING HEADGEAR WITH RADIANT HEAT FLOW

Bogerd, C.P., Brühwiler, P., Heus, R.

Empa Material Science and Technology, Switzerland

The head is one of the strongest sensors determining human thermal comfort. For this reason several thermal manikin studies have been conducted in reducing heat stress on the head. These studies focused on optimizing convective and/or evaporative heat loss. Radiant heat flow, though often mentioned as a potential factor, has been studied relatively little. Considering that radiant heat flow easily delivers 25 W to the head alone during the summer in temperate climates, this suggests that large differences among different headgear (types) could exist. Shielding solar heat flow while maintaining heat loss close to optimal favors comfort perception and might reduce heat strain. These considerations motivated the development of a prototype rowing headgear (PRH) (Bogerd et al., 2005). The goal of this study is to compare that PRH with other widely-used sports headgear in a non-sweating condition on i) net heat transfer, ii) radiant heat flow, and iii) convective heat flow.

The following headgear were studied: i) the PRH, ii) a white cotton cap (CW) and iii) a black cotton cap (CB). The experiment was carried out for different radiant arrangements: i) without radiation (NoRad), ii) with 18.7 W radiant heat flow from directly above (90) and iii) with 9.6 W radiant heat flow from an angle of 65° (65). Wind, ambient temperature and humidity were kept constant at 4 m∙s-1, 22 °C and 50%. The measurements were then repeated for arrangements NoRad and 90 with headgear PRH, CW and CB in combination with a wig.

All headgear reduced the radiant heat flow: ~80% for the caps and 95% for the PRH. Furthermore, the radiant heat flow contributed maximally for 13% to the net heat transfer indicating that convective heat flow is a more important heat transfer parameter under the tested condition. The PRH reduced convective heat flow only minimally and was therefore the only headgear outperforming the nude head in a radiant environment. The extra heat transfer obtained with the PRH in the most optimal condition and compared with the nude head is 12 W. It is known from studies with artificial cooling that a cooling power as low as 12 W results in a reduction of heat strain for pilots carrying out a flight simulator in a warm environment (Williams & Shitzer, 1974). However, it is unknown if the PRH results in a reduction of heat strain for athletes. Wearing a wig greatly reduces convective heat flow but shows similar qualitative results. The PRH is shown to be more effective in reducing heat stress of the head compared to traditional rowing headgear under the tested conditions.

PHYSIOLOGICAL, HORMONAL AND TECHNICAL ASPECTS OF THE SOCCER GOALKEEPER: A CASE STUDY

Cortis, C. 1, Tessitore, A. 1+2, Meeusen, R. 2, Pagella, A. 1, Capranica, L. 1

1 IUSM of Rome, Italy, 2 Vrije University of Brussels, Belgium, Italy

Research on the performances of soccer goalkeepers lagged behind that on the other soccer roles. Thus, the aim of the present study was to investigate physiological, hormonal and match analysis aspects of a soccer goalkeeper during a one-week competitive microcycle.

Methods

A soccer goalkeeper (age: 21 yrs; height: 185 cm; weight: 80 kg) participated in this study. His heart rate (HR) was continuously recorded (Polar, Finland; sampling = 5 s) during five 2-hour training sessions/week and a competitive match. After the warm-up, first half, and second half of the match, peak blood lactate concentrations (La), countermovement jump (CMJ) and bounce jumping (BJ) performances were measured. Pre-exercise baseline after two consecutive resting days was established for salivary cortisol (C) sampled at 8 a.m., 2 p.m., 5 p.m., and 10 p.m., and morning urinary epinephrine (EPI), norepinephrine (NE), and dopamine (DP). The same sampling schedule was maintained for the training sessions and the competitive match. The goalkeeper was filmed during his trainings and the competitive match. Videotapes were analyzed to evaluate the following motor activity parameters: running, walking, jumping, and inactivity. Thus, the following information was calculated: a) the time spent in each activity; b) the occurrence frequency for each category's; c) the percentage of total time spent in each activity. Analysis of variance (ANOVA) and chi-square tests were applied to verify significant differences ($p<0.05$).

Results

During training, mean HR was 121 ± 21 beat/min (corresponding to 61 ± 11% HRmax), with 75% of HR values <130 beat/min. During the match, the goalkeeper was actively involved in 58 occasions, while spent the rest of the match at low intensity activities (inactivity: 55%; walking: 35%), with 63% of HR values >130 beat/min. Peak La values were 2.7 and 1.8 mM at the end of the 1st and 2nd half, respectively. Both CMJ and BJ performances decreased at the end of the match (before match: CMJ 45 cm, BJ 35 cm; 1st half: CMJ 41 cm, BJ 35 cm; 2nd half: CMJ 38 cm, BJ 26 cm). At the end of the match catecholamines showed higher values (EPI: 168 mcg/l; NE: 321 mcg/l; DP: 772 mcg/l) and remained elevated the day after the match (EPI: 8 mcg/l; NE: 50 mcg/l; DP: 543 mcg/l) than baseline (EPI: 6 mcg/l, NE: 18 mcg/l, DP: 286 mcg/l) and trainings (EPI: 5 ± 3 mcg/l; NE: 19 ± 7 mcg/l; DP: 318 ± 81 mcg/l). Also C showed a similar trend with respect to baseline (8 a.m.: 11.8 ng/ml; 2 p.m.: 4.6 ng/ml; 5 p.m.: 2.1 ng/ml; and 10 p.m.: 1.2 ng/ml) for both trainings (8 a.m.: 10.0 ± 0.9 ng/ml; 2 p.m.: 4.0 ± 0.9 ng/ml; 5 p.m.: 5.1 ± 3.6 ng/ml; 10 p.m.: 1.4 ± 0.3 ng/ml) and match (8 a.m.: 12.6 ng/ml; 2 p.m.: 8.9 ng/ml; 5 p.m.: 29.2 ng/ml; 10 p.m.: 1.8 ng/ml).

Conclusion

Considering the low HR values and the elevated hormonal levels of the soccer goalkeeper, a training program should be focused primarily on the enhancement of all-out activities and on the stress management during competition.

CORRELATION BETWEEN KICKING PERFORMANCE, HORIZONTAL JUMP AND SPRINTING PERFORMANCE

Sporis, G. , Vueti, V., Mihai, V., Jukic, I.

Faculty of Kinesiology University of Zagreb, Croatia

Kicking is the one of the most important skill in soccer. The most frequently used soccer kick are the full-instep kick and the inside-of-foot-passing shot. The full-instep kick is normaly used for generation of a fast ball speed and this type of kick was used in this study. The relation between sprinting ability and performance of athlete in the field (like kicking performance) is subject of controversy not only in biomechanics, but also in other research fields dealing with muscle power.

Twenty-seven croatian national football team members (U-15) (mean (SD) age 15.8 (2.9) years, height 173.5 (5.5) cm, weight 62.1 (5.4) kg) were tested for maximal sprinting ability (sprinting 0-30 m and time over 5, 10, 20 and 30m were recorded), horizontal jump and kicking performance. The velocity of kicking was measured by a Stalker radar gun (from a standing position players took 5 meter run up and perform penalty kicks into the unguarded soccer goal). Time of sprinting was recorded by photocells. Horizontal jump was measured whit standing long Jump test (SLJ). The Person product-moment correlation was used to determine the relationship between selected variables. $P<0.005$ was considered significant.

The mean performance of sprinting test over 5m (sp5) was 1,44 (0,1) sec, 10m (sp10) 2,21 (0,12)sec, 20m (sp20) 3,53 (1,14) sec and over 30m (sp30) was 4,71 (1,19) sec. Standing long Jump (SLJ) 211,09 (15,56) cm, mean ball velocity measured by radar (vb) was 94,4 (4,38) km/h. There was a strong correlation between kicking performance (vb) and sprinting performance in all four sprinting variables sp5 ($r =0,49$, $p<0,05$) sp10 ($r =0,51$, $p<0,05$). sp20 ($r =0,45$, $p<0,05$) and sp30 ($r =0,54$, $p<0,05$), and between kicking performance and body weight BM ($r =0,53$, $p<0,05$). No significant correlation was found between kicking performance and standing long jump.

In soccer, sprinting performance affects kicking performance and can be influence by meters of run up and velocity of foot in the moment of contact whit a ball. Ability which is important in first 5 meters of sprinting is starting reaction, followed by explosive movements, and we can conclude that motor abilities which are in the basis of sprinting and kicking performance are similar. However, the relationship between these parameters and kicking performance has not been fully investigated. Further study is required to determine how these parameters influence kicking performance.

PHYSIOLOGICAL CHARACTERISTICS OF ELITE FEMALE WATER POLO PLAYERS: CHANGES FROM PREPARATORY TO COMPETITIVE PHASE OF TRAINING

Marrin, K., Bampouras, T.M.

Edge Hill College of Higher Education, United Kingdom

There is a dearth of information available on the physiological characteristics of female water polo players, and in particular differences in characteristics between periodised training cycles. The aim of this study was to determine the changes in the physiological characteristics of elite female water polo players between the preparatory and competition phases. Eight female players from the Scottish National squad (mean ± s: age 23 ± 3.1 years, height 169.1 ± 3.5 cm, mass 64.2 ± 5.7 kg) participated in a test-retest design. Subjects completed a battery of tests comprising a number of assessments to provide a profile of the water polo player. The battery of tests were conducted on two separate occasions; the first trial in the preparatory phase (Trial 1) and the second in the competition phase (Trial 2) of training. Body fat percentage was predicted from four skinfold measurements (biceps, triceps, subscapular and suprailiac). Peak oxygen uptake

was assessed via an incremental treadmill test to exhaustion, with expired air being analysed using a Cardio2 automated gas analyser. Anaerobic power (peak power, mean power and fatigue index) was measured via the Wingate anaerobic test and leg power was estimated using a vertical jump test. The Multistage Swimming Shuttle Test (MSST) was utilised as a sports specific test of aerobic power. Normality of data was examined using the Kolmogorov-Smirnov test and subsequently confirmed. Paired t-tests were conducted to determine any differences in the characteristics between the two testing occasions. Significance level was set at $P < 0.05$. The results (mean ± s) of the tests for Trial 1 and Trial 2 respectively were: mass 64.2 ± 5.7 and 63.4 ± 5.3 kg, body fat percentage 22.6 ± 3.9 and 19.3 ± 3.8 %, peak oxygen 52.8 ± 2.5 and 51.9 ± 5.2 ml·kg-1·min-1, peak power 651.7 ± 65.4 and 609.3 ± 34.7 W, mean power 452.1 ± 41.7 and 449.1 ± 41.0 W, fatigue index 48.5 ± 3.7 and 45.2 ± 10.9 %; vertical jump 33.5 ± 8.0 and 33.8 ± 7.6 cm; MSST 35.7 ± 43.3 and 43.3 ± 14.8 shuttles. The percentage differences between Trial 1 and Trial were: mass 1.1 ± 3.3 %; body fat 14.6 ± 9.1 %; peak oxygen uptake 1.7 ± 7.7 %; peak power 5.3 ± 14.9 %, mean power 0.0 ± 11.6 %; fatigue index 6.6 ± 21.4 %; vertical jump –1.7 ± 12.8 % and MSST – 15.9 ± 18.6 %. Significant differences were found between trials for body fat percentage ($P = 0.006$) and MSST ($P = 0.045$). No significant differences were found between other variables. The results suggest that the players were more muscular with a higher sport specific aerobic power in the competition phase, reflecting training adaptations due to the periodised training cycle. However, these improvements did not affect any of the anaerobic power measures and occurred without any concurrent increase in peak oxygen uptake. The latter findings may be attributed to the lack of specificity of these tests. Further studies should include more sport specific tests to provide a more complete profile.

SYSTEMATIC ANALYSIS OF RUNNING SPEED LOADS IN THE WORLD CLASS TENNIS

Pieper, S., Gemperlein, A., Weber, K.

Institute of Movement Science for Games in Sport , Germany

Introduction: The modern elite tennis has changed during the last years essentially. Comparatively young players like Andy Roddick (USA) and Roger Federer (Switzerland) play in a more dynamic way than in former times (higher stroke velocity and stroke precision). Athletic as well as conditioning demands are increasing. The importance of speed in tennis is undisputed among tennis practitioners as well as among theoreticians. Nevertheless, there exists only partly sufficient knowledge of quality and quantity of tennis-specific running speed demands. With the following contribution we could show some important results by the systematic analysis to characterize the running speed demands in elite tennis. Method: For the study thirteen clay court matches are analyzed in the men's singles during the World team cup in 2004 after a systematic criteria catalogue. The results are from 22 top players (age 26±2 y; height 184.9±5.8 cm; BMI 23.6±1.1 kg/m2). All players were at the investigation period placed on the Entry list of the ATP under the top 60. The different tactical adjustments of the players reach from the classic defensive player about the allrounder as far as the offensive player with dominant services. Therefore we can go out with the examination property of a representative sample of top world class players. The present player's observation contains all rallies from 327 pure service games and eight tie-breaks. Results: We determined that in 29% of all strokes the players are under time pressure. In 85% of these situations they run in the baseline to the side. In this connection runs to forehand corner are dominated with 55%. The rate of stroke errors under time pressure amounts to approximate 22%. The highest number of unforced errors lies with strokes under high time pressure (27%). Running distance by strokes under time pressure average four meters whereas run to forehand corner on baseline being the most frequent running direction is clearly followed by run to backhand corner. Run to net rank close up on third place. Conclusion: The game analysis covers the rising importance of running speed in the elite tennis. Compared to earlier works the findings show a bigger frequency in pressure of time situations. In modern clay court tennis every fourth stroke is played under pressure. Besides, the player causes an unforced error with approximate every fifth stroke. To our conviction the shown characteristics of running speed in elite tennis have to be equally simulated in tennis training. Start and sprint speed have to be practiced to running distances from 3 to 8m to the side, especially to forehand as well as to backhand side with or without subsequent changing direction (including stroke) on the baseline.

EFFECTS OF STRENGTH, ENDURANCE AND COMBINED TRAINING ON BLOOD TESTESTRON & CORTISOL CONCENTRATION, VO2 MAX, ANAEROBIC POWER, MAXIMUM STRENGTH AND BODY COMPOSITION IN UNTRAINED MEN

Ghahramanloo, E., Alinejad, G.

Tarbiyat Modares University, Iran

The purpose of this study was to compare the effects of three kinds of exercises (endurance, resistance, and concurrent) on blood testestron & cortisol concentratin bioenergitic characterization, maximum strength and body composition on non athletes.

Participants: 35 graduate students of TMU, randomly selected and then divided into three groups; (E; n=13, S; n=9, C; n=13)

At first blood sampling, maximum aerobic and an aerobic power, maximum strength in four movements (bench press, squat, lat pull down, and leg curl) were measured. Following this the participants conducted eight-week training program.

Endurance Training Program involved running with 65% of Max HR for thirty minutes per session and three sessions per week where the HR reached 80% towards the end of the program.

Resistance Training Program involved conducting three sets of bench press, squat, pull down and legs curl With 60% of M.S, 12 repetitions per set and three sessions per week where the intensity reached 80% of 1RM and where the repetition dropped to 6-8 towards the end of the program.

The Concurrent Training Program involved combining both of E and S groups program.

After eight weeks the variables were measured one more time in the post-test. Based on the findings of this study, Vo2 max in E group achieved maximum increase whereas the minimum increase was observed in the S group.

The rate of increase of testron and cortisol did not show any significant differences between these groups. Vo2 Max changes showed significant difference between E, S group. The rate of increase in aerobic power did not indicate any significant difference among the three groups. Similarly, the rate of increase in maximum relative strength in bench press, squat and lat pull down exhibited significant difference between S and C with E. therefore, adding strength training endurance training isn't detrimental to the improvement of vo2 max. Likewise, endurance training along with strength training doesn't have any negative effect on the improvement of maximum strength. Concurrent training is similar to endurance and resistance training in that it is conducive to enhancing body composition in non athletes.

COMBINED TRAINING INDUCES SPECIFIC METABOLIC AND STRUCTURAL ADAPTATIONS IN ELDERLY WITH HIGH INITIAL VO2 MAX

Verney, J., Kadi, F., Charifi, N., Feasson, L., Castells, J., Piehl-Aulin, K., Denis, C.

Research Unit PPEH, EA 3062, University of Saint Etienne, France

Purpose: We previously reported the effects of endurance training on satellite cells content (Charifi et al. 2003) and muscle capillarisation (Charifi et al. 2004) in still active elderly. In the present study, we investigated the specific effects of endurance and resistance training in similar elderly. A lower body (LB) endurance and upper body (UB) resistance training program was planed. We reported the effects of this combined training on fiber type, fiber area, enzyme activities and satellite cells. Muscles of interest were the endurance trained vastus lateralis and the resistance trained deltoideus. Methods: Ten healthy active elderly men (73 ± 4 yr, pre-training VO2max: 35.8 ± 7.3 mL•min-1•kg-1) were tested before and after 14 weeks of combined training (3 times.wk-1). Training session consisted in 3x12 min of interval training on a bicycle for endurance and 3x12 min of UB resistance exercises. Biopsies were taken from vastus lateralis and deltoideus. Fiber type, satellite cells, capillaries and cells expressing developmental myosins were identified by immunohistochemistry. Fiber area of type I and type IIA was measured and an index of microvessels tortuosity was calculated. Results: No significant alterations were observed in fiber type, fiber area and myonuclear number in both muscles. After the training period, significant increases in Phosphofructokinase (PFK) ($P<0.05$) and citrate synthase (CS) activities ($P<0.01$) were observed in resistance-trained deltoideus and the activity of hydroxyacylcoA dehydrogenase (HAD) and CS were significantly increased ($P<0.01$) in the endurance-trained vastus lateralis. Tortuosity of the microvessels increased significantly in vastus lateralis (+27%, $P<0.01$) but not in deltoid muscle. The number of satellite cells per fiber increased significantly ($P<0.05$) after training in both vastus lateralis and deltoideus. Percentage of fibers expressing developmental myosins increased (ns) in vastus lateralis (+50%) and deltoideus (+125%). Conclusion: Active elderly people submitted to a mixed training program (endurance LB and resistance UB) demonstrated muscle-specific metabolic adaptations. These were associated to an increase in the number of satellite cells per fiber both in the endurance and resistance trained muscles.

A THREE-DIMENSIONAL ANALYSIS OF BACKWARD FLIC-FLAC IN MALE AND FEMALE GYMNASTS

Lovecchio, N., Grandi, G., Galante, D., Milesi, I., Grassi, G.P., Ferrario, V.F.

Università di Milano, Italy

Introduction - During the performance of gymnastic techniques, a proper body form (reciprocal position of the various parts of the body in space, their movements during the execution of the routine) is the key indicator of the correctness of the movements (1, 2). In a previous study, we analyzed the body trajectories during the performance of backward flic-flac (back handspring), and we focused on some technical parameters of the first flight (2). In the present study, the analysis was extended to the complete technique.

Methods - Six male (mean age 20 y, height 168 cm, weight 69 kg) and three female (mean age 19 y, height 163 cm, weight 59 kg) experienced gymnasts were measured. Thirteen retro-reflective markers were positioned on: right and left lateral malleolus, fibular head, greater trochanter, acromion, olecranon, styloid process of the ulna; vertex. Each gymnast performed three series of five repetitions of flic-flac, starting from the standing position. The movements were recorded by an 8-TVC optoelectronic system (100 Hz sampling rate), within a working volume of 380 x 380 x 280 cm. The 3D metric coordinates of each marker were used to calculate: the lengths of first, second and total flights; the horizontal distance between foot and hip just before the beginning of the first flight; the maximum vertical position of hips during the first flight; the elbow flexion and inter-wrist distance during the double-arm support phase; the vertical displacement of the acromion during the courbette.

Results – On average, the first flight was somewhat shorter than the second flight (49% of total), and its length was more consistent within each gymnast (coefficient of variation first flight 7% men, 9% women; second flight 11% men, 13% women). The horizontal hip movement just before the beginning of the first flight was 17% of standing height (37% of the lower limb length in men, 39% in women); the maximum hip vertical distance during the first flight was 58% (men) and 62% (women) of standing height. During the double-arm support phase, the elbow flexion was 16% (men) and 15% (women) of the upper limb length; the inter-wrist distance was 34% (men) and 23% (women) larger than the inter-acromion distance; the inter-wrist line had a mean angle with the inter-ankle line at start of 8 deg (men) and 15 deg (women). The vertical displacement of the acromion during the courbette was 39% (men) and 28% (women) of the upper limb length.

Conclusions - Technical measurements are qualitatively approximated by visual observation of coaches and referees. In the current study, a series of technical measurements were obtained from 3D reconstructions of repeated backward flic-flac. The method could supply data for a quantitative analysis of the routine, to assess the effect of training, as well as to measure the influence of individual characteristics on the execution of the technique (2).

VO2 /W-RELATIONSHIP DURING RAMP CYCLE EXERCISE DEPENDS ON THE METABOLIC MEASUREMENT SYSTEM

Boone, J., Bouckaert, J., Koppo, K.

Ghent University, Ghent, Belgium, Belgium

Purpose: To test if the slope of the O2-uptake ( ) / workrate (W) - relationship during ramp cycle exercise can be influenced by the metabolic measurement system used. Methods: Eight physically active males performed two ramp cycle exercises (25 W.min-1 or 30 W.min-1). On one day the respiratory parameters were measured with a MedGraphics CPX/D system and on the other day with a Jaeger Oxycon Pro. For both tests the /W – curve was determined and the best fitting linear regression for the data above and below the ventilatory threshold (VT) were calculated . From this regression analysis the slopes above (S>VT) and below (S<VT) VT for both tests were determined and compared. Results: For the test with the MedGraphics CPX/D, S<VT was significantly steeper than S>VT (9.9 ± 1.5 ml.min-1.Watt-1 and 8.7 ± 1.5 ml.min-1.Watt-1 respectively), whereas the opposite was observed with the Jaeger Oxycon Pro system (9.9 ± 0.4 ml.min-1.Watt-1 for S<VT and 10.8 ± 0.5 ml.min-1.Watt-1 for S>VT). When the slopes between the two tests were compared, S<VT did not significantly differ, whereas S>VT was significantly steeper during the test with the Jaeger Oxycon Pro. Conclusion: The results of the present study demonstrate that the deviating results found with the MedGraphics CPX/D (i.e. a downward deflection of the /W – relationship) can not be reproduced with another metabolic measurement system.

TRUNK MOVEMENTS DURING ERGOMETER ROWING. A THREE-DIMENSIONAL NON INVASIVE STUDY

Galante, D., Lovecchio, N., Casiraghi, E., Andreoletti, M., Sforza, C.

Università di Milano, Italy

Introduction - Rowing is a strenuous sport that stresses the body with a highly repetitive activity. Literature reports several recent studies on technical execution models, on spine movements and strengths developed during simulated rowing (1), but actual three-dimensional (3D) literature data on body movements are still incomplete.

Methods - We devised a protocol for the quantitative, three-dimensional assessment of body movements during ergometer rowing (2), and applied it to seven high-level agonist oarsmen (age range 20-27 years, body weight 70-98 kg, standing height 180-193 cm). The oarsmen rowed on an ergometer (Concept 2 model) at 28 strokes/min. The three-dimensional movements of 21 body landmarks (left and right ankle, knee, greater trochanter, hip, shoulder, elbow, wrist, tragus; spinous process of C7, T2, T12, L2, L4) were detected by an optoelectronic instrument with a sampling rate of 120 Hz (SMART System - B.T.S., Milan, Italy) during eight strokes (11th-20th stroke). An additional landmark was positioned on the horizontal part of the ergometer to provide a reference. The trial was repeated three times for each rower. Nine infrared-sensitive cameras were positioned at a variable height from the floor, at various angles of a working volume of 200 x 150 x 250 cm to film each oarsman from different points of view (calibration accuracy of 0.01%). Dedicated software computed the range of motion of the posterior angles of the cervical (tragi to C7), thoracic (T2-T12) and lumbar (L2-L4) spine segments relative to the horizontal axis (1), at catch and final. Angular statistics was used to obtain mean values and relevant standard deviations across the eight strokes.

Results - The angles computed in three trials were well repeatable, with coefficients of variation up to 1% (head and neck), 2% (thoracic spine) and 7% (lumbar spine). The head and neck were approximately in line with the horizontal at catch (tragus-C7 vs. horizontal 164°), and they extended at finish (139°). The thoracic spine (T2-T12 vs. horizontal) extended of approximately 67° during the stroke; weightier oarsmen had lower ranges of motion ($r=-0.925$, $p<0.01$). The average range of motion of the lumbar spine (L2-L4 vs. horizontal) was 53°, and it was larger in younger oarsmen ($r=-0.788$, $p<0.05$).

Conclusions - The method allowed a complete measurement of the dynamic characteristics of the body during ergometer rowing. Ranges of motion of the trunk and timing of maxima and minima were in good accord with literature data (1, 3), while no data were found for head movements. The measurements agreed with conventional technical teaching. Further studies could develop useful methods to screen the movements in subjects with muscular-skeletal injuries; additionally, stress during rowing and recovery after training could be quantitatively assessed (4).

MODELING OF TRAINING AND SPORT PERFORMANCE IN SHOOTING

Gulbinskiene, V., Skarbalius, A.

Lithuanian Academy of Physical Education, Lithuania

The continual analysis of the training loads and results variation allows to manage the sport performance (Mester, Perl, 2000; Mujika et al., 1996). On the principles (Gulbinskiene, Skarbalius, 2005) of 27 weeks successfully used previous training model (rwith shot=0,510; rwithout shot=0,321) was designed 22 weeks training program for the shooter T. S. youth age member of Lithuanian rifle team in order to carried out individual interaction of training model and sport performance. Training program was made up of microcycles and computed in minutes. Sport performance was tested by Rika Home Trainer computer program during last 13 weeks and sports results of the main competition (22th week). Mathematical statistics: mean±SD, Pearson's correlation, regression were used to analyze the interaction of training program and sport performance. The two different training programs were applied in 2005/2006 experiment: basic training program prevailed 1–9 weeks (the aim – technique, training without shot) and specific training program prevailed 10–22 weeks (the aim – result: testing and competition). There was reduced training volume (training time&shots) from the 6th to 8th (three weeks) and from the 12th to 13th weeks (two weeks) of the specific training program (Banister et al., 1999). In first case there was used fast taper – training volume reduced 75% and results grew up 2,8% (Houmard, Johns, 1994). Interaction between results variation and training time with shot was r=-0,422 and without shot – r=-0,593. In the second case there was used step reduction taper – training volume was reduced 20% and results grew up 2,1%. Interaction between results variation and training time with shot was r=-0,826 and without shot – r=-0,253. Research results allows to make statement that for the shooter T. S. individual training program was optimal when 8 weeks of tapering had been used and 75% of specific exercises had been applied.

INFLUENCE OF RECOVERY INTENSITY ON PERFORMANCE DURING A SINGLE INTERMITTENT SESSION IN YOUNG ATHLETES

Thevenet, D., Tardieu-Berger, M., Prioux, J.

UFR STAPS , France

Introduction: The improvement in VO2max is generally explained by the fact that the exercises allow a high level of VO2 (90-100% VO2max) to be maintained (Wenger & Bell, 1986). Thus, time spent at VO2max (tVO2max) during exercise leads to improve performance.

The aim of this study was to determine the influence of recovery intensity on the total exercise duration, the time spent at VO2max and metabolic parameters during a short supramaximal intermittent exercise model: the 30s-30s in young athletes. Methods: Eight endurance trained males (mean age 15.88 years (0.48)) performed 4 field-tests until exhaustion : an incremental test to determine their VO2max (57.42 ml.min-1.kg-1 (2.17)) and MAV (17.88 km.h-1 (0.16)), then in a randomized order, 3 intermittent exercises consisting in repeating 30s runs at 105% of MAV alternating with 30s active recovery: 1/ 50% of MAV (IE50), 2/ velocity (vLT) associated with second lactate threshold (LT) (IELT) and 3/ velocity (vLT-d) ranging between 50% of MAV and LT (IELT-d). The delta (d) is the velocity associated with LT minus half of the difference between vLT and 50% of MAV (For a subject with a LT corresponding to 75% of MAV : vLT-d = 62.5% of VMA: [75-((75-50)/2)]). All tests were followed by a continuous test at MAV plus 1 km.h-1 in order to determine VO2max of the day (Dupont et al., 2003). Finger blood samples were obtained 2min after each test for measurement of pH and ion bicarbonate concentration ([HCO3-]). Results: tlim was significantly longer for IE50 than IELT ($p<0.001$) and IELT-d ($p<0.01$) and it was significantly longer for IELT-d than IELT ($p<0.05$). Mean tVO2max expressed in absolute value was not significantly different between IE50 and IELT-d and it was significantly higher during IE50 and IELT-d compared with IELT. Mean tVO2max expressed in relative value was significantly higher during IELT-d compared with IE50 and IELT. pH at the end of IELT was significantly lower compared with IE50 ($p<0.05$) and IELT-d ($p<0.01$).There was no significant difference in pH values between IE50 and IELT-d. [HCO3-] at the end of IELT-d was significantly higher compared with IE50 and IELT-d ($p<0.05$).There was no significant difference in [HCO3-] values between IE50 and IELT. Discussion: These results suggest that the choice of recovery depends on exercise objectives. In other words, in order to improve the aerobic system power, active recovery at vLT-d will be chosen. In the same way an active recovery at 50% of MAV will be chosen to improve the aerobic system capacity.

EARLY SPECIALIZATION VERSUS MULTILATERAL DEVELOPMENT: COMPARISON OF BODY COMPOSITION, PHYSICAL PERFORMANCE, AND PHYSICAL ACTIVITIES BETWEEN THE CZECH AND NORWEGIAN YOUNG CROSS-COUNTRY SKIERS

Randakova, R.

Faculty of Physical Education and Sport, Charles University in Prague, Czech Republic

The aim of this study was to evaluate the differences in the estimate of body fat percentage and amount of fat-free mass as well as the differences in physical performance in relation to different approach to coaching of children and physical activities in general between the Czech (in average n=12 boys) and Norwegian (n=6 boys) young regularly trained cross-country (X-C) skiers aged 13. Bioimpedance analysis was used for the determination of body composition and physical performance was estimated on the basis motor tests results twice a year before and after preparatory training period within the 3 years in the field conditions. We have found non-significantly greater FM by 0.7 %, expressively greater FFM by 3.0 kg, together with significantly and markedly higher level of physical performance in the most of physical performance variables in Norwegian X-C skiers compared to Czech X-C skiers. Norwegian approach to training of children seems to be very different to Czech access. Organized training in Norwegian young X-C skiers takes place within the less frequency and total volume, with markedly more variety of exercises and training methods, and combined with another sports and various physical activities in contrast to Czech skiers at the same chronological age. Norwegian coaching of young X-C skiers seems to be more all-round and generally centred on develop a variety of fundamental skills and motor abilities, more dynamic, and strictly negative towards early specialization using specificity exercises and training methods specific to the needs of X-C skiing against Czech approach to coaching of young skiers. In contrast to Czech conditions at school, Norwegian X-C skiers have the same physical programme including the same number of P.E. lessons such as their class mates because of missing specialized X-C skiing classes. Norwegian X-C skiers mostly combine training in terms of X-C skiing with training aimed at the other sport, together with many others various leisure physical activities in general all the year including winter competitive season. The total volume, frequency and a variety of physical activities in terms of school and after school including training seem to be expressively greater in Norwegian X-C skiers compared to Czech X-C skiers. Followed differences in the physical programme between the Czech and Norwegian young X-C skiers affected the differences in body composition and physical performance in the most of observed parameters, i.e. in Norwegian favour. Increased focus on specialization in training of young X-C skiers does not mean the higher level of physical performance. Hence, early specialization in training of young X-C skiers is unjustified. The all-round training seems to be sufficient for young X-C skiers at observed age. It appears that an existence of special sport classes with the specialization in X-C skiing at elementary school is not necessary. This study was supported by The Research Council of Norway.

PEAK POWER OUTPUT IN RESPONSE TO WHOLE-BODY INCREMENTAL SIMULATED SWIMMING USING A NOVEL ERGOMETER

Swaine, I.L., Dunford, M.J., Hunter, A.M., Carlton, K.J., Wiles, J.D., Coleman, D.

Canterbury Christ Church University, Except University of Stirling, United Kingdom

Introduction: The purpose of this study was to quantify the peak power output in response to incremental whole-body simulated swimming on a novel laboratory-based ergometer. This ergometer can measure the power output from each exercising limb during simulated swimming.

Methods: Eight masters swimmers with a mean age of 25.2 * 6.6 (yrs), stature 1.78 * 0.10 (m) and body mass of 79.2 * 3.4 (kg) gave written informed consent and participated in exercise testing on a simulated swimming ergometer (SSE). All subjects performed an incremental simulated front crawl swimming test to exhaustion. From this test, peak power output (Wpeak), peak oxygen consumption (VO2peak), peak heart rate (HRpeak). Also, individual limb power outputs were plotted during the incremental test.

Results: The mean values of Wpeak, VO2peak and HRpeak were; 302 * 28.2 W, 3.7 * 0.88 l.min-1, 179.3 * 7.2 b.min-1 respectively. On average, the contribution to the total power output from the legs and arms was 37.2 * 5.8 % and 62.8 * 4.1 % (respectively).

Conclusion: These results show that it is possible to measure limb power outputs during whole-body simulated swimming, using this novel laboratory-based ergometer. There have been no studies of limb power output during free swimming with which to compare our results for simulated swimming. However, the leg-kick appears to make a much greater contribution to overall power output during simulated swimming than it does to propulsive power during free swimming, as shown in previous studies.

PLANNING OF CHILDREN AND ADOLESCENT DISTANCES IN ORIENTEERING

Smila, B., Fernate, A.

Latvian Academy of Sport Education, Latvia

The aim of the research: to analyze the correspondence of children and adolescent orienteering distances to the criteria stated by LOF in D,H 10 – 18 age groups in Latvia main orienteering competitions.

The methods: investigation and analysis of 106 orienteering distances, inquiry, mathematical statistics.

The organization of the research: 14 distances of the Latvia Cup competitions for D,H 10 – 18 age groups have been analyzed during 2005 season. Each stage of the distance was analyzed, particularly, what technical elements should be used by the participants of the definite age group according to the distance planning criteria in order to get to the control markers. In addition, after all Latvia Cup competitions the inquiry was carried out where the leading coaches, children parents and young orienteers answered the questions about the correspondence of the planned distances to the guidelines and criteria worked out by LOF and described in LOF competition rules.

The results:

Having summed up and analyzed the correspondence of 14 Latvia main orienteering competition distances to D,H 10 – 18 age group technically-tactical preparation in 2005, we conclude:

In the groups D,H 10 the most characteristic mistake is that there is no delimitative orienteer (the marker tape is not visible enough when a child has made a mistake and gone too far);

-In the group D,H 12 distances the most characteristic mistakes are: there is no attack point orienteer before the control point; the control point is too far from handrail orienteer (more than 200 m);

-In the group D,H 14 distances the most characteristic mistake is: the winner times do not correspond to the ones stated in LOF competition rules what can be explained mainly by too complicated area;

-In the group D,H 16 distances the most characteristic mistake is: the winner times do not correspond to the ones stated in LOF competition rules;

-In the group D,H 18 distances the most characteristic mistakes are: the winner times do not correspond to the ones stated in LOF competition rules, separate stages of the distances are the same as in adult elite group distances;

-In total in 47 % of all distances there were planning mistakes;

-According to the expert (14 youth coaches; 12 children parents who train their children themselves; 42 young orientieres` aged 10 – 18) opinion when planning the distances in 50 % of the cases the distance planners have not observed the distance planning criteria (guidelines) stated by LOF.

RATINGS OF PERCEIVED EXERTION AND PHYSIOLOGICAL RESPONSES DURING AN INCREMENTAL LABORATORY TEST IN RHYTHMIC GYMNASTS

Douda, H., Panayiotou, G., Volaklis, K., Tokmakidis, S.P.

Democritus University of Thrace, Greece

Rating of perceived exertion (RPE) is widely used to evaluate physical activity, prescribe the exercise intensity during athletic performance and reveal functional abilities during laboratory tests (DeMello et al., 1987). The purpose of the present study is to examine the RPE in relation to performance ranking and physiological responses during maximal exercise between elite and non-elite female rhythmic gymnasts. Thirty-nine female rhythmic gymnasts (n=39), age 13.07±1.6 yrs, height 151.3±8.2 cm, weight 36.7±5.6 kg and body fat 13.9±1.08% participated in the study. The athletes were divided into two groups (elite, n=15 and non-elite, n=24) according to their competitive level. VO2max was determined in the laboratory using a continuous incremental exercise protocol on a cycle ergometer up to exhaustion. HR was continuously monitored with an electrocardiograph during exercise, while blood lactate was measured 3 minutes after maximal exercise. During the last 10 seconds of each stage, RPE were obtained using the 6 to 20 scale by pointing to the appropriate number (Borg, 1982). The multiple analysis of variance was applied and independent samples T-tests were used in the follow-up procedures. Pearson correlation coefficients were employed to measure the relationship among RPE and physiological measures. The analysis of data indicated that both groups gave similar values in the heart rate response [F1,37=1.59, p>.05] and blood lactate measurements [F1,37=0.03, p>.05]. Significant differences were found in VO2max [F1,37=43.03, p<.001] between elite and non-elite athletes. The RPE as well as the VO2max values were higher for elite athletes. In addition, the correlations in RPE vs physiological characteristics vary between elite and non-elite athletes, but a high correlation was obtained between RPE vs competitive performance score (r=.83, p<.01) only in elite athletes. The results of the present study indicated that rating of perceived exertion seems to provide the appropriate exercise intensity in young elite rhythmic gymnasts. Indeed, elite gymnasts had higher RPE as compared to non-elite athletes especially at maximum exercise intensity due to their ability to stress themselves more. Non-elite athletes misjudged the intensity of exercise to some extent and consequently failed to obtain the suitable levels for optimal exercise testing. On this evidence, some researches declared that Borg's scale seems to be inappropriate for preadolescent children who exercise (Pfeiffer et al., 2002; Leung et al., 2002) while others pointed out the usefulness of this practice (Ward, & Bar-Or, 1995; Lamb, 1996). Therefore, our data revealed that RPE seems to be a good performance indicator for rhythmic gymnasts and coaches should trust the perception of effort in their athletes.

TRANSDISCIPLINARY ASPECTS OF ORIENTEERS` TRAINING PROCESS

Fernate, A. 1, Smila, B. 2, Grants, J. 2

1 University of Latvia, 2 Latvian Academy of Sport Education, Latvia

Holistic education is an education in which spiritual, social, emotional, moral, and physical growth are valued in addition to cognitive development (Miller,1996). The new notion of "whole" preserves the multidimensional aspect of the object of study. Hybridization reflects the need to accomplish tasks at the boundaries and in the spaces between systems and subsystems (Gibbons, et al l994,). The transdisciplinary approach (Nicolescu, 1996) sets forth for consideration a multi-dimensional Reality, structured by multiple levels replacing the single level of classical thought -- one-dimensional reality. This proposal is not enough, by itself, to justify a new vision of the world.

The scientific problem stems out of theoretically argued and empirically approved facts of the physical literacy (Whitehead, 1990) development facilitating, developing the basic structure of orienteers' integrative work capacity development model that creates a humanistically oriented, theoretically based transdisciplinary approach to the training process.

The aim of the research: working out the model of orienteers' integrated work capacity development, creating a humanistically oriented, theoretically based transdisciplinary approach to the training process, which would facilitate the possibilities for orienteers to improve their sport proficiency.

The research methods are theoretical and empirical. The methodological basis of the research is formed up from scientists' conclusions about the paradigms of education theories, the holistic approach, the investigation of outdoor sports, the evaluation of bio-motor (dermatoglyphics (n=100), laboratory experiment and modeling), psycho-motor and social aspect of integrative capacity development and the essence of mental capacities. 69 (14-16 years old) orienteers, 36 top orienteers, 30 orienteers of different degree of preparedness, 100 LASE students, 1221 athletes of other kinds of sport.

Results of the research are interrelation between orienteers' physical and mental capacity during physical load is noticed, the most informative physical and mental capacity indices in orienteering and creating the improvement model of orienteers' integrative capacity, creating a humanistically orientated, theoretically based transdisciplinary approach to the training process that would facilitate the possibilities to develop sport proficiency.

COMPARISON OF TWO SPECIFIC ICE HOCKEY ENDURANCE FIELD TESTS, ON-ICE AND OFF-ICE, WITH A CYCLE ERGOMETRY-LACTATE THRESHOLD TEST IN JUNIOR ELITE PLAYERS

Clenin G., Fluri P., Altorfer R., Zürcher, S., Tschopp, M., Marti, B.

Swiss Federal Institute of Sports Magglingen, Switzerland

Introduction: The endurance capacity of ice hockey players is believed to play an important role in performance . Lactate threshold tests conducted on a cycle ergometer are commonly used. However, there is a lack of sport specific ice hockey field tests in performance assessment.

Research question: How does the endurance capacity of elite ice hockey players as assessed by a laboratory lactate threshold test on a cycle ergometer compare to a) a progressive stage test using a Slidingboard method (off-ice) and b) a progressive Skating stage test (on-ice)?

Methods: 29 Ice hockey players from the Swiss National Junior team (18.7y ± 0.6, 182cm ± 5.6, BMI 25.5 ± 2.0) completed over the course of 3 days 3 different endurance capacity tests: The slidingboard-Test (SB) is an off-ice test, where the athlete attaches a gliding board on the bottom of his shoes, which slide on a mat the width of two leg lengths. The athletes slide sideways from one end of the mat to the other at a given rhythm by a cadence meter. This pacing starts at a cadence of 18/min and increases gradually with the best performance at a cadence of 31/min.

The ice skating test in a figure eight (8erT) is an on-ice test with full equipment with a length of the figure eight of 160 meters. The initial pacing is at 15km/h, with an increase per stage of 1 km/h for every 320 meter.

The incremental lactate threshold test on a cycle ergometer was used to determine the individual anaerobic threshold (LTT). First stage was at130 W and increased 30 W every 3 minutes. All tests were completed to voluntary exhaustion. Heart rate, lactic acid concentrations and rating of perceived exertion (RPE) were collected.

Results: The maximal speed in the 8erT had a high correlation ($r=0.73$; $p<0.01$) with the LTT in W/kg, whereas the maximal performance in SB test had a low correlation ($r=0.39$) with the LTT. The correlation between the 8erT and the LTT was less strong when compared in absolute terms ($r=0.56$). Time to exhaustion in the LTT was 22min, in SB 11min and in the 8erT only 9min. Maximal lactate concentration was significantly ($p<0.001$) higher in the LTT than in SB or 8erT, but in SB clearly lower. Maximal RPE was significantly lower in the 8erT than during the LTT.

Conclusions: Assuming that the performance level in the field test on-ice (8erT) is most relevant to icehockey specific endurance capacity, we found a surprisingly good correlation between the 8erT and the cycle ergometry test (LTT), and only a low correlation between the two tests thought to be both hockey-specific (8erT, SB). We feel that the SB test is not an adequate test to measure endurance capacity of ice hockey players. However the results of the LTT when reported in relation to BW, over estimated the endurance capacity of the lightweight players, while the results in absolute terms overestimated the endurance capacity of the heavy players.

DISABILITIES AND LIFESAVING SPORT

Magini, V., Vossel T., Dapretto, L., Robert, P., Andreana, G.

University Institute for Movement Sciences, Rome, Italy

INTRODUCTION

People with disabilities can be involved in lifesaving programs according to their level of disability.

This concept has been supported by the experience acquired in lifesaving activities since 2003 at the Department of Human Movement and Sport Sciences, University Institute for Movement Science in Rome.

This activity allows students to become lifesavers and/or lifeguards; moreover, about 25% of students having physical and sensorial disabilities had the possibility to successfully become assistant – lifesavers / lifeguards.

Lifesaving as sport is an activity which aims to train lifesavers in rescue operations, through specific competitions. Currently, in literature, nothing has been written about lifesaving practising with disabled people .

MATERIALS AND METHODS

Almost 30 athletes with physical disabilities belonging to two relevant swimming teams in Rome (Villa Fulvia and Santa Lucia Sport) were observed. These athletes showed different levels of physical disability, classified from S2 to S10 according to "Paralympics International Committee" parameters.

Two specific events were proposed: these were included in the "Competition Manual of Lifesaving Section" of Italian Swimming Federation - 50 M swimming with obstacles (vertical, 50 cm deep) and 50 M heavy-bag (3 Kg) carry.

The training period lasted four months, from November 2005 to February 2006.

RESULTS

All the athletes completed successfully the 50 M swimming with obstacles.

The second event presented some troubles: not all the athletes with disabilities classified from S2 to S5 could complete the 50 M heavy-bag carry, as it was too difficult to them.

DISCUSSION AND CONCLUSION

The experience showed how all the athletes involved in this programme had reacted with extreme interest to the lifesaving sport activities; moreover,

it has been accepted by the group with great satisfaction.

This study has been extremely useful for its social impact: as a matter of fact, it has increased water self confidence for all the athletes involved.

This project demonstrates that lifesaving as sport activity should be considered, in relation to these two events, and integrated with the swimming programme, as a new and revolutionary offer for people with disabilities.

ACKNOWLEDGMENTS

The Authors thank for the support given to the clubs "Santa Lucia Sport" and "Villa Fulvia", and Aquatic Department of C.I.P. (Italian Paralympics Committee).

SPECIFICATION OF EPISODE CLASSES IN SOCCER AS CONTRIBUTION FOR MODELLING

Gäbe, M., Holzer, C., Hartmann, U., Radig B., Beetz, M.

Technical University Munich, Faculty for Sport Science, Germany

1. Introduction

Within the co-operation project „Football Interaction and Process Model" of TUM and Cairos technologies corp. an automated model to represent match behaviour in soccer will be developed. Segmentation and classification belong to those basic factors of modelling (Perl et al. 2002).

With a view to map the soccer game completely (Lames 1994), Cairos technologies corp. offers a suitable approach of information acquisition. Permanent independent identification of observed objects provide a basis for a high automation-level of the soccer-information-system.

2. Method

Amongst other the TUM applies to the information-theoretical processing of the position data based on an expressive model.

Starting point of the model construction is the continuous tracking of the ball and all players. Based on the movement information the modelling to perform in several hierarchic levels (Holzer 2003). One primary component of the whole model is the episode model. It is used for the segmentation of the continuously data flow in sports-practically relevant episode classes. The direct interaction possibilities between ball and player forms an episode structure with increasing complexity. The originated episode classes cross all superior model levels and have to be defined conceptual.

3. Results

By the above-mentioned approach a model with several levels was developed. The >>Movement Model<< represents the fundamental part. The next level is the >>Episode Model<< in which the basic segmentation takes place. Consecutive hierarchically the >>Situational Model<<, the >>Tactical Model<< and on the top the >>Analytic Model<< follow.

Structurally the >>Episode Model<< is characterised by so-called >>Ball-operation-episodes-classes<< as well as >>Sub-classes<< and generates >>Hyper-classes<<. The increasing complexity of the model levels complicates the well-defined determination of the >>Hyper-classes<<.

Based on the mentioned model structure a catalogue of potential episode classes was compiled. Their definition was developed under an uniform procedure according to principles: a) existing definitions, b) description of the situation and c) determination by the position data. In the process automatic detection and classification of the several episodes was a priority criterion.

TIME AND TECHNIQUE ANALYSIS OF A JUDO FIGHT: A COMPARISON BETWEEN MALES AND FEMALES

Van Malderen, K., Jacobs, C., Ramon, K., Evert, Z., Deriemaeker, P., Clarys, P.

Hogeschool Antwerpen; Vrije Universiteit Brussel; Vlaamse Judo Federatie, Belgium

Introduction

In a previous presentation exercise and recuperation times of a judo fight were reported as well as the distribution between nage waza fight (standing) and ne waza fight (ground fight). Moreover, the techniques used and the efficiency of the techniques were analyzed for the different weight categories. However, data were only obtained after analysis of the males competition. It was the aim of the present experiment to determine these parameters for male and female athletes during the Belgian Senior Championship 2004 and to compare the time and technique profiles between the males and females.

Methods

All matches of the Belgian national championships (November 2004) were video taped and analysed.

Analyses were performed per weight category. Only first round fights were analysed in order to avoid dominant patterns of judoka's continuing in subsequent rounds.

Results

No differences were found for the total activity time and the total interruption time for the males nor for the females when comparing the different weight categories. Mean total activity time was 152 ± 100s while mean interruption time was 71 ± 65s. For the females total activity time was 87 ± 66s while mean interruption time was 36 ± 30s.

The mean duration of the actions (time between "mate" and hadjimi" both nage waza and ne-waza) was for the males 18.8 ± 9.0s and for the females 19.9 ± 7.3s. The mean duration of the interruptions for the males was 9.13 ± 5.1s and for the females 7.5 ± 6.2s. The distribution of the activity time between nage waza and ne waza for the males was 84.7 % versus 15.3 %. For the females we see a slight different pattern with a distribution of respectively 65 % nage waza fight and 35% ne waza fight.

The rank order of the used techniques for the males was: sweeps (39.5%), pick ups (21.6%), hip throws (20,4%), shoulder throws (12,4%) and arm throws (6.5%). For the females the following rank order was found: Sweeps (45.2%), hip throws (24.8), pick ups (11.1%) arm throws (9.9%), shoulder throws (9.1%). For the males the most efficient throws were from the group hand techniques (efficiency = 20%) while the least efficient were from the group of sweeps (efficiency = 5.3%). For the females the most efficient throws were from the group of pick ups techniques (efficiency = 36.7%) while the least efficient were from the group of sweeps (efficiency = 5.5%).

Discussion

Our preliminary analyses indicate that total activity time is longer for male judokas compared to female judokas. However, the intermittent activity pattern of active fight and interruptions was comparable for both sexes. Our results indicate equally that the ground fight seems to be more important for the female judokas compared to the male judokas. For both sexes the sweeps were the most frequently used techniques but with a very low efficiency. The weak differences found between male and female competition do not ask for specific training programs for males and females.

IS INITIAL AEROBIC PHYSICAL PERFORMANCE LEVEL ASSOCIATED WITH THE CHANGES IN VO2MAX DURING 8-WEEK MILITARY BASIC TRAINING?

Tanskanen, M., Uusitalo, A., Huovinen, J., Linnamo, V., Kyröläinen, H.

University of Jyväskylä, Finland

The fitness level of conscripts entering to military service has declined. Since 1979 to 2004 the mean distance of 12 minute running test has declined from 2760 m to 2434 m, and the number of recruits in "good" and "excellent" categories in muscular strength tests has decreased from 67 % to 41 % during the years of 1992 and 2004 (Santtila et al. 2006). When physical fitness level of the conscripts varies, it is not known, whether the training load is suitable for all the conscripts. Therefore, the purpose of the present study was to assess if the basic military training (T) has similar effect on aerobic physical performance of the conscripts with the different initial aerobic capacity.

To determine the maximal oxygen uptake (VO2max), 59 voluntary conscripts (mean age of 19 yrs) performed the treadmill test (speed and/or inclination increasing every three minutes) three times during T; week 1(wk 1), 5 (wk5) and 8 (wk8). Pulmonary ventilation was measured on-line using breath-by-breath-methods. Mean values of registrations at every minute were used in further statistical analysis. Based on the wk1 test VO2max (ml/kg/min), the conscripts were divided into the three groups; VO2max>46 ml/kg/min - group 1 (N=18), 41-45 ml/kg/min - group 2 (N=21), <40 ml/kg/min - group 3 (N=20). In addition, the body-weight (BW), BMI, waist-hip ratio (WHR), relative fat (F%) and fat free mass (FFM) were determined. During the 8-week T there were 23 dropouts, 20 of them because of upper respiratory track infections (URTI). Thus in the final analysis the total N was 36 conscripts (group 1 N=11, group 2 N=16, group 3 N=9).

The conscripts responded to training with a significant increase (11%, $p<0,01$) in VO2max since wk1 until wk5. VO2max increased in the group 3 by 20 % from 34 to 41 ml/kg/min ($p<0,001$), and significantly less ($p<0.05$) in the group 2 by 10 % from 43 to 48 ml/kg/kg ($p<0,001$) and in the group 1 ($p<0,001$) by 4% from 51 to 53 ml/min/kg ($p<0,05$). The group 1 had significantly lower BW, BMI, WHR and F% than group 3 ($p<0,05$-$0,001$). The group 2 had significantly lower BMI, WHR and F% than group 3 ($p<0,05$-$0,001$). From wk5 to wk8 VO2max did not change significantly in any studied groups and BW did not change throughout the whole T. F% decreased and FFM increased in group 1 ($p<0,05$), while WHR decreased in group 2 ($p<0,05$) and F% in group 3 ($p<0,001$).

The present study shows that the initial aerobic physical performance influences the changes in VO2max during 8-week T. The lower the initial aerobic physical performance the more remarkable increase was found during the first 5 wk of T after which many URTIs was observed. However, it should be emphasized that the best group also increased their aerobic capacity. The relatively high physical training load with the other army stressors could sensitize the recruits for the viruses around the army circumstances, which could also be one reason for stagnation of increase in physical aerobic performance.

BIOMETRIC PROFILE OF BELGIAN KAYAK ATHLETES

Duquet, W., Deriemaeker, P., Okunkova, O., Clarys, P.

Vrije Universiteit Brussel, Faculty of Physical Education and Physiotherapy, Belgium

Introduction: In several studies high bodyweight together with a high fat free mass and a low fat mass is found in kayak athletes. The aim of the present study was to determine the profile of the Belgian kayak athletes and to compare with other international studies.

Methods

Thirty eight Belgian kayak athletes (27 male and 11 female) were examined. Categories were made in function of sex, age (Aspirants (A) 15-16y, Juniors (J) 17-18y, Seniors (S) 19y), discipline and level. Bodyweight, 6 lengths, 4 breadths, 9 girths and 6 skinfolds (SF) were measured, allowing amongst others the calculation of fat% and somatotype.

Results

For the male athletes, in function of age, group A athletes had smaller values than the S and J for all parameters, except for the ectomorphy component. The A were at average 14 kg lighter than the S and J, who did not differ from each other. Significant differences were found for 7 of the 9 body girths. Handgrip strength of A was significantly lower compared to S and J. Respective somatotypes were: for A 1.4 - 4.1 - 3.6 (ecto-mesomorph); for J 1.6 - 4.4 - 3.2 (ecto-mesomorph); for S 1.9 - 5.0 - 2.6 (ecto-mesomorph). Discriminant analysis indicates that in S athletes neck girth is for 75% sport level predictive. Kayak discipline discrimination for the male athletes can be done for 90% on the following predictors: arm girth (tensed), SF subscapular, SF medial calf.

For the female athletes, average somatotype was: for the A 3.0 - 3.7 - 2.6 (endo-mesomorph); for the J 3.4 - 3.6 - 2.3 (endo-mesomorph); for the S 2.6 - 4.0 - 2.4 (balanced mesomorph).

When considering male and female athletes in comparison with international studies Belgian kayak athletes have lower mesomorphy but comparable endomorphy and ectomorphy.

Conclusion

For the male kayak athletes we found significant differences in function of age and level. Again for the male athletes some of the evaluated parameters had a very high predictive value for the level (neck girth) and for the discipline (arm girth tensed, SF subscapular and SF medial calf.

Our results indicate that in Belgian kayak the mesomorphy component is dominant which corroborates the international literature. However, when comparing Belgian athletes with international and Olympic athletes we found a significant lower mesomorphy component and comparable endomorphy and ectomorphy component.

COMPARISON OF MOTOR ABILITY OF YOUTH PRACTISING AND NOT PRACTISING EASTERN COMBAT KUNG-FU SPORTS

Witkowski, K., Stefaniak, T.

University of Physical Education , Poland

Rapid development brought many positive and also negative elements into human life.

The main goals of the paper were differences between motor abilities of youth practising kung-fu combat sports and their idle peers, the level of physical fitness of youth at age 14-17 years and evaluation of motor ability at sportsmen.

The investigated group comprised 44 persons aged 14-17 years including 22 subjects practising kung-fu sports and 22 not practising any sport. In the research, The International Test of Physical Fitness was applied in which points scales for evaluating physical fitness of the Polish youth are used.

In speed and agility tests, non-training youth achieved better results. Such an astonishing result may be the effect of greater pressure put on sequence of movements and endurance training at sportsmen. The results in endurance test confirm this point of view. The youth practising kung-fu sports were much better in this trial. The greatest differences were noted i static and dynamic strength and power tests. The subjects training sports achieved essentially better results. Both groups were almost identical in relative power test.

Conclusions

1. The level of physical fitness of youth at age 14-17 years is average in both groups.

2. The youth practising eastern combat sports represents a little higher level of motor ability than their non-training peers. There are no cases of low physical fitness in any group.

3. The youth who practised training proved much better in static and dynamic strength as well as power. In agility and endurance trials, they were also superior but in lesser extent. The non-training group keeps up with their practising peers in flexibility, speed and relative power.

4. Much attention must be paid to improvement of all motor features to advance the level of general physical fitness in both groups.

5. Sport training influences physical fitness at youth at age 14-17 years but its impact is not so decisive as on the higher level of sport training.

CHANGES IN MATCH-SPECIFIC SPRINTING PERFORMANCE IN RELATION TO TRAINING LOADS IN ELITE RUGBY LEAGUE PLAYERS

Coutts, A., Sirotic, A., Knowles, H.

University of Technology, Sydney, Australia

Introduction

To date, no studies have examined the development of match-specific sprint performance during the preparation phase of training in elite team sport athletes. Therefore, the purpose of this study was to examine the changes in match-specific running performance in relation to training loads during a match simulation during the preseason preparation in professional rugby league players.

Methods

Ten top professional rugby league players completed a 12 min rugby league specific match running protocol, based from recent time-motion analysis (1), on a non-motorised treadmill (NMT) (Woodway Force 3.0) and computer simulation interface at the commencement of preseason training and at 2, 4, 10 and 12 wk of preseason training. The intermittent running protocol was designed so that seven 2 s sprints (including a repeat sprint bout of three 2 s sprints in 90 s) were completed. Total distance, sprint distance, peak sprint power, maximal speed, repeated sprint bout distance and power were taken as performance measures during each 12 min NMT protocol. High-intensity, endurance running performance was measured with a maximal 5 min maximal run (5TT) for distance on each testing week. Training loads were recorded for each training session using the session-RPE method (2) and HR were also recorded. One-way ANOVA and Pearson's correlations were calculated with  set at 0.05.

Results

The weekly training load during the preseason was 2644 ± 263 AU. There were significant improvements sprint distance (24.8±15.8%), mean peak sprint speed (12.0-26.5%) and mean sprint power (43.2-66.5%) for each of the seven sprints, as well as repeated bout sprint distance (22.4±15.4%) and power (47.8±12.3%) in the 12 min NMT protocol following 4 wk of training and these improvements continued to significantly improve until week 12. After 4 wk of training, the power and distance covered during each sprint was significantly improved. 5TT performance did not significantly improve. The players global RPE and HR during the 12 min NMT protocol tended to decrease with increased training. The change in total sprint distance (r=0.79) and repeated sprint bout distance (r=0.79) were both related to total time spent above 92% HRmax.

Discussion/Conclusion

These results show large increases in both individual 2 s sprint efforts and repeated-sprint ability with 12 wk of training. Importantly, the key performance changes were related to time spent >92% HRmax. Furthermore, there was a large variability in time spent >92% HRmax despite players completing similar training programs, highlighting the need for individualised physical training programs. Collectively, these results show that specific high-intensity training is an important determinant of match-specific running performance improvements during pre-season training in top level professional rugby league players.

THE EFFECTS OF TWO METHODS OF PLYOMETRIC AND WEIGHT TRAINING ON THE KICKING, EXPLOSIVE POWER AND THE SPEED OF SOCCER PLAYERS

Hojjat, S., Tarverdizadeh, B., Sheikh, A.K.

Islamic Azad University, Branch of Karaj, Iran

Introduction

Increasing knowledge of trainers and athletes about new methods in soccer is one of the

most important factors in developing soccer. Constant changes has mad it clear that soccer has gone beyond a mere sport and changed into since of soccer.

Based on these arguments and regarding the importance of strength, speed and explosive power in soccer, the researcher tried to investigate the effects of two methods of plyometric exercise and weight training on the mentioned factors.

Material and methods

To investigate the study and achieve the intended purposes,20 male players, aging 17-20 among the 140 players participating in Mahabad city adult team were underwent the training and selected .

The selected group divided randomly in to equal groups .The pre-test was composed of kicking test .Vertical jump and running velocity 45m (V45m).Plyometric and weight training were participated by two respective groups during 24 sessions within 8 week.

Having given the post-test and obtaining the data, the researcher came up with the following results :(finally data assessment by statistically methods: paired-samplesT.test, two indepent –samples T.test and Levene test

Results

1. There is a significant relationship between the plyometric training and the kicking, explosive power and the speed of players.

2. There is a significant relationship between weight training and kicking, explosive power and the speed of players.

3. The analysis of the data showed that the effect of plyometric exercises on explosive power and speed is more than the effect of weight training on the respective factors, while there is no significance difference between the two methods on players on players kicking.

PRE- AND POST-DECISIONS OF TOP HANDBALL COACHES BEFORE AND AFTER GAMES AND TRAINING SESSIONS

Sequeira, P., Rodrigues, J.

Sport Sciences School of Rio Maior, Portugal

The purpose of this study is to find out if the coaches' decisions before and after a training session before a game, during a game and during a training session after a game are consistent or if there are any changes.

Our sample was composed by 6 handball coaches, 18 handball games and 33 handball training sessions from the 2000/2001 and 2001/20002 seasons. We interviewed each coach in 3 games, 3 training sessions before the games and 3 training sessions after the game, in a total of 108 interviews. The development of the interview was based on the SOTA observation system.

Before the training sessions before the game the coaches' main decisions are: spend short time in organization, demonstrate some exercises, much prescriptive information, some questioning, long period of pressure, positive affective interactions and short time in silent observation.

After the training sessions before the game the coaches' main decisions were: spend more time in organization than he planned, demonstrate some exercises, short time with prescriptive information, some questioning, pressure during some time, positive affective interactions and spend much time in silent observation.

Before the game the coaches' main decisions are: give much prescriptive instruction, some questioning, pressure during a long period of time and spend some time in silent observation.

After the game the coaches' main decisions were: gave much prescriptive information, some questioning, long period of pressure, positive and negative affective interactions and not much time in silent observation.

Before the training sessions after the game the coaches' main decisions are: spend short time in organization, demonstrate some exercises, give much prescriptive instruction, some questioning, no pressure, positive affective interactions and spend much time in silent observation.

After the training sessions after the game the coaches' main decisions were: spend time in organization, no demonstrations, gave much prescriptive instruction, no questioning, no pressure and much time in silent observation.

Concerning the results we identified that the coaches decisions before and after the training sessions is much more consistent then before and after the handball competitions.

ENHANCING VERTICAL JUMP PERFORMANCE OF VOLLEYBALL ATHLETES – A COMPARATIVE STUDY BETWEEN RUBBER BAND ASSISTED AND TRADITIONAL PLYOMETRIC TRAINING

Angelo, R., Carvalho, A., Mourão, P., Pereira, N., Carvalho, C.

Higher Education Institute of Maia, Portugal

Introduction: Successfull participation in team sports requires specific use of pre-determined skills. When analyzing global game-play performance in Volleyball we are able to easily assess the importance of vertical jumping abilities for an increased rate of success in both offensive (spiking) and defensive (blocking) skills. Vertical jumping is thus perceived as a fundamental skill for further development in order to achieve higher performance levels. The ability to jump higher is mostly associated with muscle mechanical properties and is consistently based in lower limb muscle power output. In this way when facing the recent development of team sports we are certainly persuaded to search for new and improved methods for training optimization. Therefore our main goal in this study was to compare the effects of a new plyometric training program based in rubber band resistance, with those most commonly obtained through the use of traditional plyometric training methodologies.

Methods: For this purpose we used a sample of 12 volleyball players randomly assigned among two experimental groups. The first group of subjects (G1) performed rubber band resistance plyometric training and the other one performed traditional plyometric training. Both groups we subjected to the same training volume and exercise type. As such each group performed 8 weeks of two times per week plyometric training, wich consisted in three sets of 12 repetitions in 6 specific plyometric exercises, with 30 second recovery time between repetitions and 120 second recovery time between sets. The ony methodological difference between training programs was the use or not of rubber bands for increased muscle work intensity. Power output of the lower limbs was determined through Bosco's protocol using the ErgoJump electromechanical device in the following parameters: Squat Jump, Counter Movement jump, CMJ for blocking, CMJ for spiking and Drop Jumping from 40cm Height. Statistic t-tests (both independent and repeated measures) were applied to the obtained data matrix in order to assess between and within group difference.

Results: Our results demonstrated that both of the experimental groups presented stattistically significant vertical jumping improvements in all of the selected testing parameters (with the exception of G2 in counter movement jumping). When comparing both protocols with each other we verified that in general G1 (ruber band group) presented slighly higher test performances than those obtained by G2, however this differences were not stattistically significant.

Conclusion: After thorough data analysis we may conclude that allthough G1 presented slightly higher performances than G2 these differences were not sufficiently significant to consider that the rubber bands allow for an increased performance and should be used to replace traditional plyometric training methods. We believe that plyometric training is essencial for an increased vertical jumping ability however the traditional methods still prove themselves to be most efficient and practical.

EVALUATION OF POLING FORCES AND TIMING IN ROLLER SKIING AT DIFFERENT GRADES

Pellegrini, B., Bortolan, L., Schena, F.

CeBiSM, Center of Bioengineering and Motor Sciences, Italy

INTRODUCTION

A significant part of the propulsive force in cross country and roller skiing is generated by poling forces. The amount of this contribution changes significantly depending on technique adopted and total power required. Arm propulsive action can be evaluated using poles instrumented by means of force transducers. From force data parameters like cycle and poling duration, peak and average force can be extracted. The availability of pole inclination data could provide additional useful information as they allow to decompose force vector into perpendicular and parallel component, the last being the sole responsible to forward motion.

The aim of this study was to evaluate time variables, force, force decomposition during roller skiing to deter-mine the effect of increasing slope.

METHODS

Nine male cross-country skiers (years, body weight, height) members of the Italian National Team partici-pated to the study. The tests were performed in diagonal stride technique using roller skis on a large tread-mill. A speed of 10 km/h was chosen whereas the inclination was increased by 1° every 3min starting from 2° to 9°.

The pole forces was measured by a single-axial force transducer mounted inside the pole grip. An opoele-tronic motion capture system was used to record pole inclination. Both force and kinematical data were re-corded for the left side and for a 20 second period each step.

Cycle and poling phase duration were extracted from data force. Duty cycle were then calculated as ratio between poling and cycle duration. Pole inclination data were used to decompose force value into parallel and perpendicular component respect to forward direction. Average total, parallel and perpendicular force were calculated over poling duration.

RESULTS

Cycle duration show a significant decrease with the slope increasing due to a decrease of the recovery phase while the poling phase remains substantially unchanged. Duty cycle that has a value of 33% for the lower grade increase starting from 4° and reach a value of 40% at 9°. Average force and has a mean value of 50.1±9.0N at minimal elevation and shows linear increase with the slope reaching a value of 67.3±17.9N at the maximum grade. Parallel force component remains always lower than the perpendicular one with a mean ratio of 73.2% between them. Both parallel and perpendicular force increase but a greater increase for parallel component has been found.

DISCUSSION

Skiing at increasing grade requires significant changes on both time-related variables and poling forces. and power values. The increase of the duty cycle demonstrate that the proportion of the cycle spent generating propulsive forces from the pole was greater at steeper

grade. Significant linear increasing has been found for total poling force and this force decomposition become more effective for propulsion.

COMPUTER SIMULATION OF THE KINETICS OF THE MUSCULAR ENERGY METABOLISM IN AN INDIVIDUAL TIME TRIAL - A CASE STUDY

Weber, S., Platen, P.

Ruhr Universität Bochum, Germany

Introduction

Modelling the drag and the performance in individual time trialling (ITT) has been in the focus of several research projects in the recent past (Basset 1999). The power output has thereby often been taken as constant. For this study a computer simulation (CS) of the energy metabolism (EM) has been developed to explore the basic mechanisms which underlay the sustained power.

Methods

One elite cyclist (male, 62kg, 178cm, 22yrs) performed two lab tests on a cycling ergometer to determine his maximum aerobic (VO2max) and maximum glycolytic (VLamax) performance. Four days after these tests, the subject competed at the national 30km ITT championships. The data of the lab tests were used to predict the power output during the race (Mader 2003, Weber 2003). To calculate the kinetics of the EM during the race, the power output was recorded using a SRM powermeter. The possible racing speed was calculated considering the course profile and available equipment (Basset 1999).

Furthermore two hypothetic scenarios (S1 and S2) were used in a computer simulation to explore unused potential for increasing the overall performance. In S1 the VLamax was reduced by 10%. S2 was based on a different pacing strategy at three ascends. Instead of a higher power output during the climb and therefore a lower in the descend, the power output was kept constant in S2 throughout the climb.

Results

The subject had a VO2max of 77.0 ml/min/kg and a VLamax of 0.54 mmol/l/s. There was only a small difference between predicted and actual power output as well as riding speed (305 vs. 297 Watt / 44.5 kph vs. 43.9 kph).

The CS of the EM during the ITT showed that the lactate concentration was approx. 3 mmol/l in the middle of the race but up to 5-8 mmol/l in the beginning and the end of the ITT. The calculated saturation of the pyruvatedehydrogenase complex (PDH) with pyruvate was -0.008 ±0.09 mmol/l/min.

In S1 the saturation of the PDH would have been at a higher VO2 (59.7 ml/min/kg vs. 61.6 ml/min/kg). Therefore the available power output would have been increased to 310 Watt, resulting in an increased racing speed by 0.23 kph and a total time saving of 38s.

According to the CS, S2 would have resulted in a smaller lactate accumulation during the two ascends in the ITT. The time loss in the uphill would have been smaller than the saving in the downhill part. According to the computer model, this different strategy would have caused a time saving of 6s.

Discussion

This investigation indicates the potential of CS as a tool to increase cycling performance. Applied to races such as ITT, they can provide rather exact metabolic profiles of the race situation which could help creating better competition results.

A test ride on a given course prior to the race, which is a common practice in professional cycling, would furthermore make it possible to suggest a better pacing strategy.

PHYSICAL ACTIVITY OF WOMEN DURING PREGNANCY

Psalman, V., Ruzickova, D.

Faculty of Physical Education and Sports Bratislava, Private gynaecological clinic, Bratislava, Slovakia, Slovakia

Introduction. It is known that human being have different level of physical activity. It depends on many factors like interests, habits of family, friends and neighbours, type of job, leisure time, health etc. Based on physical activity and personal energy during pregnancy women can be devided into these three groups. The first group is better stimulated to act physical activity and women have more energy. Second group seems to be neutral and women do not react for pregnancy changes. Women which belong to the third group are negatively influenced by pregnancy changes, they have less energy, fatique is increased, they need more sleep and less physical activity.

Methods. Six months observation confirmed above mentioned information. We could see women which belonged to all three groups. Special physical activities and appropriate exercises very realised with women which belonged to groups 1 and 2. The first group consisted 41 women, the second one 32 and the third one 58. The age of observed women was in range from 22 to 35. Specific physical loading was analysed with the help of heart rate monitoring system Polar.

Results. During the observed period women from the first group had their exercise two times a week and the second group of women practised just once a week. Each practise session lasted 90 minutes and was led by experienced and well educated assistent. Specific loading during the exercise sessions brought following values of heart rate: 75 to 83 in lying and sitting positions in light intensity, 81 to 105 in moderate activity and 101 up to 121 in the highiest possible activity. These values are high enough comparing to normal before pregnancy values with their personal heart rate max from 179 to186. All recorded values are very individual based on actual state, special skills, length of pregnancy, mood, exhaustion and so on. The level of measured heart rate represents both physical and psychological loadings.

Conclusions. Properly done physical activities with suitable exercises are highly recommended almost to all expectant mothers. There exists some exception in risk pregnancy. Gynaecological experiences show that adequate exercises realised in suitable intensity are very helpful during the childbirth which should be less complicated.

A RE-APPRAISAL OF THE RELIABILITY OF THE 20 M MULTI-STAGE SHUTTLE RUN TEST

Lamb, K., Rogers, L.

University of Chester, United Kingdom

The progressive, maximal Multi-Stage Shuttle Run test (MSSRT) is used widely in many sporting, occupational health and PE settings to predict maximal oxygen uptake (VO2max). However, studies that have set out to quantify the test-retest reliability of the MSSRT have typically used inappropriate statistics and/or one of two possible calculation methods for deriving their predictions of VO2max (PVO2max). Moreover, most studies have not considered the impact of habituation on performance and therefore the value of examining whether its reliability improves after a third repeat trial. The aim of this study was to assess whether the test-retest reliability of the MSSRT is affected by having a third trial and the method of deriving the PVO2max scores. Twenty-two healthy male (20.9 +/- 1.5 yr, 79.6 +/- 9.3 kg, 1.79 +/- 0.07 m) and 13 female (19.6 +/- 1.0 yr, 67.9 +/- 10.8 kg, 1.62 +/- 0.07 m) active university sports players volunteered to take part. Each participant performed the MSSRT (Brewer et al., 1988) on three occasions, one week apart, under very similar environmental conditions. Individual total numbers of completed shuttles (TSC) were calculated along with PVO2max values using both an equation (Léger et al., 1988) and a table (Brewer et al., 1998). The consistency of the TSC and PVO2max scores across trials (t1 v t2, t1 v t3 and t2 v t3) were quantified with the 95% Limits of Agreement (LoA) analysis (Bland and Altman, 1986). The mean (+/-SD) TSC in each trial was 93.4 (28.8), 98.7 (30.4) and 96.5 (27.7) for t1, t2, and t3, respectively. Analysis revealed t2 and t3 means to be significantly ($p< 0.05$) higher than t1, but not different to each other. The overall mean PVO2max scores from the equation method (52.5 ml/kg/min) were significantly higher than the table (46.9 ml/kg/min), whilst the t2 and t3 scores (both 50.1ml/kg/min) were significantly higher than t1 (48.9 ml/kg/min), but not different to each other ($p> 0.05$). The LoA for the TSC were -5.3 +/- 16.3, -4.3 +/- 19.2 and 0.8 +/- 18.2 shuttles for t1-t2, t1-t3 and t2-t3, respectively. For PVO2max via the table method, the LoA were -1.4 +/- 5.0 (t1-t2), -1.3 +/- 5.8 (t1-t3) and 0.0 +/- 5.5 ml/kg/min (t2-t3), and for the equation method -1.1 +/- 4.7 (t1-t2), (t1-t3) and 0.0 +/- 5.0 ml/kg/min (t2-t3). Whilst these results suggest that systematic bias is eliminated after the first trial (due to habituation), a relatively large amount of random error remains, regardless of the type of score calculated. Hence, among our sample the MSSRT does not appear to have sufficient reliability to be able to detect changes in PVO2max following appropriate training. Moreover, as the PVO2max scores differ due to the method used to calculate them, it is recommended that emphasis is placed on the TSC as a performance indicator, rather than the PVO2max.

POSITION SPECIFIC SOMATOTYPES OF TOP-LEVEL AND JUNIOR AUSTRIAN MALE HANDBALL PLAYERS

Clarys, P., Taeymans, J., Clijsen, R., Rothe, H., Duquet, W.

Vrije Universiteit Brussel, Belgium , Belgium

Introduction

Position specific somatotypes have been reported in different team sports. It was the aim of this study to investigate the position specific (wing attack (W) and back court (B)) anthropometric characteristics and somatotypes (S) of top-level and junior male handball players.

Methods

Sixteen handball players (W=7;B=9) (26.4 ± 4.4 yr) from an Austrian 1st league team and nine junior players (W=4; B=5) (5.3 ± 0.6 yr) participated in this study. Anthropometric measurements were conducted using the ISAK guidelines. Somatotypes were calculated using the Heath-Carter method.

Results

Mean height (HGHT) of the 1st league W players was 183.9±4.7cm and mean weight (WGHT) was 93.9±9.2kg while mean BMI was 27.7±1.4kg/m2. Mean S were 4.0–6.7–1.2 (± 0.6–0.5–0.3). Mean HGHT of the 1st league B players was 194.1±4.1cm and mean WGHT was 95.3±8.2kg while mean BMI was 25.3±2.4kg/m2. Mean S were 3.1 –5.3–2.6 (±1.1–1.6–1.1). The differences in HGHT, BMI, meso- and ectomorphy between the W and B players were significant ($p<0.05$). Compared to the data of the B players, the relatively low SD of the W players indicated small variance (distribution). Compared to the B players bisceps and abdominal skinfolds (SF) of the W players were higher ($p<0.05$). The HGTH difference between the W (183.9±4.7cm) and the B players (194.1±4.1cm) was significant in the stepwise discriminant analysis and was discriminative for 83.1% whilst the bisceps and abdominal SF were discriminative for 39.4% and 56.1% resp. Mean HGHT of the junior (JR) team was 179.1±6.2cm and mean WGHT was 70.5±12.3kg while mean BMI was 21.9±2.9kg/m2. Mean S were 3.5–4.4–3.3 (±1.4–1.1– 1.3).

Discussion

S of elite W handball players (endomorphic mesomorph) form a cluster whereas the mean S (balanced mesomorph) of the B show larger standard deviations (SD). In function of playing position, W players in our sample tend to be more endomorphic compared to B players but less ectomorphic. HGHT is a strong discriminant for W or B players, meaning that in 83.1% of the cases, players with higher values on HGHT are B players. The results of the B players are comparable with studies from top European handball players (2.9-5.1-3.0) and with Croatian/Bosnian B players (3.0-4.6-2.7). In our team, endomorphy in W players is high compared to the references. In the JR team, mean S is central but with a high degree of variance (mesomorph-endomorph to mesomorphic ectomorph). This may be related to maturity status. Therefore, coaches may recruite the mesomorph-endomorph JR players for later W players, whereas the mesomorphic ectomorph JR players may become later B players.

Conclusion

Compared to the reference values, the W players have a higher degree of endomorphy but are less ectomorph. HGHT is strongly discriminative for player position. S of the W players form a cluster. Mesomorph-endomorph JR players may become later W players, whereas the mesomorphic ectomorph JR players may become later B players.

INVESTIGATION INTO THE RELATIONSHIP BETWEEN ANAEROBIC COMPONENTS OF PHYSICAL FITNESS (POWER AND CAPACITY) AND AEROBIC POWER IN PARALYMPIC ATHLETES WITH LOCOMOTOR DISABILITY

Bernardi, M.1,2, Alviti F.1, de Blasiis E.1, Di Giacinto B.1, Guerra E.1, Marini, C.3, Sardella F.3 and Marchetti M. 1.

1Sc. Spec. Medicina dello Sport- Dpt. Fisiologia Umana e Farmacologia - Univ. of Rome, 2Comitato Ital. Paralimpico (C.I.P.), 3Istit. Nazionale di medicina e Scienza dello Sport, CONI, Italy

Anaerobic power (AnP) and capacity (AnC) have been demonstrated to be directly associated with performance in numerous sports practiced by athletes with locomotor disability (LDA)1-3. In subjects with spinal cord injury (SCI) AnP has been also correlated with performance in activities of daily living 4. AnP and AnC are typically assessed through "sprint" all-out exercise tests (AOts). AOts are supposed to be the most appropriate stimuli to increase both lactate and growth hormone blood concentration 5-,6. We formulated the following hypotheses related to Paralympic LDA:

1. AnC, expressed as total mechanical work (MWtot) carried out by a LDA either in a time limited AOt or in an up to exhaustion AOt, is strictly dependent on his active muscles and his functional class (FC).

2. A direct association exists between MWtot and oxygen consumption peak (VO2peak), confirming a previously stated positive correlation between anaerobic and aerobic power in SCI individuals 7.

3. Blood lactate peak (BLp) is associated more with MWtot than with mean power (mP).

Seventy-two male LDA (41 with SCI, 17 amputees, 8 with poliomyelitis, 1 with spina bifida, 3 with orthopedic disorders, 2 with cerebral palsy), competing in Athens 2004 Summer Games (40 LDA) and in Turin 2006 Winter Games, underwent to an arm cranking ergometer (ACE- ER800, Cosmed, I) maximal incremental exercise test to evaluate their V'O2peak (Quark b2, Cosmed, I). Summer games group performed an ACE 30 second long constant torque Wingate test (W-AOt). Winter games group performed an ACE constant power (CP-AOt), at 130-150%V'O2peak intensities. Earlobe blood samples were collected at the end of both AOts to evaluate BLp.

The two groups did not differ in age, mass, height, skin-fold measurements (sum of biceps, triceps, subscapulae and suprailiac), FC (6.87±1.8) and V'O2peak (30±8.7 ml-1•kg-1•min-1). W-AOt results (mP 311±99 watt; MWtot 9.2±3 kJ;) were directly correlated with FC (r=0.62; r=0.79) and V'O2peak (r=0.54; r=0.58). In CP-AOt mP (235±56.9 watt) correlated with FC and V'O2peak (r=0.61; r=0.55) but not MWtot (17±5.2 kJ). BLp (9±1.8 mM in W-AOt; 11±2.4 mM in CP-AOt) correlated with MWtot in both tests (r=0.53; r=0.67) and with mP only in W-AOt (r=0.47).

Anaerobic mP is affected by aerobic power in LDA. Grouping together the AOT results of all LDAs, MWtot resulted highly correlated with BLp (r=0.71), demonstrating the strict relationship between sprint performance and anaerobic metabolism.

THE EFFECT OF HIGH-INTENSITY INTERVAL TRAINING COMBINED WITH APPLICATION OF EXTERNAL PRESSURE ON THIGHS ON PEAK POWER OUTPUT

Keramidas, M., Kounalakis, S.N., Anastassopoulos, S., Nassis, G., Koskolou, M.D., Geladas, N.D.

National and Kapodistrian University of Athens, Greece

The purpose of this study was to investigate the effect of a short-term, high-intensity interval training combined with thigh external pressure application (90 mmHg) on peak power output (PPO).

Twenty-one healthy young untrained participants (6 men and 15 women) were stratified (for age, sex and aerobic capacity) and randomly assigned either to a control (CON) or to an experimental (CUFF) training group (CON: n = 10, age = 22.70±4.72 yrs, height = 168.78±12.34 cm, mass = 67.60±18.69 kg, and VO2max = 2.56±0.78 l/min; CUFF: n = 11, age = 23.00±3.85 yrs, height = 168.15±6.22 cm, mass = 61.41±9.69 kg and VO2max = 2.24±0.50 l/min). All participants performed one incremental exercise test to exhaustion without cuffs (VO2maxNor) and another one with thighs cuffs inflated to external pressure of 90 mmHg (VO2maxPress) before as well as after the training program. The PPO was defined from VO2maxNor and VO2maxPress as the last completed work rate plus the fraction of time spent in the final non-completed work rate multiplied by 20 Watts. Both groups trained 3 days/week for 6 weeks. The CON group trained on cycle ergometer without cuffs, whereas the CUFF group trained with cuffs on thighs inflated at external pressure of 90 mmHg (cuffs deflated during active recovery) at the same relative intensity. Each training session consisted of 2-min work : 2-min active recovery bouts. The intensity of training work rate was at 91.00±12.22% of VO2maxNor for CON group and at 89.53±6.57% of VO2maxPress for CUFF group. In both groups, the mean duration of the training session was 32.50±2.73 min.

Both VO2maxNor and VO2maxPress did not change with training in any of the two experimental groups. Nevertheless, regardless of training type, PPO improved by the end of training period ($p<0.05$). Moreover, after training CUFF group improved PPO (ΔPPO) in both tests clustered together more than CON group after training (CUFF: ΔPPO: 34.39 ± 21.85 Watts; CON: ΔPPO: 18.17 ± 38.47 Watts, $p<0.05$).

The increased PPO in CUFF group maybe indicative of a higher contribution of anaerobic system to the total energy expenditure after this specific training. In conclusion, short-term, interval training combined with external pressure of 90 mmHg on thighs increases PPO despite unchanged VO2max.

EFFECT OF HIGH-INTENSITY INTERVAL TRAINING ON MAXIMAL AND SUBMAXIMAL PERFORMANCE

Keramidas, M., Kounalakis, S.N., Nassis, G., Koskolou, M.D., Geladas, N.D.

National and Kapodistrian University of Athens, Greece

The purpose of this study was to examine the effect of short-term, high-intensity interval training on respiratory responses and muscle oxygenation during maximal and submaximal exercise.

Ten healthy (3 men and 7 women) young untrained subjects (age = 22.70±4.72 yrs, height = 168.78±12.34 cm, mass = 67.60±18.69 kg, pre-training VO2max = 2.56±0.78 l/min) volunteered to participate in this study. All participants were required to train 3 days/week for 6 weeks on cycle ergometers. Each session consisted of interval training using 2-min work : 2-min active recovery bouts at 91.00±12.22% and 52.61± 16.81% of VO2max, respectively. The mean duration of each training session was 33.12±2.56 min. Initially, the subjects performed an incremental exercise test to exhaustion (VO2max), one 6-min bout of submaximal constant work rate exercise (Sub) at 77.23±2.99% of the initial VO2max and a short intensive performance test (time to fatigue at 150% of peak power output) (TF150). After completing the training program, the subjects repeated the Sub and the TF150 tests at the same absolute workload as before training. The coefficient of variation for the TF150 was 0.19±0.01%.

Whereas oxygen consumption and muscular oxygenation measured by near infrared spectroscopy (NIRS) during maximal effort did not change with training, TF150 increased significantly (pre: 58.54 ± 12.73 sec; post: 79.89 ± 9.32 sec, $P<0.05$). In addition, VO2, VCO2 and VE were significantly lower during Sub after training ($P<0.05$). These changes observed after training were accompanied by significantly ($p<0.05$) lower values of total hemoglobin (HbT), a reflection of blood volume and an index of leg blood flow measured with NIRS.

Thus, the aforementioned specific high-intensity training regime improves maximal and submaximal performance probably by enhancing the contribution of anaerobic mechanism in the total power output production and/or by improving muscular efficiency.

HEART RATE MONITORING AT OFF SHORE SAILING

Psalman, V., Kasa, J., Balás, J.

Faculty of Physical Education and Sports Bratislava, Slovakia

Introduction. Off shore sailing belongs to very popular sport and recreational activity for many people. Main advantages are: excellent nature conditions, permanently changing situations, crews consisted of many sailors and experienced skipper. High level skipper is able to arrange everything which is regarding to sailing and staying during days and nights. Based on each personal sailing experiences and skills there is a real possibility to find the best and suitable place and position for everybody. Depending on skills and abilities there is a choice to sail in recreational way or to do it as a sport.

Methods. One week sailing trip brought ideal and continual possibility to watch 9 person crew. Age of crew was from 18 to 24 years, skipper had 44. Forty two feet long boat was choosen and all crew members were from Slovak sailing clubs. But individual sailing skills and level of sailing experience were very different. The whole experiment was realised in variable sea conditions in Adriatic in September 2005. Specific sport loading was analysed with the help of heart rate monitoring system Polar. Also quality of special sailing skills in different wind and wave conditions and positions on the boat were taken into the consideration.

Results. During daily sailing trips in various wind and wave conditions we could diagnostic specific loading and following values of heart rate were obtained: starting at the easiest conditions and positions with 93 beats per minute and finishing at the most difficult conditions (very strong wind and huge waves) in skipper position and achieving values at about 170 (maximum 174). All recorded values appear to be strictly individual based on specific conditions, sailing skills, exhaustion and responsibility. Above mentioned factors are connected not only with physical loading but also with specific sailing loading which includes psychical attributes as well. There appeared also some signals of anxiety and scare mostly in cases of very big distance from the shore and during sailing in skipper position responsible for the whole crew at heavy sea conditions.

Conclusions. All mentioned factors work together and heart rate monitoring with maximal values indicates suitable and appropriate loading. From this point of view we can advice this type of specific loading which offers a very quality sport activity. Except of almost optimal loading the off shore sailing has a positive influence for development of sailing skills, coordination abilities, especially balance abilities. Also stress situations are under the control. For these reasons we can highly recommend off shore sailing for males and females in any age with different sailing skills.

KINETIC RESPONSE OF CORTISOL AND TESTOSTERONE TO FOUR DIFFERENT EXERCISE PROTOCOLS PERFORMED BY WELL TRAINED SWIMMERS

Rama, L., Rosado, M.F., Teixeira, A.M.

Faculty of Sport Sciences and Physical Education Coimbra University, Portugal

The aim of this study was to clarify the possible role of salivary testosterone and cortisol as useful non-invasive markers of training load. Although contradictory research results exist, some studies point to the advantage of these hormonal markers (1).

Twelve male swimmers of the Portuguese national team (17.030.89 years old, height 177.107.16cm, weight 66.457.16Kg, 7.330.88 years of training), participated in this study. During 10 days they performed 4 protocols: two swim aerobic tasks – a 20 minutes continuous swim and an intermittent 5 x 400 meters with 45" rest; and two land protocols- the Luc Léger running test aiming to estimate the VO2 max, and the Wingate Anaerobic Test used to determine the maximal anaerobic power. Both swimming tasks were preceded by a normalized warm-up. The schedule used on this study alternated land and water protocols, with at least 48 hours between testing sessions. All sessions took place at the same hour of the day (7.00 pm). During the study athletes participated on their normal training schedule corresponding to a stabilizing workload period. Capillary blood samples were taken after exercise to evaluate lactate. Heart Rate and perception of effort (Cr10) were also controlled. Saliva samples were colleted for determination of cortisol and testosterone concentrations. These were determined using ELISA kits (Salimetrics, USA) according to the manufacturer instructions. The testosterone/cortisol ratio (T/C) was also determined. The collection time points were: immediately before de exercise;

15', 1,5h and 2,5h after; in the next morning at wakeup; and 24h after the test. To compare the testosterone and cortisol values between moments and protocols, the Wilcoxon test was used.

Our results showed that: i) significant higher values of salivary cortisol and lower T/C were found immediately after the intermittent aerobic protocol. ii) higher values of testosterone and T/C were found 1,5h after the Wingate test. iii) no significant differences were found between the initial and the 24 hours after values for cortisol, testosterone and T/C for the swimming protocols and the Wingate test. On the other hand with the Luc Léger test, the 24 hours after values were still significantly higher for cortisol than the initial ones. When variation between the initial values and the other time points were compared, differences were found between the 24h time point for the Luc-Léger and the T20 tests, for the cortisol concentration and the T/C. For the testosterone concentration the higher variations were found for the Wingate and Luc-Léger tests 2,5h after. In general, the swim protocols induced less variation in the parameters studied than the Wingate and Luc-Léger tests. In the latter both the cortisol and the T/C were still affected 24h after the test.

SPORT DIRECTORS REPRESENTATIONS ABOUT THE SOCCER COACH

Costa, J.P., Rosado, A.

Sport Sciences School of Rio Maior- Institute Polythecnic of Santarém, Portugal

Introduction

This study intends to identify the representations of soccer directors concerning coaches' competencies profiles and their education models. We also analyse their conceptions about coaching and initial and continuous coach education. The study describes soccer director's general demographic characteristics, their general level of education, the representations of the soccer coach functions and competency profiles, their view of coach education access conditions and about the entities they see as responsible for initial and continuous professional education, the strategies of continuous education they value and the sources of professional knowledge perceived by them as important to be a coach.

Method

In this study the subjects were 50 soccer directors. Data gathering was obtained through a questionnaire. An independent "specialist validation" process was undertaken to assure the validity of the instrument. Several measures of fidelity were also undertaken. We confirmed the normality pre-requisites with the Kolmogorov-Smirnov test and the homogeneity of variances with the Levene test. We applied Anova One-Way test with the post-hoc calculations.

Results

The directors value a multifaceted function and competency profile, eclectic, where different aspects of the scientific, pedagogical and human being education are, globally, view as important. About access conditions to initial coach education, the director's thinks that all candidates should have access to the coach career (not being necessary experience as player) if they have an age between 18-21 years and possesses specific formal training. They value the secondary education (12º year) as the education entry level. The coach initial education must be carried through sport and the educative system. They value continuous education and emphasise the need of lectures, the frequency of recycling work shops and the observation of coach experts.

Discussion/Conclusions

Sport directors are very important in sport development. Describing their representations about coach education can contribute to enhance sport and coach education. We have to consider, also, the opinions of the different sports agents, to get a broad picture of coach education, contrasting several views, representations and perspectives. This approach is a fundamental step in the coach education and certification process.

SOCCER COACH´S REPRESENTATIONS ABOUT COACH EDUCATION MODELS

Costa, J.P., Rosado, A.

Sport Sciences School of Rio Maior- Institute Polythecnic of Santarém, Portugal

Introduction

This study intends describe soccer coach education in Portugal. We, also, analyse the influence of coaches' demographic variables in their conceptions about initial and continuous coach education. The study describes coach's general demographic characteristics, their general level of education, the self representation of their education courses, their view of coach access conditions to formal professional training and about the entities they see as responsible for professional education and training.

Method

In this study the subjects were 116 coaches. Data gathering was obtained through a questionnaire. An independent "specialist validation" process was undertaken to assure the validity of the instrument. Several measures of fidelity were also undertaken. We confirmed the normality pre-requisites with the Kolmogorov-Smirnov test and the homogeneity of variances with the Levene test. We applied Anova One-Way test with the post-hoc calculations.

Results

Coach's value a multifaceted function and competency profile, eclectic, where different aspects of the scientific, pedagogical and human being education are, globally, view as important. In the evaluation of their formal education, contents, education strategies and the pedagogical level and knowledge of the teachers and instructors were assessed. In a general, the satisfaction levels are satisfactory. Practical component duration was clearly the dimension less satisfactory. About 45% of the participants did not participate in continuous training programmes. About access conditions to initial coach education, coaches thinks that all candidates should have access to the coach career (not being necessary experience as player) if they have an age between 18-21 years and possesses specific formal training. About the entrance education level we verify some dispersion; each group tends to value the educational levels they possess and prefers access conditions that meet its own qualifications. The coach initial education must be carried through sport and the educative system. They value continuous education and emphasise the need of lectures, the frequency of recycling work shops and the observation of coach experts.

Discussion/Conclusions

Coach educational models must consider their opinion about the profession [1]. Describing their representations about coach education can contribute to enhance sport and coach education. In their view, education models must be more diverse and reflexive, accommodating new competencies and looking to develop skills seen, nowadays, as necessary. Formal education must, also, be more qualified and an emphasis on continuous education was seen as fundamental.

PLASMATIC AMINO ACIDIC BALANCE AND DIET SUPPLY DURING CYCLING TRAINING

Merni, F., Faina, M., Bargossi, A.M., Fiorella, P., Posabella, G.

Faculty of Exercise and Sports Science, Italy

Introduction

Structural and functional molecules (enzymes) at roots of life are proteins, the daily protein intake is basic in the sport world.

In the last years food integration with amino acids (AA), mainly branched chain (BCAA), has become of frequent use in the resistance sports too. In fact the BCAA are used by the muscles also for energetic purpose (1,2), therefore BCAA are considered particularly useful during heavy training or race periods.

Our aim is to analyze the relationships among different AA in the plasma, through some systematic controls executed on cycling national Italian team, during various training periods (aerobic or anaerobic) with BCAA supply.

Methods

In a period of 7 month, 11 athletes of the national pursuit team were monitored, through 5 gathering and 5 venous blood samples.

In the 1st two gathering the job was mostly aerobic. A supply of 0.1 [g]∙per [kg] per day of BCAA was provided. A wash out or control period was performed in the month before the 2nd gathering. In the 3rd gathering the training was mixed: aerobic and anaerobic, while in the last 2 gatherings the training was in track and mostly anaerobic.

A 21 AA plasmatic chart has been executed with specific chromatographic techniques (HPLC) on coldly separated plasma.

The blood samples were always executed in the morning, under at least 8 hours of food abstinence and after an easy training day. The blood was collected by 19 gauge needle on Li-Eparine and placed to 4 [°C] Crioplast, centrifuged and the serum was finally frozen to -20 [°C] and analysed.

Pearson correlation, cluster and Factorial Analysis have been used to study the relationships among the AA.

Results

Most elevated correlation coefficients (r) have been found among the BCAA (Leu-Ile .86, Val-Ile .77, Val-Leu .72).

r>70 has been found also between: Thr-Ser .85, Thr-Gln .73, Thr-Met .702, Lys-Orn .73.

r>60 are numerous (12): 5 of them refers to relationship among BCAA and other AA.

Cluster analysis (hierarchical and not) shows 3 defined AA groups:

a) BCAA b) Ser, Thr, Gln, Met c) Lys, Orn, Pro, Cys.

The Factorial analysis, with Varimax rotation, explains 75% of the variance with 4 factors (Fct):

– 1st Fct(25%) introduces elevated saturations with BCAA, Tyr, Ala.

– 2nd (20%) explains the variance of Ser, Thr, Gly, Gln, while Met is saturated with all this 2 Fct

– 3rd (19%) comprises Lys, Orn, Pro, Cys.

– 4th is saturated better with the Phe; while Glu and His are saturates in the 3rd Fct too.

Data projection on factorial axis, varying experimental conditions, show that supply gives unlike results in the BCAA than in other AA like Orn, Lys, Cys. The aerobic or anaerobic training brings to unlike answers for Phe group.

MOVEMENT ANALYSIS OF DEGENERACY IN BASKETBALL SHOOTING AT VARIABLE DISTANCES

Mayer-Kress, G., Chiang, H., Liu, Y.

Penn State University, United States

There are infinitely many ways to shoot a basket, a phenomenon known as "Degeneracy" especially for top players. We are interested in the behavioural origin of this variability under the most simple constrains of the player standing undisturbed at different distances from the basket.

We examined 3 basketball players of different skill levels with 126 clean shots for each player from 21 positions systematically arranged relative to the basket. The angular kinematic data of lower limbs (LL) and upper limbs (UL) were derived from a 3-D motion capture system "PhaseSpace" using 480 Hz sampling rate. A 3-D regression analysis on the 3 lower joints (LJ) and the 3 upper joints (UJ) peak angular velocity showed a higher linear correlations among the LJ compared to the UJ. Further examination of the spatial relation between every 2 joint angles for the UJ and the LJ showed similar results: UJ relations were more variable than their LJ counterpart, and further away from the basket more variability was observed in the UL relations. We conclude that the LL performed a more consistent movement pattern in providing the basic support and strength for the shooting movement whereas the more variable UL movement controls the performance accuracy. The movement degeneracy of the basketball clean shot resides largely in the UL, especially in the coordination between elbow and wrist movement.

EVALUATION OF RAPIDITY IN KARATE

Merni, F., Pecoraioli, F.

Faculty of Exercise and Sports Science, Italy

Introduction

Rapidity is an important ability of many sports, in karate it becomes a performance's conclusive factor and it is important to study this ability. The purpose of this study is to compare groups of karate apprentices with male and female Sport Science Faculty students using general and karate specific tests. We will try to underline the possible differences on reaction time between the expertise levels and also between genders.

Methods

The examined sample contains: 16 males (MS) and 14 females (FS) students, and 6 males (MK) and 5 females (FK) karate apprentices from two clubs. The average ages are (MS 22.4 yr; FS 21.5 yr; MK 20,8 yr; FK 20,4 yr). The average anthropometric data are: weight (Kg) MS 75.5; FS 54.5; MK 77,8; FK 55,8, height (cm) MS 177.8; FS 161.5; MK 178,8; FK 163,6), arm's length (cm) MS 62,8; FS 57,1; MK 61,7; FK 57,0.

The following tests have been used for rapidity evaluation:

1) Drop test, following Lehman's indications, that appraises the contact time (seconds*10-3) on electric footboard on the ground, after a fall of 20 cm.

2) Tapping test to detect of two feet cyclic frequency (Hz).

3) Punch simplex test, that consists of voluntary execution of karate punch technique (gyaco-tzuki) recorded using a punch-bag fitted without stimulus. The punch-bag was hung so that the centre was set at the height of the subject's solar plexus (Layton). The measurement was made in seconds*10-2 from start with photocells and stop with shoot detector.

4) Punch reflex test, an execution of the same technique after a light stimulus.

An independent samples T test was used to discover the significant differences between groups.

Results

Drop test, tapping test, punch simplex don't show significant differences between groups. The average values are:

Drop test 0,160±0,022 s,

Tapping test 11,6±1,3 Hz. Calculating the rapidity quotient, as proposed by Lehmann (QR=tap. freq./drop), the average value is 73,9±12,8.

Punch simplex test 0,479±0,069 s.

Punch reflex test 0,429±0,095 s.

In this case there are significant differences between male experts (0,498 s) and students (0,374 s), and between male and female (0,493 s) students.

Conclusions

The results, particularly in the last test, show that students are faster than experts. Students' better results can be explained thanks to the atypical starting signal and the different movement execution in its preparatory phase. This conclusion agrees to Mori S. et al. statement.

EFFECTS OF ELITE RHYTHMIC GYMNASTICS TRAINING ON VOLUMETRIC BONE DENSITY AND BONE GEOMETRY OF PREPUBERTAL GIRLS AS ASSESSED BY PERIPHERAL QCT

Michopoulou, E., Leontsini, D., Tournis, S., Raptoy, P., Michalopoulou, M., Krekoukia, M., Fatouros, I., Godolias, G., Taxildaris, K., Lyritis, G.

Democritus University of Thrace, Greece

Introduction

Several cross-sectional studies have shown that high impact weight-bearing activity is beneficial for the load-bearing sites of the skeleton (1). Elite female gymnasts favour a low body fat mass and weight for the somatotype required to perform the complex movements associated with the specific sport activity (2). Moreover, prepubertal elite rhythmic gymnastics (RG) athletes are subjected to strenuous physical training and substantial psychological stress that may influence subsequent pubertal development. Although, the impact of intense RG training on growth and pubertal development has been adequately studied (3), it is not clear whether RG affect positively or negatively prepubertal bone geometry as this is assessed by peripheral quantitative computerized tomography (pQCT). The aim of the present study was to study bone geometry in prepubertal RG elite athletes relative to healthy controls.

Methods

This was a cross-sectional study. Tibias of 30 elite prepubescent female rhythmic gymnastics athletes (RG) and 30 age-, sex-, body weight- and height-matched controls (C), aged 10–11 yr, were scanned at midsite by using pQCT to determine volumentric bone density, periosteal circumference, pericortical circumference, cortical thickness, polar moment of inertia, strength strain index. Clinical evaluation included body composition (percent body fat assessed by skinfold measurement), body mass index (BMI), and breast and pubic hair assessment development according to Tanner's stages of prepubertal development. Skeletal maturation was determined by x-ray of the left hand and. Bone age was determined according to Greulich-Pyle standards (14). Data were analyzed with t-test ($P<0.05$).

Results

The two groups had comparable bone age and prepubertal development. There were no differences between groups in body composition and BMI. RG athletes had higher (14%) volumetric bone density, pericortical circumference (9%), cortical thickness (15%) polar moment of inertia (21%) and strength strain index (18%) than that of the controls. No significant differences were noted for periosteal circumference.

Discussion

We conclude that elite rhythmic gymnastics training affects positively the mechanical properties of prepubescent girls bone and this response is related to geometric adaptations.

MOTOR SKILLS AND PHYSICAL PERFORMANCE IN BRAZILIAN WHEELCHAIR BASKETBALL PLAYERS

Zoppi, C.C., Almeida, M., Schwingel, P.A., Sá, C.K.

Faculdade Social da Bahia , Brazil

There are scanty data in literature concerning parathletes fitness level. This situation turns difficult to establish standards that could lead to performance enhancement and comparisons between different training level athletes as well. Purpose: The purpose of this study was to describe some of the main physical characteristics and motor skills that determine athletic performance in wheelchair basketball. Methods: Five male local level wheelchair basketball players (mean ± SD: 45.4 ± 9.6 years old; 73.6 ± 6.6 kg of body mass; 85.4 ± 3,8 cm of seated stature), all of them had more than five years of experience in this sport modality. Voluntaries were submitted to the Wingate test, handgrip measurement, upper body power by medicine ball throwing (2Kg) and performed a shuttle run using each one their own wheelchair. Results: Results are here presented as mean ±SD, maximum and minimum values. Peak Anaerobic Power 420,2 + 80,1 W (Range:504,0 - 334,8 W). Low Anaerobic Power 133,3 + 27,2 W (Range:153,6 and 90,0 W), Total Work 7083,6 + 1291,5 N.m (Range: 8568,0 and 5535,0 N.m), Mean Anaerobic Power 236,1 + 43,1 W (Range: 285,6 and 184,5 W) Shuttle run 17,9±1,6 s (Range: 20,3 and 16,1 s), Right Hand Grip 14,5±1,6 psi (Range: 17,0 and 13,0 psi), Left Hand Grip 13,9±1,9 psi (Range:16,0 and 11,5 psi), Upper body power 4,0+ 0,4 cm (Range: 4,7 e 3,5 cm). Conclusion: Although we had reported here the results from a small size sample, this study presented some preliminary standard data concerning experienced wheelchair basketball players motor skills and fitness level as well. Other statement that arises from this work is the need to enlarge the size of the sample to accurate the values and therefore the comparison standards for wheelchair basketball players.

INFLUENCE OF SPRINT TRAINING UNDER HYPOXIC CONDITIONS ON THE RATE OF MUSCLE OXYGEN CONSUMPTION AFTER MAXIMAL PEDALING EXERCISE

Ito, O., Katsumura, T., Kawahara, T.

Japan Institute of Sports Sciences, Japan

Recently we reported that peak pedaling power output was improved by sprint training in the hypoxic conditions. The purpose of this study was to investigate the hypothesis that hypoxic sprint training improves the rate of muscle oxygen consumption during and after maximal pedaling exercises.

Fourteen male students aged 21.6±0.8 yrs participated in this study. They underwent 10 weeks (2 times / a week) sprint training using cycle ergometer (PowerMax VII, Combi). Seven subjects trained at a simulated altitude of 3000m (14.5%O2) for 8 weeks following 2 weeks training in normoxia (Hypoxic group). The other seven subjects trained in normoxia throughout the period of training (Normoxic group). Peak power output during 15 seconds maximal pedaling exercise tests were measured before and after training. Moreover, oxygenations at vastus lateralis musle during and after tests estimated from kinetics of oxygenated hemoglobin (O2Hb/Mb) and deoxygenated hemoglobin (HHb/Mb) were measured using near-infrared spectroscopy (NIRO-300, Hamamatsu photonics). The rates of muscle oxygen consumption were determined as a gradient of O2Hb/Mb decrease by intermittent arterial hemostasis after pedaling tests.

In normoxic group, peak power output during maximal pedaling exercise tests significantly increased only during initial 2 weeks of training period, whereas they kept on increasing throughout training period in hypoxic group. There was significant difference between groups for increasing ratio of peak power at the end of training (Normoxic group: 3.7 +/- 3.3%, Hypoxic group: 11.5 +/- 4.9%). The rate of muscle oxygen consumption after maximal pedaling test significantly improved by hypoxic training. Furthermore, it was significantly related between peak power output and the rate of muscle oxygen consumption after sprint training. These results suggest that the improvement of the rate of muscle oxygen consumption by hypoxic sprint training would contribute to the increase of peak power output.

TESTS OF PHYSICAL EVALUATION AND PERFORMANCE LEVEL: COMPARISON BETWEEN NATIONAL AND REGIONAL BOXERS

Michielon, G., Scurati, R., Roione, G.C., Longo, S., Invernizzi, P.L.

Faculty of Exercise Sciences, University of Milan, Italy

INTRODUCTION

Several studies in the fighting sports have evaluated the efficiency of a specific training or the capacities of the athletes. Using some "field" evaluation test many authors have studied the explosive force of the lower limbs (Bosco 1985 and 1992, Iglesias 2001), the simple responses to a visual stimulation (Simkin 1969, Zatsiorsky 1971) and looked at tests to evaluate the fatigue condition in the fighting sports (Stercowicz 1995 and 1999, Franchini 1998).

The aim of this study is to compare the results of some specific evaluation test of physical capacities between national and regional level boxers.

METHODS

The study involved 5 national boxers of Italian senior national team (age 22±1.2, height cm 172.8±5.3, weight kg 63.9±4.5, BMI 21.39±1.18) and 5 athletes practicing boxing at lower level in regional-level teams (age 23.2±0.8, height cm 173.6±3.1, weight kg 68.1±4.8, BMI 22.60±1.36).

The athletes were tested in the squat jump test (SJ) and in the counter movement jump (CMJ) by a Microgate Optojump.

Other tests using the Optojump placed on vertical plan were submitted to evaluate the upper limbs. The following measures have been recorded: the response time from a visual stimulation to an execution of a right arm hit (RTR) and of a left arm hit (RTL); the number of hits on 8 seconds (H8); the number of hits on 20 seconds (H20).

In the end a Special Judo Fitness Test modified in boxing techniques was submitted to evaluate the fatigue condition of the athletes. To calculate the index (IND) the heart rate at the end of the test (HRE), the heart rate at 1 minute after the end of the test (HR1') and the number of three-direct-hits executed in the test (JC) have been recorded.

Data were analyzed by the Student's t test ($p<0.05$).

RESULTS

In the lower limbs no significant differences were found between national and regional boxers (SJ cm 28.34±3.1 vs. 29.70±4.7, p>0.05; CMJ cm 29.96±3.6 vs. 32.62±5.6, p>0.05).

Also in the upper limbs no differences were found (RTR ms 281.0±24.9 vs. 303.2±27.8, p>0.05; RTL ms 270.6±27.3 vs. 294.4±23.8, p>0.05; H8 54.0±7.5 vs. 48.6±7.1, p>0.05; H20 133.2±17.1 vs. 115.2±19.8, p>0.05).

In the evaluation of the fatigue condition of the athletes neither differences appear in the index calculated by Special Judo Fitness Test modified (IND 9.10±0.6 vs. 9.67±0.4, p>0.05) nor in the heart rate (HRE ppm176.6±3.0 vs. 176.2±4.8, p>0.05; HR1' ppm 146.4±5.5 vs. 140.8±10.1, p>0.05).

On the contrary the national athletes performed a higher number of three-direct-hits during the test than the regional level boxers (JC 35.6±1.9 vs. 32.8±1.3, p<0.05).

DISCUSSION

From the results it seems that national and regional boxers achieve a similar physical performance, even if the first ones practiced and matched more than the others (27±5.2 vs. 7.7±2.5 training hours per week, p<0.05; 66.8±32.5 vs. 17.2±14.9 matches nr made, p<0.05).

PERFORMANCE EFFICIENCY IN KARATE: A SPECIFIC TEST TO EVALUATE IT IN THE KUMITE

Michielon, G., Scurati, R., Roione, G.C., Longo, S., Invernizzi, P.L.

Faculty of Exercise Sciences, University of Milan, Italy

INTRODUCTION

According to several studies in the karate's kumite the anaerobic metabolism is the main energetic source (Dzurenkova 2000), while according to others it is the aerobic one (Beneke 2004). In the karate's exercises the VO2max, the heart rate and the [La] are moderates (Imamura 2003) and the training induces a little increase of the VO2max (Imamura 1999).

A specific test (SJFT - Special Judo Fitness Test) was proposed by Stercowicz (1995) to evaluate the performance efficiency in Judo.

The aim of this study is to apply and verify a SJFT modified with karate techniques (SKFT) in the evaluation of the athletes.

METHODS

The study involved 20 male subjects practicing karate: 10 black belt and brown belt athletes (age 23.4¬±14.1, height cm 165±9, weight kg 67.2±16.8) and 10 white belt to blue belt athletes (age 21.3±13.0, height cm 165±8, weight kg 67.8±18.2).

The SKFT was conducted following the original protocol of the Stercowicz SJFT, but adapted to karate: the subject has to shuttle and to perform a SanBon Tzuki technique against each of the two athletes placed 3mt to him. Three trials with pauses of 10 sec had to be executed: the first one of 15 sec, the second and the third of 30 sec in length. The heart rate at the end (HRE) and at 1 minute after the end (HR1') were recorded by a Polar T31 heart rate monitor and the total number of combinations (TC) was taken. The SKFT index was then calculated: SKTF index = (HRE+HR1')•TC-1.

Subsequently the heart rate of the athletes in a simulated competition of 3 min of length was recorded (HR3L).

The data analysis has been carried out by the Student's t test (p<0.05).

RESULTS

In the Special Karate Fitness Test, a significant difference between the group of the black and the brown belt athletes and the group of the white to blue belt athletes was found (SKTF index 11.36±0.73 vs. 13.06±1.15, p<0.001).

No significant differences were found between the heart rate at the end of the SKFT and the heart rate after a 3 min long kumite in either group of the athletes.

DISCUSSION

The lower SKFT index in the black and the brown belt athletes shows that the results of the test agree with the level of the athletes and with their performance efficiency.

As no differences between the test and the competition simulation were found regarding the heart rate, we can also state that between the SKFT and the kumite there isn't any difference about the overall workout intensity.

Therefore the SJFT could be employed into karate and the SKFT could be considered as a valid tool to evaluate the performance efficiency in the kumite.

DIFFERENT CONTRIBUTION OF STEP RATE AND STEP LENGTH TO 40M-SPRINT RUNNING PERFORMANCE IN SWISS JUNIOR NATIONAL TEAM SOCCER PLAYERS

Tschopp, M., Hübner, K., Zürcher, S.

Swiss Federal Institute of Sports Magglingen, Switzerland

Sprint running plays an essential role in the performance of soccer1. High sprint running speed is achieved by both a high step rate and long step length2. Little evidence exists to which extent each of these two factors influence running speed over the acceleration phase (0-40m) of sprint running. This may be of particular interest in soccer since most sprint bouts during a soccer game are shorter than 40m. The aim of the study was to determine to what extent step rate and step length differentiate between junior elite soccer players with different sprint abilities in the acceleration phase.

Methods 39 junior elite soccer players (age:17.4±0.8 y) , all members of a Swiss junior national team, participated in the study. A maximal-effort 40m-sprint was performed. Step rate, step length, contact time and flight time were measured with the Optojump Microgate measuring system (Bolzano, Italy). According to their 40m sprint running time, the subjects were divided into quartiles. For data analysis, the fastest group (FG: n=11; 40m sprint time: 5.31±0.12sec; 16.9±0.6y; height: 177.5±4.5cm; body weight: 72.4±5.2kg) was compared with the slowest group (SG: n=10; 5.68±0.07sec; 17.3±0.6y; 183.1±10.0cm; 75.7±11.0kg). Multivariate approach to repeated measures ANOVA with the kinematic variables (average values of every 10m) as dependent variables and group as the independent variable was used for statistical analysis. * p<0.01; **p<0.001

Results Significant effects of group membership were found in step rate (SR)*, contact time** and - trivially - speed**, with the FG having higher speed (highest values: FG 9.05±0.27 vs. SG 8.33±0.10ms-1) and SR (4.82±0.15 vs. 4.53±0.31Hz) and lower contact time (112±4 vs. 125±7ms) values respectively. No differences between FG and SG were found in step length (SL) and flight time. In both groups, speed**, SL** and flight time** increased over the course of 40m. SR** and contact time** decreased significantly. However, there was no change in SR between the first and the second 10m, whereas contact time did not further decrease in the forth 10m-segment. Interaction between kinematic variables and group membership was found in SR and SL. The highest SR in the SG group was found between 0-10m, whereas for the FG it was 10-20m. The FG had a higher increase in SL between the third and the forth 10m-segment. Conclusion Better sprint time in the FG was achieved predominantly by higher step rate over the whole 40m. Higher step rate was linked with shorter contact time. Sprint training should therefore include aspects that generate short contact times and high step rates. Yet, it should be considered that improvement in sprint running by increasing step rate occurs only if step length does not decrease concomitantly at the same rate, since different sources of negative interaction between step rate and step length do exist2.

ANALYSIS OF THE TEMPORAL AND THE TECHNICAL STRUCTURES EMPLOYED IN JUDO COMBAT BY YOUNG ATHLETES AT REGIONAL AND NATIONAL LEVEL

Scurati, R., Michielon, G., Roione, G.C., Longo, S., Invernizzi, P.L.

Faculty of Exercise Sciences, University of Milan, Italy

INTRODUCTION

In literature several studies have analyzed the techniques and the tactics in fighting sports and in judo (Rossi, Nougier 1996; Sterkowicz, Maslej 1996; Mauro, Invernizzi et al. 2001, Invernizzi, Roione et al. 2005).

The aim of this study is to compare the temporal and the tactical conducts employed during the judo combat by young athletes in competitions at regional and at national level.

METHODS

10 national-level and 15 regional-level competitions of young Cadets athletes (weight 66 kg.) have been video-recorded by camcorders located according to the Sterkovicz protocol (1996). The video-recordings of the competitions have been subsequently analyzed and the following data were obtained from: some temporal parameters such as Attack Length (AL), Attack Frequency (AF), Rest among Attacks (RA); some technical parameters such as Number of the Standing Techniques (NST) and Number of Techniques on the Ground (NTG).

Surveys have been carried out during an interval of 4 minutes (the whole competition).

The results have been compared by the Student t-test ($p<0.05$).

RESULTS

By comparing the mean results of the temporal structures of the combat we can observe a higher attack length in the regional-level competitions than in the national-level competitions (ALregional = 10.3±0.7 sec vs. ALnational = 6.4±0.4 sec, $p<0.001$).

Also the attack frequency is higher in the regional-level competitions than in the national-level ones (AFregional = 5.1±0.5 vs. AFnational = 4.2±0.4, $p<0.01$).

On the contrary, the rest among attacks is lower in the regional-level than in the national-level competitions (RAregional = 7.6±0.6 sec vs. RAnational = 9.3±0.7 sec, $p<0.001$).

Referring to the technical structures of the combat, the mean number of the standing techniques is higher in the regional-level competitions (NTSregional = 5.6±0.5 vs. NTSnational = 4.6±0.6, $p<0.05$).

No differences were found in the number of the techniques on the ground.

DISCUSSION

The results obtained might be indicative of the inclination for more instinctively of the young regional-level athletes (higher frequency of the attacks, less rests, higher length of the attacks). Moreover from the video analysis, they seems not much schemers and often to perform randomly the technical actions without careful precision and efficiency. Otherwise the data seems to indicate that the national-level athletes have a different approach to the competition. They show to be highly aware of the tactical and strategic components of the competitions and to have a more qualitative combat.

PROFESSIONAL COMPETENCE IN ORIENTEERING

Carvalhinho, L., Bento, P.

Sports Sciences School of Rio Maior - Polytechnic Institute of Santarêm, Portugal

Summary

Introduction and Objective

This study was carried-out, in the field of Outdoor Sports Activities and the objective was to study the opinions of the technicians in Orienteering with respect to their professional competence, their expectations for advancement opportunities and the ongoing development/recycling of their professional knowledge and abilities.

Methods

The sample was made-up of 20 individuals Orienteering activity, according to their experience. To obtain the data we used open-interviews and semi-structured interviews. We used the content analysis method, selecting the information by means of semantic logic. In dealing with the data, we used descriptive statistics as well as comparative statistics to verify the significant differences among the various groups in the sample. In this case, we used the Chi-Square (Fisher's) statistical technique.

Results

In this activity, we verified there are no significant differences among the groups, in relation to the professional competence (0,107«P«0,500). However, in relation to their expectations for advancement opportunities and ongoing development/recycling of their professional knowledge and abilities, there are significant differences (0,001«P«0,050) among the groups in the study.

Conclusion

In general, we can conclude that despite their differences in terms of professional experience, there is no difference in opinion among the sports technicians in the area of Orienteering.

However, in relation to their expectations for advancement opportunities and ongoing professional development/recycling, there is a tendency in the group of the more experienced technicians to give more importance to the recycling and up dating of their knowledge.

FEEDBACK IN SWIMMING BY MEANS OF A SUBAQUATIC CHRONOMETER

Pérez, P., Llana, S.

University of Valencia., Spain

INTRODUCTION. Coach-swimmer communication during training is a very difficult task if compared with other terrestrial sports such a basketball or volleyball. In these sense, numerous studies indicate the importance to provide real time feedback for technique improvement (Sanderson & Cavanagh, 1990; Mendoza & Schollhorn, 1993). The aim of the present communications is double: first, to present a new sub-aquatic chronometer system that provide real time feedback without interfering with swimmer's execution and applications to swimming training, second, to evaluate if feedback that chronometer provide is better than other manner employed by coach-swimmer. METHODS. A) Its developed a sub-aquatic chronometer system that it consists on a leds screen (water resistant) installed on the bottom of the pool, so that swimmers can see it every time they perform a turn. The chronometer is connected to a PC by means of a telemetry system without cables, which permits register lap times and provide feedback to swimmers easily. All system works with a small battery, installed outside of swimming pool. B) Feedback tests: Six swimmers of national level perform the tests. In this study was compared the feedback provided by the sub-aquatic chronometer with "coach feedback" and "no feedback" condition to control swimmer race pace in aerobic and anaerobic threshold speeds. RESULTS. Results show little dispersion on lap time with chronometer feedback at aerobic race pace. At an anaerobic threshold race pace, dispersion was similar between "coach feedback" and chronometer feedback, and a little more dispersion in "no feedback" condition. DISCUSSION. Results shows the utility of the new training system, since dispersion on lap times with it are little than with traditional feedback or without feedback. In addition, coach-swimmer can have registered all swimmers time automatically to analyse the race pace control. REFERENCES: 1) Mendoza, L. Schoellhorn, W. INFLUENCE OF SAMPLING RATE ON THE EVALUATION OF ACCELEROMETRY DATA OF CHILDREN

Ruch, N., Mäder, U., Rumo, M.

Swiss federal Institute of Sports Magglingen, Switzerland

Introduction

The objective measurement of physical activity (PA) in free-living individuals is essential for the estimation of the PA - health outcome relationship. Accelerometry is known as a valid and reliable system to measure PA in adults as well as in children. Although the issue of sampling rate has not been studied in adults, the use of cut-off points based on 1-min sampling mode may be inappropriate in children and may result in underestimation of PA. The aim of this study was to determine the effect of accelerometer sampling rate on PA measures in children.

Method

25 girls and 21 boys (age: 11±1 y, weight: 39,1± 8.1 kg, height: 1.49±0.09 cm) were included in the study. They wore hip-placed accelerometers with a sampling rate of 1 s for seven consecutive days. Activity counts were subsequently reintegrated into 60-s intervals and classified as either low, moderate, vigorous as well as moderate and vigorous (MVPA) using a children MET prediction equation.

Results

Daily accumulated time classified as MVPA was significantly lower in 1-s than 1-min sampling mode (1-s: 126±23 min, 1-min: 137±35 min). Time spent in moderate activity was significantly lower in 1-s than in 1-min sampling mode (1-s: 87±16 min, 1-min: 119±32 min), while time spent in low (1-s: 683±49 min and 1-min: 671±58 min) and vigorous (1-s: 39±12 min and 1-min: 18±12 min) activities was significantly higher in 1-s than 1-min sampling mode.

Discussion

In comparison to the 1-s sampling mode, the integration over 60 s leads to a significant under-representation of high- and low-intensity activities and to a significant over-representation of moderate-intensity activities. Therefore, sampling mode should be chosen accordingly to the questions to be studied. Further studies should quantify the differences in the estimation of PA between sampling modes in adults.

DEVELOPMENT OF HEALTH PROMOTION SYSTEM BY THE COMPUTER ADAPTED TEST

Nanba, H., Nakano, T., Hasebe, K., Nishijima, T., Kuno, S.

University of Tsukuba, Japan

Background: The health promotion is expected for the prevention of metabolic syndrome and bedridden. It is important that many people practice health promotion, and that the health system is developed. The mechanism of our health promotion system is that the assessment of physical fitness level for individual by using CAT (Computer Adapted Test) based on IRT (Item Response Theory), the prescription for the motor program suitable for the individual, and in recurring, the effect of the motor program is confirmed. The purpose of this study is to develop the health promotion system based on the EBH for many middle and aged people. Methods: The questionnaire survey on physical fitness was carried out for general and healthy man and woman of 485 persons (40～88-year-old). The questionnaire content is consistent of 63 items on physical fitness in the daily life. And, physical performance test of 6 items were doing to man and woman of 128 persons (40～79-year-old) of the inside which replied in the questionnaire for the validity of the questionnaire. For analysis of item characteristic curve, we used a two-parameter logistic model. Test characteristic was calculated by Test characteristic curve and Test information function. Results: Sixty-three items of the questionnaire were classified into 4 regions by the factor analysis. They were active physical fitness, body function of daily life, coordination, and, flexibility. Between total physical fitness evaluation according to the questionnaire and physical fitness score of the field physical performance test, there were significant correlation both man and woman, respectively r=0.76 (p<0.001)and r=0.66 (p<0.001). Between coordination according to the questionnaire and 10 m obstruction walking, the correlation coefficient was r=0.65 (p<0.001). Between flexibility according to the questionnaire and performance test of flexibility, the correlation coefficient was r=0.57 (p<0.001). We made the computer adaptive test based on these results. In addition, we were made to develop to system of the health promotion. The physical fitness age was calculated from physical fitness level (θ) by CAT. The 10 stage evaluation was respectively calculated from result of the above-mentioned 4 regions. A risk of the lifestyle habit illness was expressed by body composition measurement by the impedance method and the physical activity quantity by the pedometer. The prescription program is consistent of aerobics and strength training. It is being made from physical fitness evaluation by CAT, body composition, physical activity quantity, age, gender and so on. Conclusion: This study was shown that the physical fitness evaluation based on IRT was moderate appropriate for a wide age group in the 40～79-year-old. We made algorithm for CAT based on IRT and developed health promotion system. The development of this study is to clarify effect and problem of the practical application of the health promotion system made.

2-YEARS FOLLOW-UP DATA OF DIFFERENT WALKING TECHNIQUES TO IMPROVE CARDIOVASCULAR RISK PROFILE IN DYSLIPIDAEMIC POSTMENOPAUSAL WOMEN

Laqué, M.K., Becker, S., Knigge, H., Montiel, G., Predel, H.-G.

Institute of Cardiology and Sports Medicine, Germany

The menopause is associated with the development of cardiovascular (CV) risk factors leading to an increased prevalence of the "postmenopausal metabolic syndrome". Hereby lack of physical activity is at the centre of attention. Therefore, postmenopausal women (PW) turn out to be the largest physically inactive demographic population group (1). Furthermore, exercise capacity constitutes a strong predictor for cardiovascular disease.

This study evaluates the long term effects of different walking techniques (WT) and a combined dietary modification on the plasma lipid-(LP) as well as on the overall CV risk profile and on the exercise capacity of physically inactive PW with dyslipidaemia.

27 PW (age: 56,5±5,6 yrs, weight: 73,1±12,5 kg, BMI: 26±3,8 kg/m2, BP: 130,4±12,3/83,9±8,7 mmHg, T-C: 266,2±53,7, HDL-C: 60,1±15,2, LDL-C: 177,9±40,7, TG: 146,9±67,7 mg/dl) were randomised and divided in one walking-, one power- and one nordic-walking group. A 16 week walking programme was supplemented after the 12th week by a dietary modification. CV risk factors were determined at the beginning (V1), after 12 (V2), 16 (V3), 48 (V4) and 96 (V5) weeks. No lipid lowering medication was taken two weeks before and during the study. A walking test (2) examining the exercise capacity (V1), (V3), (V4), (V5) was applied as well as a bicycle ergometry test (BET) investigating the physical performance (V1), (V2), (V3). Training (4x 90min/week) was set at 2.0 mmol/l lactate level in each group and controlled by the training heart rate. Following the study (V3) the PW were advised to continue the walking training.

The results of the CV risk factors at V1-V5 showed no group differences. Walking time decreased from 3,5x75 (V1-V3) to 2,5x67 min/week after two years (V5). In V2 and V3 weight, BMI, BP, T-C, (p<0,01) as well as LDL (p<0,05) were minimized. Additional, dietary modification had no significant influence.

From V3 to V4 BMI (p<0,05) and BP increased (p<0,01). Also enlarged were weight (p<0,05), BMI, BP and TG (p<0,01) from V3 to V5. By contrast HDL-C improved from V3 to V4 and to V5 (p<0,01). Thus, only LDL-C remained reduced (p<0,05) (V5).

The walking test demonstrated an improved exercise capacity without group differences after the study (V3), after one (V4) and after 2 years (V5) (p<0,01). The relative physical performance at 2.0 mmol/l increased during the BET from V1 to V3 in all groups (p<0,01).

All WT (3,5x75 min/week) effectively improved the LP and reduced the overall CV risk. Walking duration of 2,5x67 min/week proved to be not sufficient enough to normalise the LP as well as the CV risk profile. Nevertheless, exercise capacity remained improved by the various WT applied.

A life-style intervention based on regular aerobic exercise performed by different WT, constitutes an effective non-pharmacological therapeutical option for PW with increased CV risk.

LONGITUDINAL ANALYSIS OF WEIGHT TRAINING INJURIES IN DE NEISS DATA BASE

Morencos, E., Benito, P.J., González-Gross, M., Calderón, F.J., Díaz, V., Martín, C., Peinado, A.B.

Politecnical University of Madrid, Spain

INTRODUCTION

It has been estimated that there were 26831 health clubs, with a total of 41.3 millions of members in the USA in 2005 (1). The aim of this study was to analyse the Wt-related injuries rates (IR) and type of Wt equipment that produces the highest (IR).

METHODS

Estimates of injury (I) trends, products related to the I, primary diagnosis, anatomic location, I severity, descriptions of the emergency departments visit and a brief narrative of the I incident between January 1, 2002, and December 31, 2004, were obtained from the National Electronic Injury Surveillance System (NEISS) database (product code 3265) (2). The IR were analyzed per 100000 subjects for Wt by age-group (Ag) and gender.

RESULTS

From 2002 to 2004, the NEISS identified 6007 cases (1279 women and 4728 men). In an attempt to extrapolate these data for all the USA, the total estimated number of Wt-related cases has been set in 218864 (47274 women and 171590 men), only for the year 2004 it accounts for 70379 cases, a 17,2% higher than in 1998 (60039 cases).

Mean IR per 100000 subjects by Ag for males and females, respectively, are: 0-4 years (40.6 and 76.9), 5-14 years (115.6 and 172), 15-24 years (338.4 and 231.3), 25-44 years (330.8. and 279.2), 45-65 years (80 and 122), Ag of +65 (13 and 20.4). In the analysis of the equipment involved in the incident, 87.3% was attributed to an unspecific category called "Wt". The 6.4% of the accidents occurred with barbells, 4.8% with dumbbells, 3.1% with benches, 2.0% are related to machines, 1.3% were due to different elements of free weight equipment.

DISCUSSION

Through the studied period, all the IR increased for all Ag. This could be explained, partly, because of the 8.7% increase in the US population, between 1998 and 2004. We do not have data about the specific Wt population increment in this period, phenomenon that could explain the spectacular IR increment in comparison with the data obtained by Jones et al. (3) in their study. In our data, as in others, the Ag 15-24 years has the highest IR. In contrast to the Jones´ study were there is a decline in the IR in the 25-44 Ag, our data indicate that the rates keep balanced in men and increase in women. This could be due to the continuity in the training of the subjects that in 1998 were part of the 15-24 years Ag.

CONCLUSION

The information presented about the way the I happens is really useful for the professionals of this area. But the fact that an 82.4% of the information is attributed to the unspecific "Wt" does not contribute with substantial information.

REGULARLY PERFORMED SWIMMING EXERCISE DOES NOT INDUCE INCREASE OF BASAL METABOLIC RATE ASSOCIATED WITH SOFT LEAN TISSUE MASS IN POSTMENOPAUSAL WOMEN

Usui, C., Miyatani, M., Sanada, K., Miyachi, M., Tabata, I., Higuchi, M.

Waseda University School of Human Sciences, Japan

Introduction: Basal metabolic rate (BMR) accounts for 60～80% of daily energy expenditure and is influenced of various morphological and physiological factors. However, it is not known whether regularly performed swimming exercise induces an increase of BMR which is related to fat free mass (FFM) such as internal organs and skeletal muscles in postmenopausal women. Purpose: The purpose of this investigation was to examine the relationship between BMR and body composition in postmenopausal female swimmers using the cross-sectional design. Methods: A total of 52 Japanese women aged 50-75 yr who were either less or well swimming trained were studied. Systemic and regional body compositions were measured by dual-energy x-ray absorptiometry (DXA). Soft lean tissue mass (SLTM) was calculated from FFM and bone mass (BM). Peak oxygen uptake (VO2peak) was determined by using a graded exercise test on a treadmill. BMR was measured after subjects had fasted 12-hr. Upon arrival at the laboratory in an early morning, the subject rested for over 30 min to reduce previous disturbing influences, and BMR was assessed by collecting expired gases in Douglas bags during 20 min (10 min×2 times), and analyzed O2/CO2 by mass spectrometer. The data are presented as the mean ± SD. Statistical analysis was performed using unpaired t-test. And, a stepwise multiple linear regression analysis was used to determine which body constituents were associated with BMR. Statistical significance was defined as $p<0.05$. Results: There were no significant differences in age, height, weight and years since menopause (YSM) between the two groups (Less-trained group (LT): n=24, Age 63.3±5.9yr., Ht 154.3±5.6cm, BW 56.5±4.9kg, %fat 31.6±4.2%, YSM 13.0±7.5yr., Well-trained group (WT): n=28, 61.3±5.9yr., 154.2±5.7cm, 54.2±6.7kg, 28.4±4.6%,12.1±7.0yr.). VO2peak was significantly higher in WT compared with LT (31.0±5.6 vs 26.5±4.7ml/kgBW/min, $p<0.01$). Whole body fat mass (FM) in WT was significantly lower than in LT (15.6±3.8 vs 18.0±3.4kg, $p<0.05$). No difference was observed in FM of head and trunk between the two groups. FM of limbs in WT was significantly lower than in LT (6.9±1.8 vs 8.1±1.3kg, $p<0.01$). However, there were no significant differences in SLTM of whole body and different regions between the groups. No difference was observed in BMR between the two groups (WT vs LT: 1087±94 vs 1082±101kcal/day, 20.3±2.2 vs 19.2±1.7kcal/kgBW/day, 30.7±2.4 vs 30.5±2.5kcal/kgSLTM/day, respectively). In the results of multiple-regression analyses on BMR (dependent variable) with body constituents (independent variables), significant independent variable was only Head & Trunk SLTM (BMR(kcal/day)=30.7×(Head & Trunk SLTM)+440, $R2=0.355$, SEE=78.0, $p<0.001$). Conclusion: The present investigation provided the evidence for suggesting the possibility that long-term regularly performed swimming reduces FM and enhances aerobic capacity in postmenopausal women. However, this study also suggested that regular swimming exercise can not induce a large increase of SLTM highly associated with BMR.

IS COMPETITIVE SWMMING A SUITABLE VEHICLE TO ACHIEVE HEALTH BENEFITS?

Rivero, O., Sarmiento, L.

University of Las Palmas de Gran Canaria, Spain

Introduction.

Swimming has always been perceived as a healthy and complete sport. This is due to both the environment where it is practiced and the whole participation of the body.

Since water is a hipogravitatory means, it is a suitable environment for therapy treatments as it releases both muscular and skeletal structures of tension. A body completely immersed withstands nearly the 3% of their total weight (1).

However, the obtention of positive or negative health results depends on the sort of activity developed in it. When a swimmer is involved in high-milleage and long hours of training required in modern competitive swimming, chronic overuse of the shoulder, neck, back and knees may lead to a troublesome cycle of pain, inflammation, tissue injury, and more pain (2).

Richardson y Miller (3) believe that despite being practiced in a hipogravitatory environment, competitive swimming is a "spine-intensive" activity because it requires the extension and twisting of the neck and lower back.

Therefore, Is the competitive swimming a suitable vehicle to achieve health benefits?

Material and methods.

Participants were young swimmers aged between 11 and 18 (21 female and 19 males). 87.50% of those had been competing for 3 years. Data were collected by means of a multiple-choice questionnaire about the reason that led them to practice swimming, as well as their pathologies.

Results.

Most of the poll's respondents (62.50%) perceived swimming as a complete sport. In fact, 55% believed that swimming is a suitable sport to improve health condition. 40% of the polled swimmers suffer some type of pathology, and the spine problems are represented by a 62.50% in this group.

43.75% of the young with health problems needed medical attention. Swimming was the recommended therapy, specially for those with back problems (71.43%).

Conclusion.

This study shows that parents, swimmers and doctors perceive swimming as a sport which provides health benefits: that is the most important reason for the swimming practice.

However, most people who go to swimming under medical recommendation join competitive swimming teams or unsuitable aquatic programs for their pathologies. Those practices have no benefits in case of the back problems as the on going pain shows.

THE RELATIONSHIP OF CARDIORESPIRATORY FITNESS VERSUS SELF-REPORTED PHYSICAL ACTIVITY WITH BLOOD PRESSURE, BODY MASS INDEX AND WAIST CIRCUMFERENCE IN MIDDLE-AGED MEN AT RISK OF METABOLIC SYNDROME

Scott, A.T., Woolf-May, K., Swaine, I.L.

Canterbury Christ Church University, United Kingdom

Introduction: The metabolic syndrome is a cluster of cardiovascular disease risk factors and is characterised by hypertension, insulin resistance and dyslipidaemia in the presence of abdominal obesity (Reaven, 2002). Furthermore, individuals with low levels of physical activity and low cardiorespiratory fitness (CRF) are more at risk of metabolic syndrome. However, whilst CRF can be objectively measured physical activity levels are often self-reported, thus introducing subjective error to the measurements. The purpose of this study was to explore the relationships of both CRF and self reported physical activity (SRPA) with blood pressure (BP), waist circumference (WC), waist hip ratio (W:H) and (BMI) in middle-aged men at risk of metabolic syndrome.

Method: Twenty one men with a mean age 52.33 ± 7.53 yrs, height 1.79 ± 0.05 m, body mass 93.01 ± 13.22 kg and waist 104.07 ± 10.23 cm participated. Height and body mass were measured using a stadiometer and beam balance scales, respectively (both Seca), and BMI was calculated. WC was measured at the level of the umbilicus and hip circumference was measured at the largest circumference of the hips above the gluteal fold to calculate W:H. Blood pressure was measured using an aneroid sphygmomanometer (Accosson) and stethoscope. CRF was predicted from submaximal heart rate and oxygen consumption values using age-predicted maximum heart rate (220-age), which were collected during a modified Stanford protocol on a treadmill (HP Cosmos) by an online gas analyser (Oxycon-Pro). SRPA was assessed using a 7-day recall questionnaire (Sallis et al. , 1985). The relationships between CRF, SRPA and BP, WC, W:H and BMI were explored using Pearson's product moment bivariate correlation.

Results: CRF correlated with SBP (r=-0.493; P=0.023), BMI (r=-0.481; P=0.027), and WC (r=-0.586; P=0.005), whereas no such associations existed for SRPA and SBP (r=0.309; P=0.198), BMI (r=0.296; P=0.218) or WC (r=0.207; P=0.396).

Conclusion: These findings indicate that CRF is significantly associated with BP, BMI and WC in middle-aged men at risk of metabolic syndrome, whereas SRPA is not. This may be because SRPA does not accurately reflect the quantity and/or quality of physical activities that this population performs.

EFFECTS OF EXERCISE ON FAT OXIDATION RATES IN OBESE CHILDREN

Zunquin, G., Theunynck, D., Sesboue, B., Arhan, P., Bougle, D.

Université du Littoral, CHU de Caen, France

Some of the benefits of performing regular exercise, such as decreased insulin resistance, reduced hypertension, and reduced plasma low-density lipoprotein concentration, are likely to be related to enhance fat oxidation. This effect could be direct by adaptations in fat metabolism pathways or indirect reducing fat mass. So regular exercise training has been included in rehabilitation exercise protocol in obese individuals to improve fat oxidation and diminish the consequences of obesity. Previous studies have shown that during puberty, children utilize less and less fat as substrate oxidation during exercise at similar relative intensities. PURPOSE: We investigate effects of

one year follow up (exercise training 2h/week at 45% of peak of VO2) on substrate oxidation during exercise. METHODS: 15 obese pubescent (6 prepubertal PP: BMI= 24.9±3.1, Z-score=5±2.5; 9 pubertal P: BMI=26.41±3.3, Z-score= 4±1.3) underwent an incremental cycle ergometry test (20 Watts increments, 3,5 min intervals) to exhaustion with measurements of breath by breath gas exchange and heart rate before and after one year follow up. Fat rates were determined from indirect calorimetry during the 30 seconds of each stage as described previously by Achten (2001) and expressed per kilogram lean body mass (LBM). Body composition was assessed by DEXA. RESULT: When the fat oxidation rates are reported to LBM, fat oxidation rates are identical after one year follow up. Maximal fat oxidation rates occured at the same relative intensity than before follow up (PP: 48.7±1.03% vs 48.2±1.2 %; 47.2±1.2% vs 46.9±1.1%) CONCLUSIONS: This exercise protocol is applicable to obese children for examining fat oxidation rates and permits to save fat oxidation rates which are decreasing during pubertal period.

DIFFERENCES IN DAILY ACTIVITY LEVELS, DIETARY INTAKE, AND BODY COMPOSITION IN PRIMARY SCHOOL CHILDREN WHO WALK TO AND FROM SCHOOL COMPARED TO THOSE WHO TRAVEL BY CAR

Ford, P.A., Bailey, R., Coleman, D., Swaine, I.L.

Canterbury Christ Church University, United Kingdom

BACKGROUND: Evidence suggests that walking to school may contribute to increasing activity levels and elicit health benefits in children. Although previous studies have measured effects on activity, no studies have assessed the effects of walking to and from school on body composition and dietary intake. The purpose of this study was to combine these variables to measure differences in primary school children who walk to and from school compared to those who travel by car.

METHODS: 239 participants (125 boys and 114 girls) took part in this cross-sectional study. Mean age (±SD) was 8.0 (2.0) years. Body mass and statue were 30.0 (8.6) kg and 1.31 (0.1) m respectively. Two groups were studied: children who travel to and from school by car (C), and children who walk to and from school for periods >10mins more than 3 times a week (W). Activity levels were measured using MTI accelerometers. Participants wore the monitors from 7am to 9pm for 5 consecutive days. Dietary Intake was assessed with a 3-Day Recall Sheet, where participants noted food and drink consumed with their parents' supervision. Calorific intake was calculated using DietMaster Pro v6.0 Software. Body composition was measured using the BodPod Self-Test. Data was analysed using SPSS v13.0, with both parametric and non-parametric differences tests. Significance accepted at $p<0.05$.

RESULTS: Total daily activity levels did not differ between W and C (607.2 ± 169.7 vs. 604.8 ± 169.9 activitycounts.min-1 respectively). W were significantly more active between 8-9am and 3-4pm (917.9 ± 368.7 and 1048.5 ± 346.2 activitycounts.min-1 respectively) compared to C (685.7 ± 222.4 and 839.6 ± 245.5 activitycounts.min-1 respectively). Male W were significantly less active than male C during school hours (596.0 ± 162.3 vs. 685.2 ± 222.1 activitycounts.min-1 respectively). Similarly, junior W were significantly¬ less active than junior C during school hours (569.7 ± 158.1 vs. 634.4 ± 190.6 activitycounts.min-1 respectively). There was no significant difference in dietary intake between W and C (1622.9 ± 410.6 vs. 1705.2 ± 428.1 kcal respectively). There was no significant difference in % body fat and fat mass (kg) between W (16.4 ± 0.7 % and 5.4 ± 0.4 kg respectively) and C (16.2 ± 0.8 % and 5.4 ± 0.4 kg respectively).

DISCUSSION: Our study identifies that although activity levels going to and from school were increased for W, there was no significant difference in total daily activity levels between W and C. Our findings suggest that male C are significantly more active during school hours than male W. Similarly, junior C are significantly more active during school hours than junior W. According to our study, whether primary school children walk to and from school or travel by car, it seems to have little influence upon body fatness and dietary intake.

STANDARDIZATION OF THE WC, WHR, WSR, AND PERCENT BODY FAT AND THE INVESTIGATION OF RELATIONSHIP BETWEEN THEM, AND PHYSICAL ACTIVITY AMONG 30-55 YEAR OLD WOMEN IN TEHRAN

Fathi, R., Gharakhanlou, R., Agha Alinejad, H.

Tarbiat Modares University, Iran

Standardization of the WC, WHR, WSR, and percent Body fat and the investigation of relationship between them, and physical activity among 30-55 year old women in Tehran

Introduction: The prevalence of obesity among societies is the outcome of lack physical activities. Obesity lays the ground for mortality in many facts and it is always remembered as a heath risk factor. Most of researchers recommend the measurement of anthropometric indexes as the easiest method to measure obesity and hence, the risk of cardiovascular and diabetes diseases. The anthropometric indexes of WHR, WC, BMI, WSR and percent body fat are the important and more practical anthropometric indexes .the given anthropometric indexes are influenced by age , gender ,ethnicity , race and culture. The present study aimed at the standardization of the WC, WHR, BMI, WSR and percent body fat and the investigation of relationship between them, and physical activity among 30-55 year old women of Tehran.

Material and Methods: this study was completed over 443 women of 30-55.in order to tally the cut-off points of the anthropometric indexes for subject's descriptive statistics (especially mean, medium , percentile) were implemented parsons correlation analysis was used to look at the relationship between the the given indexes.

Results: And in order to investigatigate the relationship between the given indexes and physical activities, Pearson correlation analysis were run. The results of analysis are as follows. Significant relations were observed between physical activities and WHR, WSR, WC, BMI and percent body fat.

Discussion: The cut-off points of WHR, WC, BMI, WSR and percent body fat were noticeably high among the 30-55 year old women in Tehran.

Conclusions: as a result significant relation and opposite between them and physical activity , this relation with BMI as compared with other anthropometric factors were stronger than this relation with WHR either.

WALKING AND BODY COMPOSITION: HOW MANY DAYS NEED TO CHANGE BODY COMPOSITION?

Jafari, A., Moradi, M., Salimi, A.

Azad University, Iran

PURPOSE: Scientific literature suggests at least 60 min of moderate-intensity physical activity may be necessary to maximize weight loss and prevent significant weight regain (John M Jakicic & Amy D Otto, 2005). For individuals constrained by a busy lifestyle, an exercise prescription that delivers benefits with the minimum investment of days is attractive. The purpose of the present study, therefore, was to

comparing the effect of one, two and three days of brisk walking on some of the body composition factors in over weight sedentary females.

METHODS: Thirty six sedentary Iranian females, aged 38.2± 4.4 yr (M±SD) were randomly assigned to three groups, 12 each, with following walking days per week: One day in the first group, two days in the second group and three days in the third group. Participants took 60 minutes of brisk walking with 50-70% VO2max for 12 week in the walking days. The walking was completed on a treadmill (T 9700 HRT, USA Fitness), which is capable for monitoring heart rates, so that the intensity of the walking can be controlled (e.g., if a participant was trained with at 140 beats/min heart rate (HR), we could adjust treadmill speed and elevation to keep HR at the targeted zone). Body weight, BMI, percent body fat, and waist and hip circumferences were measured before and after the intervention. All participants were asked not to change their eating habits during the intervention period, and food diaries were kept and monitored weekly.

RESULTS: All participants completed the12-week program of exercise. Means (±SD) of pre-test weight, body fat, WHR, BMI in all groups were 69.15±9.7 kg, 32.71±4.6 percent, 0.82±0.065, 26.99±3.4 kg/m2, respectively. ANOVA test showed that there was significant difference among mean variables among three groups after the 12-week intervention. Tukey post-hoc tests showed that it was the third group differing from others. Follow-up paired t-test for the third group indicates the pre- and post-test means were statistically significant ($p<0.05$): Weight, body fat, WHR, and BMI (M±SD) 72/41±10.75kg, 33.10±4.2 percent, .80±.043, 26.73±3.35kg/m2 changed to 68.81±9.86 kg, 30.36±5.3 percent, .78±5.7, and 25.72±3.16 kg/m2) after the intervention. Only third group significantly reduced body weight, body mass index, and percentage body fat and waist circumference ($p < 0.05$).

CONCLUSIONS: Brisk walking for 60 min one or two days a week for 12 weeks could not improve body composition of overweight females. This finding suggests that at least 3 days a week with 60 min of moderate-intensity physical activity is necessary to improve body composition. Many health benefits from physical activity can be achieved if duration and days of training is increased appropriately.

PHYSICAL ACTIVITY AND PREGNANCY OUTCOME. AN OBSERVATIONAL STUDY

Barakat Carballo, R., Rojo González, J.J., Rodriguez Cabrero, M.

School of Sciences of the Physical Activity and the Sport, Polythecnic University of Madrid, Spain

INTRODUCTION

The influence of physical activity and its effects on pregnancy outcome remains uncertain.

Throughout history, recommendations for physical activity during pregnancy have been based more on cultural and social mores than on scientific evidence. (2)

Theoretic concerns arise regarding the effects of physical activity on pregnant women. Objective data on the impact of exercise on women, the foetus and the course of gestation are limited, and results of the few studies in humans are often contradictory. Consequently, the pregnant woman and her physician may be uncertain about the safety of exercise during pregnancy. (3)

There is an urgent need for a scientific information on pregnancy outcomes (maternal and foetal) to both physical and occupational activity. (1)

The aim of this investigation is to know the influence of the physical exercise during gestation in some maternal and foetal pregnancy outcome.

METHODS:

Study desing: a retrospective observational study was used. An extensive questionnaire collected information on different variables.

177 participants provided information about the type, intensity, frequency, and duration of physical activity performed before and during pregnancy.

Pregnancy outcome were collect by perinatal inform:

 Gestational age.

 Maternal weight gain.

 Birth weight.

A structured questionnaire, administered during the participants' postpartum period was used to collect information about medical, occupational, and lifestyle characteristics.

Written informed consent was obtained in the same questionnaire.

For the construction of variables, women were divided in groups related with the developed physical activity, for example:

- Physical activity before pregnancy: 0= Sedentary, 1= Some active, 2= Active, 3= Very Active
- Physical activity during pregnancy (PADP): 0= Sedentary, 1= Active
- Occupational activity (OA): 0= Housewives, 1= Active job, 2= Sedentary job

RESULTS:

We find smaller birthweight and smaller maternal weight gain in pregnant that carried out exercise during the pregnancy that in those that didn't make it.

BIRTHWEIGHT (grs.)

– PADP (Mean):

– Sedentary (N= 87): 3267,30

– Active (N= 84): 3146,96

MATERNAL WEIGHT GAIN (grs.)

– PADP (Mean):

– Sedentary (N= 87): 12101.15

– Active (N= 84): 11544.64

CONCLUSION:

Our results show that the physical exercise during the pregnancy can cause a small reduction of birthweight and maternal weight gain, although these differences are not statistically significant. In relation to the occupational activity and the exercise developed before the pregnancy, seemingly these variables don't have influence in pregnancy outcome.

PELVIC FLOOR IN ATHLETES. A PROPOSAL OF WORK

Rojo González, J.J., Rodriguez Cabrero, M., Barakat Carballo, R.

School of Sciences of Physical Activity and Sport, Spain

INTRODUCTION:

Some of the most important causes in the weakness of the pelvic floor are the impact exercises (jumps, pliometric exercises, etc.) and weight training. This weakness of the pelvic floor has as direct consequence different incontinence types (urinal, fecal).(1)

In that sense, the training of an elite athlete has great quantity of exercises of this type during practically all its sport life.

The aim of this investigation work is to present a program for the invigoration of the pelvic floor in athletes of elite that serves as prevention of future complications.

METHODS:

Our program proposes two phases: one of identification and understanding of the different muscular groups of the pelvic floor and another phase in which series of slow and quick contractions of the musculature of the pelvic floor are included in the athlete's weekly training.

The Kegel exercises are an excellent option for the invigoration of the pelvic musculature. (2, 3)

DISCUSION:

The situation of the elite athletes in relation to the complications of the pelvic floor can be very complex, because to a weak muscular tone of the pelvic area it should unite the invigoration of the other walls that serve as lodging of the organs and viscera, increasing but even the intra-abdominal pressure.

CONCLUSION:

It is necessary to prepare the athlete's body so that during and at the end of their sport life she doesn't suffer the complications of the pelvic floor.

EXERCISE DURING TWIN PREGNANCY. IS IT POSSIBLE?

Rodriguez Cabrero, M., Barakat Carballo, R., Rojo González, J.J.

School of Sciences of the Physical Activity and the Sports, Spain

INTRODUCTION:

Pregnancy is a time of significant changes in the maternal body and systems. From a biological viewpoint, pregnancy is a unique process in which the function of virtually of the body's control systems is modified to maintain both maternal and foetal homeostasis. (3)

Those modifications are duplicated when it is a twin pregnancy.

In that sense, the twin pregnancy has been a cause for no realization of physical exercise. (1)

Nevertheless, some investigation works show that it is possible to develop a program of physical exercise during the twin pregnancy if there are not obstetric complications and the pregnant has practiced physical activity before the pregnancy. (2)

OBJECTIVE:

To value the influence of the moderate and aerobic physical exercise developed during twin pregnancy without obstetrics complications.

METHODS:

A program of moderate and aerobic exercise has been designed, it has been carried out from the week 12 until the week 34 of gestation.

Exercise program consisted on 3 sessions (weekly) of 25 minutes of aerobic and moderate exercise, during the second and third trimesters.

A moderate criteria was observed taking into account a Borg Scale: 10-12, and heart rate no more than 140 lat/min.

All exercise sessions consisted in 7-8 minutes of warm up, 10 minutes of aerobic conditioning and 7-8 minutes of could dawn.

Each session include specific exercises that avoided overextension and exercises performed on the back, avoided hard surfaces when exercising, limit repetitious movements to 10.

Ballistic movements, jumps, extreme stretching, heavy weight lifting were not performed; also warm up and could down were gradually.

RESULTS:

Maternal and foetal pregnancy outcome have been normal in both cases and between normal medical parameters.

MATERNAL

Gestational age: 263 (days)

Weight gain: 14.200 (grs.)

Type of delivery: Normal

FOETAL

Birth weight (grs.):

Boy: 2815

Girl: 2140

Size (cm.):

Boy: 51

Girl: 45

APGAR Test 1 min.:

Boy: 10
Girl: 9
APGAR Test 1 min.:
Boy: 10
Girl: 10
CONCLUSION:
The realization of 3 weekly classes of 25 minutes of moderate aerobic exercise seems not to present a risk for maternal and foetal pregnancy outcome in twin pregnancy.

ISOKINETIC STRENGTH EFFECTS OF WATER-BASED VS. LAND-BASED FITNESS PROGRAMS IN OLDER ADULTS

Carvalho, J. 1, Fontes, S. 1, Soares, J. 2, Mota, J. 1

1Research Center in Physical Activity, Health and Leisure, Faculty of Sport Sciences, University of Porto, 2 Laboratory of Physiology, Faculty of Sport Sciences, University of Porto, Portugal

The aim of the present study was to evaluate the effectiveness of a generalized water-based exercise program (WP) compared to a land-based (LP) on improving knee extensor and flexor isokinetic peak torque of elderly. Thirty-four subjects aged 60 -83 were randomly assigned to control group (C - n= 12, mean age= 69.0±4.9 yrs.; mean height= 1.58±0.1m; mean weight= 70.1±11.5 Kg), WP (n= 10, mean age = 66.0±2.8 yrs.; mean height= 1.60±0.1m; mean weight= 76.9±13.8 Kg and LP (n= 12, mean age= 68.0±5.4 yrs.; mean height= 1.66±0.1m; mean weight= 74.1±10.5 Kg). The training period was 5 months, within 2 sessions per week of 50 min. All subjects were tested for maximal strength of quadriceps and hamstrings on an isokinetic dynamometer (Biodex system 2, USA) at 60º/sec. and 180º/sec. before and after the training period. After an initial exploratory analysis, comparison between groups was performed by an analysis of covariance (ANCOVA). The main results showed significant differences after training on knee flexion of the non-dominant leg at 60º/sec. (50.2±19.2 vs 59.0±18.2 Nm) and knee extension of the dominant leg at 60º/sec. in group WB (96.9±26.4 vs 109.8±30.10 Nm). Further, only in those movements was possible to find a significant difference between group WB and C after training (60ED - 109.8±30.1 (W) vs 92.8±31.8 Nm (C); 60FND - 59.0 ±18.2 (W) vs 44.9±14.5 (C) Nm). No other parameter presented significant alterations after training. The findings of the present study seems to hypothesize that five months, twice a week of generalised training regardless being water-based or land-based was not sufficient to induced marked changes in muscle strength of healthy and active community-dwelling older adults. The lack of significant improvements can be due to different reasons: (i) low workloads; (ii) lack of specificity of the stimulus and (iii) the relative high strength values before the start of the training period or even (iv) the training's frequency.
However, the results of this study should be confirmed by others investigations using more subjects to make possible a more strong analysis between exercise and isokinetic strength relationship in elderly.

PHYSICAL ACTIVITY, BALANCE AND FEAR OF FALLING ON INSTITUTIONALIZED ELDERLY SUBJECTS

Carvalho, J., Pinto, J., Mota, J.

Faculty of Sports, Portugal

Falls are one of the major health problems affecting the quality of life among older adults. Many elderly people experience poor balance and fear of falling. This is sometimes associated with activity limitation; witch has potential adverse health implications. The main aim of this study was to explore the relationship between fear of falling, balance and physical activity in institutionalized older adults. Fifty eight subjects aged 65 or older living in nursing homes participated in the study and was divided according to physical activity (participants' vs non-participants of physical activity programs) and gender. Balance (Performed-Oriented Mobility Assessment - POMA I) and fear of falling (Falls Efficacy Scale – FES) were assessed as risk factors for falls. The occurrence of falls during the 12 months prior to the study was self-reported by participants. After an initial exploratory analysis, comparison between physical activity and gender was performed by respectively, an unpaired student's t-test and Mann-Whitney test. Spearman correlation was used to analyze the association between physical activity patterns and fear of falling and balance. The level of significance was set at $p<0.05$.
The results showed: (i) no significant differences in balance according to gender; (ii) Men reported less fear of falling than women (68.8±15.9 vs. 51.7±23.2; p=0.01); (iii) Active elderly subjects showed significantly higher values of balance (25.7±2.8 vs.18.4±5.7; $p<0.001$) and less fear of falling (69.1±16.5 vs. 48.9±22.4; $p<0.001$) compared to non-participated in organized exercise programs; (iv) a moderate positive correlation was observed between fear of falling and physical activity ($r=0.47$, $p<0.01$); (v) a strong positive association was found between balance and physical activity ($r=0.67$, $p<0.01$); (vi) there was no significant differences between older subjects according to history of recent falls.
We concluded that gender did not influence balance but affects negatively fear of falling. On the other hand, participation in physical activity programs seems to be associated and to have positive effects on balance and fear of falling. Finally, the occurrence of recent falls didn't have great impact on fear of falling.
With regard falls, physical activity programs should be considered as a strategy designed to reduce falling and fear of falling and improve balance in institutionalized older adults.

FLOW VISUALIZATION AROUND A HIGH-LEVEL SWIMMER:COMPREHENSION OF DRAG INFLUENCE

Taiar, R., Zaidi, H., Polidori, G., Houel, N., Valois, Y., Laville, M.

Laboratoire d'Analyse des Contraintes Mécaniques LRC CEA EA3304, Université Reims, France, France

INTRODUCTION: Decrease drag during swimming movement in the aim to improve performance (Taiar and al, 2000) appear like a good research way to discriminate the high level parameters. Our approach was to understand out-flows around a high-level swimmers in order to determine the current lines applied to a swimmer during curling movement.

METHOD

To permit this visualization, the method chosen in this study was the parietal thread, "Surface Tuft Method"(G. Polidori, 1994). We have put threads (10cm length) on the swimsuit each 3 cm. The positions of these flexible threads was between shoulders and knees area and represent the interesting out-flows visualization of the body during movement.

Nine international swimmer's levels took part to the experimentation. The task that they have done was to make some dynamics thrusts to the wall, follow-up of curlings. For the data acquisition, we have used a submarine camcorder and camera. For the data treatment, we used the image software and analyzed frame by frame the swimmers movement. We visualized the current lines around the bodies and we determined three characteristics positions during curling (the highest hips, the hips in the alignment of the body and the lowest hips). Finally, with these pictures, we lied the threads directions to found the parietal out-flows, and the boundary layers' separation.

RESULTS AND DISCUSSION

In the three positions chosen, our results showed that the current lines goes from shoulders to the inside of thighs passing by the hip contour. We observed that the boundary layers' separation was located mainly downstream the hip as well as in the middle of the back and downstream the head. These zones are more or less pronounced according to the swimmer's position. For example, in the position where hips are highest, the boundary layer separation was situated downstream the hips and appear more important than when the hips is lowest. The boundary layer separation had a direct effect on the drag, and therefore on the swimmer's performance. To decrease this drag, it's possible to discriminate the positions where the separation of the boundary layer is late. Swimmer's must assure the perfect dorsal alignment fixation from the neck until knees in order to decrease drag.

DIFFERENTIATION OF THE RISK FACTORS IN AGREEMENT WITH THE LEVEL OF PHYSICAL ACTIVITY

Lima, W.A., Glaner, M.F.

Catholic University of Brasília, Brazil

Several risk factors are associated to the development of cardiovascular diseases as the excess of relative body fat (%F), the accumulated fat in the trunk (%F trunk), arterial hypertension, dyslipidemia, physical inactivity, among others (Grundy, 1998). However, the objective of this study was to verify the risk factors if they differentiate in agreement with the level of physical activity (LPA). The sample for this study was 80 male individuals. The LPA was estimated by the questionnaire of habitual physical activities, developed by Pate (1995), being the individuals classified in four categories: Group 1 (G1)= inactive, Group 2 (G2)= irregularly active, Group 3 (G3)= moderately active, Group 4 (G4)= very active. The other risk factors measured were: systolic blood pressure (SBP), diastolic blood pressure (DBP), abdomen perimeter (AP), enzymatic glucose (EG), total cholesterol (TC), high density lipoprotein (HDL), low density lipoprotein (LDL), triglycerides (TG), %F and %F trunk. These last two were estimated for the dual energy X-ray absorptiometry. The blood was taken after fasting for 12 h and the sanguine analysis was made by the enzymatic method. The groups, by LPA were compared through analysis of variance between groups and Scheffé's test (ap<.05). The results obtained for G1, G2, G3 and G4 were: SBP= 133.0 +/- 12.7; 133.0 +/- 19.3; 130.9 +/- 18.2 and 128.5 +/- 19.6 mmHg; DBP = 90.0 +/- 10.5; 86.5 +/- 14.0; 83.3 +/- 14.0 and 84.1 +/- 17.1 mmHg; APa= 94.0a +/- 3.8; 89.3ab +/- 9.3; 87.9ab +/- 9.1 and 82.9b +/- 10.7 cm; %F= 25.6 +/- 3.7; 21.9 +/- 7.2; 19.7 +/- 7.8 and 17.8 +/- 9.2%; %F trunk= 29.7 +/- 4.9; 23.1 +/- 9.0; 22.5 +/- 9.4 and 19.9 +/- 10.6%; EG= 97.7 +/- 10.7; 93.6 +/- 15.7; 95.2 +/- 9.3 and 95.1 +/- 27.3 mg/dL; TC= 179.5 +/- 27.7; 159.8 +/- 39.0; 161.3 +/- 36.9 and 149.2 +/- 32.2 mg/dL; HDLa= 36.4 +/- 7.5; 41.5 +/- 11.7; 38.1 +/- 9.9 and 46.0 +/- 13.7 mg/dL; LDLa= 114.7 +/- 27.7; 92.5 +/- 35.4; 100.2 +/- 29.7 and 82.2 +/- 29.5 mg/dL; TG= 143 +/- 62.8; 134.1 +/- 59.6; 116.8 +/- 70.1 and 107.9 +/- 64.3 mg/dL, respectively. The individuals from the moderately and very active group apparently presented less expressive mean values for the factors of cardiovascular risk in all the variables, but, this difference was only shown significant for AP, HDL and LDL. However Scheffé's test evidenced differences between inactive and very active individuals in AP. In spite of limited questionnaires to estimate LPA, the obtained results are good indicators as how the physical activity can be beneficial to reduce and/or to control the risk factors for the cardiovascular diseases.

RISK FACTORS BETWEEN MEN WITH POSITIVE OR NEGATIVE FAMILY REPORTS FOR CARDIOVASCULAR DISEASES

Lima, W.A., Glaner, M.F.

Catholic University of Brasília, Brazil

Several risk factors are associated to the development of cardiovascular diseases (CVD), above all, in the individuals that already possess a positive family report (Navas-Nacher, 2001). Therefore, the objective of this study was to verify if there are differences, in the risk factors, among subject with positive family reports (FR+) and negative (FR-) for CVD. The sample of this study was 78 males from which 24 presented FR+ and 54 presented FR- for CVD. The mean body mass and stature were: FR+ = 74.6 +/- 8.8 kg and 169.5 +/- 7.5 cm; FR- = 70.5 +/- 9.2 kg and 167.7 +/- 6.3 cm, respectively. The risk factors measured were: systolic blood pressure (SBP) and diastolic blood pressure (DBP), abdomen perimeter (AP), % body fat (%F), % trunk fat (%F trunk), enzymatic glucose (EG), total cholesterol (TC), high density lipoproteins (HDL), low density lipoproteins (LDL) and, triglycerides (TG). The %F and %F trunk were estimate for the dual energy X-ray absorptiometry. The blood was taken after fasting for 12 h and the analysis was made by the enzymatic method. The groups were compared by Fischer's statistics F (*p<.05). The results obtained for FR+ and FR- were: age 38.0 +/- 10.6 and 34.2 +/- 9.7 years old; SBP*= 138.5 +/- 20.4 and 127.5 +/- 15.9 mmHg; DBP= 88.1 +/- 16.7 and 84.1 +/- 13.1 mmHg; AP*= 92.2 +/- 8.5 and 85.4 +/- 9.6 cm; %F*= 25.3 +/- 7.6 and 18.3 +/- 7.3; %F trunk*= 28.8 +/- 9.0 and 20.1 +/- 8.6; EG= 95.3 +/- 11.4 and 95.3 +/- 19.3 mg/dL; TC*= 181.3 +/- 36.7 and

151.6 +/- 31.4 mg/dL; HDL= 40.4 +/- 10.2 and 41.0 +/- 12.2 mg/dL; LDL*= 112.8 +/- 33.4 and 88.6 +/- 28.5 mg/dL; TG= 139.9 +/- 57.3 and 113.4 +/- 68.6 mg/dL, respectively. The results found indicate that individuals with FR+ should receive larger attention in the primary analysis and in the follow up of these factors that presented significant difference. The age did not explain the differences between the groups once these did not differ statistically. The results demonstrated agreement obtained by Nicklas et al. (2004), which emphasizes that the development of CVD is associated with the genetics as well for bad incorporate habits of the social environment.

PHYSICAL EVIDENCES OF DISEASE RISK FACTORS IN FEMALE EMPLOYEES

Oliveira, F.P., Vigário, P.S., Terra, B., Vieira, R.S., Jotta, B., Rodrigues, C.

Health Promotion Center (HPC) , Brazil

Introduction:Nowadays, obesity is considered one of the most important public health problems being associated with chronic diseases. The World Health Organization (WHO) estimates that there are 300 millions of obese people in the world. In Brazil, according to Health Ministery's data, 32.9% of the population is obese. Besides others projects, Petrobras has created, in 2004, the Health Promotion Center (HPC) for its employees. The project includes all employees that present risk factors and/or chronic diseases, detected on the annual medical evaluation. All employees selected to participate of HPC, are submitted to functional and nutritional evaluations and, from those information, individual fitness training programs are developed.

Objective:The aim of this work was to analyze biochemical's data and body composition of female HPC participants.

Methods:A total of 316 Petrobras' female employees (41±9 years) participated of this sectional investigation. Biochemical's data were obtained from the Medical Service of the company (data available for only 184 participants of this study). The anthropometric method was adopted and Height (cm), Body weight (kg), Skinfolds thickness (mm), Bone diameters (cm), Perimeters (cm), Circumferences (cm) were measured and Abdominal perimeters; Body Fat Percentage (%BF) - obtained from Body Density estimated according to the equation developed by Jackson et al. (1980); Body Mass Index (BMI= weight/Heigth2,kg/m2); and Waist/Hip ratio were studied. Theses parameters were analyzed considering risks of obesity and others diseases.The calculation and descriptive statistics of the variables were performed with the software "Excel" (2002).

Results/Discussion:A high frequency of women presented alterated biochemical's results. An expressive number of women presented high levels of Total Cholesterol (> 200 mg.dl, 64.5%) and high levels of Low-Density Lipoprotein Cholesterol (LDL-C >160 mg.dl, 57.4%). Results of HDL-C, Serum Triglyceride and Glucose were in the normal pattern. It was also verified that 14% of the women presented Metabolic Syndrome (Brazilian Society of Cardiology, 2005 –three or more risk factors). The anthropometric analysis showed that 56.0% (n= 177) of the female have high %BF and 46.5% (n=147) have high BMI (32.6% classified as overweight; 10.5% classified as obesity I and 2.5% classified as obesity II). The other two anthropometric indexes, important for health, analyzed in this study, pointed out for serious alterations: 87% of the woman has abdominal perimeters higher than the expected value for genre and 71.2% presented Waist/Hip ratio pointing to high or very high risk of disease.

Conclusions:The expressive presence of women with alterated biochemical's results and classified as obese is preoccupying because these indexes express potential cardiovascular morbidity and mortality. With the enrollment of these women, in the HPC, these results will certainly improve. Physical activity added to dietary intervention is effective in weight loss and in the improvement of cardiovascular system.

IS PHYSICAL ACTIVITY LEVEL REDUCED IN CHILDREN WITH CHRONIC DISEASES ?

Farpour-Lambert, N.J., Martin, X., Keller-Marchand, L., Trigona, B., Oehrli, M., Schwitzgebel, V., Aggoun, Y., Hofer, M., Beghetti, M.

University Hospitals of Geneva and Lausanne, Switzerland

BACKGROUND: Physical activity may be reduced in children with chronic diseases due to overprotection, social exclusion, low physical fitness, lack of information or pain. However, there is little information about physical activity in this population. OBJECTIVE: To compare the physical activity level of children with type 1 diabetes, obesity, or juvenile idiopathic arthritis with that of healthy children. METHODS: This was a cross-sectional study including 30 children with type 1 diabetes (DIAB, 10.5 +/- 2.3 yr), 32 obese children (OB, 9.5 +/- 1.1 yr), 26 children with juvenile idiopathic arthritis (JIA, 10.0 +/- 2.5 yr) and 122 healthy controls (CON, 9.9 +/- 2.8 yr). We measured the physical activity count and the time spent in light, moderate, hard and very hard activities using an uniaxial accelerometer (MTI Actigraph 7064) worn at the waist during 7 days (24 hours /day), except during aquatic activities. We also assessed past 12-month leisure-time physical activity by the Modifiable physical activity questionnaire for Adolescents, and anthropometrics. RESULTS: Groups were matched for age and height. Obese children had higher body weight (52.6 +/- 14.0 kg) and body mass index (25.2 +/- 5.4 U) compared to other groups. Physical activity count was decreased in DIAB (303.9 +/- 104.2 cpm, p=0.011), OB (308.2 +/- 53.5, p=0.016) and JIA children (316.4 +/- 82.2, p=0.048) compared to controls (361.3 +/- 125.2). There were no significant differences among the three groups with chronic diseases. Time spent in moderate physical activity was significantly decreased in DIAB and OB compared to JIA and CON groups, and time spent in hard activities was reduced in OB compared to CON. Past 12-month leisure-time physical activity was significantly reduced in OB (0.6 +/- 1.1, hours/week, p=0.001) compared to DIAB (4.0 +/- 4.1), JIA (4.3 +/- 3.2) and CON groups (4.2 +/- 4.6). CONCLUSION: Our study demonstrates that children with type 1 diabetes, obesity and juvenile idiopathic arthritis have reduced physical activity levels compared to healthy children. As physical activity is an important determinant of health and quality of life during growth, these children should be encouraged to be more active.

EFFECT OF AN INPATIENT INTERVENTION ON AEROBIC FITNESS IN PATIENTS WITH JUVENILE OBESITY

Knöpfli, B.H., Schätzle, B., Lehmann, M., Radtke, T.

Alpine Children's Hospital Davos, Switzerland, Switzerland

Background: In most patients with juvenile obesity limitations in aerobic fitness occur, especially if the overweight exceeds the age related 98th percentile. Such deconditioning leads to restrictions in the career prospect or even to physical disability. Specific therapeutic exercise is needed to treat those patients. The present study evaluates a 14-month follow-up of an inpatient intervention on aerobic fitness. Methods: 17 obese girls (n=9) and boys (n=8) were tested at the beginning (IN), at the end of an inpatient program lasting 8 weeks (8W), after 6 month post-hospitalization program (6MFU = 6-month follow-up) and again 8 month later (14MFU = 14-month follow-up). They were

13.4±1.8 years old with a body weight of 87.5±19.2 kg and a body mass index of 32.6±4.8 kg/m2 (for all subjects age related percentile >98). The inpatient program was based on a multicomponent treatment and education focusing on nutritional changes, behavioral modifications and physical activity (at least 45 min/day; 50-75% of maximal heart rate; in swimming, walking, hiking, jogging, skiing, and ball games), in which the participants took part in daily organized activities. In addition, patients were encouraged to use active pursuits as part of their daily life in the hospital. A major effort was done in planning for, and monitoring each patient's post-hospitalization program including the identification of a team of health professionals located close to the patient's home. This was done in coordination with the referring health professional. Maximal aerobic power tests were performed on a cycle ergometer. The study was analyzed, using a one-way ANOVA with repeated measurements. Results: VO2max per body weight significantly increased throughout the inpatient program from 26.8±5.2 to 33.1±4.3 ml/min/kg (pIN-8W<0.001). This increase lasted for the whole outpatient period: at 6MFU 33.1±6.5 and at 14MFU 32.0±5.7 ml/min/kg; pIN-6MFU<0.001 and pIN-14MFU<0.001; p8W-6MFU=ns(1.00), p8W-14MFU=ns(0.61). A similar pattern occurred in VO2max percent predicted (IN 58.1±12.3, 8W 71.5±10.1, 6MFU 71.6±13.5, 14MFU 69.7±12.8 %predicted; pIN-8W<0.001, pIN-6MFU<0.001, pIN-14MFU<0.001; p8W-6MFU=ns(1.00), p8W-14MFU=ns(0.76)) as well as relative peak me-chanical power (IN 2.03±0.39, 8W 2.72±0.43, 6MFU 2.82±0.54, 14MFU 2.74±0.56 Watt/kg; pIN-8W<0.001, pIN-6MFU<0.001, pIN-14MFU<0.001; p8W-6MFU=ns(0.64), p8W-14MFU=ns(1.00)). Absolute VO2max as well as absolute peak mechanical power significantly increased throughout the in- and outpatient periods (IN 2333±581, 8W 2470±461, 6MFU 2470±543, 14MFU 2631±440 l/min; pIN-8W=ns(0.34), pIN-6MFU=ns(0.34), pIN-14MFU=0.003; p8W-6MFU=ns(1.00), p8W-14MFU=ns(0.21). IN 173±35, 8W 203±41, 6MFU 213±39, 14MFU 225±45 Watt; pIN-8W<0.001, pIN-6MFU<0.001, pIN-14MFU<0.001; p8W-6MFU=ns(0.40), p8W-14MFU=0.002). Conclusion: A specific therapeutic exercise as a component of a multidisciplinary inpatient program and a comprehensive follow-up outpatient program is a successful method to improve a clinically relevant aerobic deconditioning to an almost normal fitness.

ECCENTRIC ERGOMETRY AS STRENGTH TRAINING FOR ELDERLY SUBJECTS

Havas, E., Purtsi, J., Heiskanen, J., Selanne, H., Vihko, V.

LIKES-Research Center, Jyväskylä, Finland

Purpose: Eccentric exercise has recently been proposed as a feasible and effective method for strength training especially for the elderly. This experiment compared the effectiveness of endurance type eccentric ergometer and traditional strength training emphasized on knee extensor muscles in improving knee extensor strength and functional capacity of the subjects.

Methods: Altogether 72 voluntary subjects (42 females and 30 males, mean age 64 (range 55-78) yrs) completed the study. The subjects were randomized into three experimental groups, traditional strength training (GYM), eccentric ergometer training (ECC) and non-training control (CRTL). The training regimen of the GYM group consisted of 3 sets of 8-12 repetitions (60-80% of 1RM) at four different leg and knee extensor exercises, totalling on the average of 130 repetitions during a single training session. The ECC group trained at motor driven eccentric ergometer by resisting the movement of the ergometer´s pedals. Typically the number of contractions per ECC training session exceeded 1000. Both groups trained 4 first weeks twice a week, and next 6 weeks three times a week. The intensity of each training session was individually adjusted and progressed targeting at RPE values 14-15 in both groups. The CTRL group continued their normal habitual activity. The functional capacity of the subjects was assessed using TUG-test, stair ascending and descending tests, and the main outcome measure of the training intervention was isometric force production of the knee extensor muscles. The measurements were carried out before, after 4 weeks and after 10 weeks of training.

Results: The average number of training sessions completed was 20 (sd 2) in both training groups. The mean RPE value was 14.5 in the ECC and 14.0 in the GYM. The mean duration of the training session in the ECC was 24 min and 58 min in the GYM. There were no significant differences in results any of the functional capacity measurements between the groups, ie. all groups improved the results by 13-17 % during the intervention period. However, the maximal isometric knee extension force remained unchanged (+5%) in the CRTL group, but was equally improved in the GYM group (+15%) and ECC group (+16%).

Conclusion: Eccentric ergometry was as effective as focused strength training program in improving maximal isometric knee extensor muscle force at same perceived exercise intensity. However, the time required per training session for the improved results was less than half using eccentric exercise than it was using traditional (concentric) strength training program. This supports the concept of using eccentric exercise as a feasible and effective training modality in improving muscle strength.

SELF-REPORTED WAKING AND SLEEPING PERIODS VERSUS VALUES ESTIMATED FROM ACCELEROMETRY DATA

Rumo, M., Ruch, N., Mäder, U.

Swiss Federal Institute of Sport, Switzerland

INTRO: Accelerometers are widely used in the objective measurement of physical activity. In order to adequately interpret behavioural pattern concerning physical activity, it is crucial to determine waking and sleeping periods. Globally fixed points of time for getting up and going to bed do not take individual differences into account, so one can rely on diaries or try to estimate sleeping and waking periods from the accelerometry data. Differences between estimated and self-reported time points for rising and sleeping were investigated.

METHOD: Accelerometry data was recorded from 50 individuals (26 males, 24 females; age: 39 ± 11 years) wearing an Actigraph (Manufacturing Technology Inc. (MTI), Fort Walton Beach, FL, USA) for 4 to 7 consecutive days. All subjects had to indicate for each day the time of getting up and the time of going to bed in a diary. 332 valid days were used for the analysis. Counts were recorded minute-by-minute. For each day the longest time period, during which the mean counts over 10 minutes do not exceed 180 were considered to be the sleeping period. The time points estimated in this way were compared to the indications from the diary.

RESULTS: The mean of the time that was reported by the subjects for rising in the morning was 7h58 ± 1h38 and for the time of going to bed 23h07 ± 3h19, the means of the algorithms estimation were 8h14 ± 1h57 and 23h52 ± 12h07 respectively. The differences between the two methods did reach statistical significance.

CONCLUSION: The automated estimation tends to assign later time points to the start and the end of the waking period. The gap between the estimated time of rising and the self-reported one can be explained by the fact that the subject put on the accelerometer short after he / she actually got up. The estimation of the times for going to bed seems to be a harder problem to automate.

METABOLIC SYNDROME AND PHYSICAL ACTIVITY LEVEL IN PREPUBERTAL OBESE CHILDREN

Farpour-Lambert, N.J., Keller-Marchand, L., Martin, X., Trigona, B., Schwitzgebel, V., Aggoun, Y., Beghetti, M.

Pediatric Cardiology Unit, Switzerland

BACKGROUND: Obesity is a major public health problem that is associated with the Metabolic Syndrome, defined by body fatness, dyslipidemia, hyperinsulinemia, hypertension, and low aerobic fitness. Foundation of cardiovascular diseases may appear early in life in this population. OBJECTIVE: To assess the main components of the metabolic syndrome and physical activity level in prepubertal obese children. METHODS: Cross-sectional study including 47 prepubertal obese children and 47 matched lean controls (mean age 9.1 +/- 1.5 years). We measured fasting blood lipids, glucose and insulin levels; body fatness by DXA; 24-hour systolic and diastolic systemic blood pressure; maximal aerobic capacity (peakVO2) by a treadmill test, 7-day physical activity count by uniaxial accelerometer (MTI Actigraph), and anthropometrics. RESULTS: Age, height and pubertal stage (Tanner 1) were similar among groups, however obese children had higher body weight (48.4 +/- 13.6 vs 31.8 +/- 7.0 kg), BMI (25.1 +/- 4.7 vs 16.4 +/- 1.9 U) and body fatness (41.4 +/- 9.2 vs 21.1 +/- 7.4 %). Obese children had lower cholesterol-HDL (1.11 ± 0.26 vs 1.42 +/- 0.32 mmol/l, p=0.001), and higher cholesterol total/HDL ratio (4.12 +/- 1.31 vs 3.21 ± 0.72, p=0.001) and cholesterol-LDL/HDL ratio (2.83 +/- 1.17 vs 2.00 +/- 0.64, p=0.001) compared to controls. Insulin levels (12.0 +/- 6.3 mU/l vs 4.6 +/- 3.2, p=0.001), mean 24-hour systolic (124.7 +/- 14.0 vs 101.8 +/- 18.3 mmHg, p=0.001) and diastolic blood pressure (72.9 +/- 7.1 vs 63.8 +/- 5.4 mmHg, p=0.001) were augmented. Seven day physical activity count (317.6 +/- 57.2 vs 376.5 +/- 119.0 cpm) and VO2peak (35.9 +/- 6.6 vs 44.2 +/- 7.8 ml/kg/min, p=0.001) were reduced in obese children. CONCLUSIONS: Our study demonstrates that main components of the metabolic syndrome appear before puberty in obese children. Therefore, there is an urgent need to develop prevention strategies early in life. The treatment of obese children should include adapted physical activity, to prevent the development of cardiovascular diseases and type 2 diabetes risk factors.

THE RELATIONSHIP BETWEEN THE RESPIRATORY FUNCTION AND MOTOR ABILITIES OF THE ELDERLY

Rozek, K., Ignasiak, Z., Piechura, J., Slawinska, T.

University School of Physical Education, Poland

Because of the growth of life expectancy in all the industrialized countries, the number of elderly people increases. The society of our country is also getting older. Physical ability, which is one of the indexes of human development and health, is not only a popular subject but also one of the main topics of researches on physical culture. The importance of the researches grows while the human physical activity declines and the number of "civilization diseases" rises.

The aim of the research was to present the level of physical fitness of elderly people and to characterize the relationship between motor abilities and some of the chosen functional parameters of lungs.

The research group consist of 72 randomly chosen "students" of the University of the Third Age in Wroclaw – 45 women and 26 men. Among them, 73,1% of the men and 68,2% of the women declared to do some exercises every day.

The following measurements have been analysed: height and weight of a body, BMI, waist to hip ratio (WHR) and results of tests measured with some chosen European Personal Fitness Tests "Eurofit": plate tapping, shuttle run, hand grip, sit and reach, and ball threw. Additionally, the activity of lungs was examined and the following parameters were chosen for analysis: FVC, FEV1, MEF50, and MVV.

The analysis was conducted on the base of basic descriptive statistics and path analysis.

The relationships presented above show that the level of physical fitness has a great influence on basic respiratory parameters, in which the strength of muscles is of a great importance. Therefore the coefficients describing strength abilities are more visible and the values of the anatomic ones are smaller (MEF50).

The initial results of the analysis show that the most significant factors determining breathing parameters are strength abilities and flexibility

Conclusions

1. It was observed that more men than women were physically fit and had more favorable level of activity parameters of the respiratory system.

2. Among all analysed motor abilities, the strongest influence on breathing parameters of lungs had: static strength of hands' muscles and explosive strength of upper limb.

RELATION OF BODY MASS INDEX TO FAT AND FAT-FREE MASS AMONG GREEK CHILDREN

Christodoulos, A., Tokmakidis, S.P., Douda, H.

Democritus University of Thrace, Greece

Introduction

The Body Mass Index (BMI, kg/m²) is widely used as a proxy measure of adiposity. However, it is rather a measure of excess weight relative to height, than excess body fat. Moreover, the interpretation of BMI among children is further complicated by the occurring changes in weight, height and body composition during growth (Horlick 2001). The relatively weak correlations (r<0.6) reported between BMI and body fat among children (Widhalm et al. 2001, Kerruish et al. 2002) underline the need for further research, especially in different subgroups. Thus, the purpose of the current study was to examine the relation of BMI to levels of fat mass and fat-free mass among healthy Greek children.

Methods

128 randomly selected 11-year old children from the greater area of North Attica, Greece, were examined. BMI was calculated for all subjects. Percentage body fat, calculated from two skinfolds (i.e., triceps and medial calf, average of two measurements) (Lohman 1992), was used to measure fat and fat-free mass. These measures were standardized for height by calculating the fat mass index (FMI, fat mass/ht²) and the fat-free mass index (FFMI, fat-free mass/ht²). Pearson correlation coefficients were used to examine the relation of BMI to FMI and FFMI. Stratified analyses examined whether the relation of BMI to FMI and FFMI varied across categories of BMI.

Results

BMI levels were more strongly associated with FMI (r=0.95-0.96) than with FFMI (r=0.58-0.88). Stratified analyses indicated that these associations varied across the BMI-for-age categories. Among children with a BMI <50th percentile (P), BMI levels showed stronger association with FFMI (r=0.73-0.87) than with FMI (r=0.51-0.58). In contrast, among relatively heavy children (BMI ≥85th P), BMI was more strongly associated with FMI (r=0.86-0.89) than with FFMI (r=0.31-0.64).

Discussion/ Conclusions

Our results show that BMI performs well among relatively heavy children, but not among thinner children, indicating that BMI levels should be interpreted with caution. Although a high BMI-for-age is a good indicator of excess fat mass, BMI comparisons among non-overweight children need to be interpreted carefully, as they may be largely due to differences in fat-free mass.

THE EFFECT OF PHYSICAL ACTIVITY ON POSTURAL STABILITY IN OLDER WOMEN

Ostrowska, B.

Academy of Physical Education in Wroclaw, Poland

One of main problems connected with the process of ageing is balance disturbance and higher susceptibility to falls. Therefore, it is vital to identify the risk factors of falls and to control the implementation of intervention programs.

To investigate the role of physical exercise program on postural performance in postmenopausal women we measured postural sway (COP) in 60 physically active and 31 sedentary subjects using a force plate. The recorded data were used for computing measures of the COP dispersion (range, mean velocity and mean radius) and the frequency of the "COP minus center-of-mass" difference (corrective signal) [1]. Physically active subjects have participated in general fitness program for at least 6 months prior to the study with intensity of 2 to 3 one-hour workouts a week.

Lower values of the mean velocity and mean radius in the exercising group ($p<0.05$) indicate their better balance. In the sedentary group we found high correlations between age and measures of the COP: mean velocity ($p<0.001$) and other parameters ($p<0.05$). It means that the sedentary group represents a model of aging characterized by an inevitable decline in neuronal function, while active persons a model of stable optimal neuronal function with age [2]. The combined comparison of measures of the COP dispersion with the frequency of the corrective signal lets us infer that physically active subjects have stabilized their postural performance at an acceptable level, while the sedentary persons cannot effectively overcome the challenge of their deteriorating balance.

To conclude, the results of this study provide evidence that participation in a systematic general fitness program may significantly improve balance and decrease prevalence of falls and subsequent fractures in postmenopausal women.

6-YEAR EVOLUTION OF PHYSICAL ACTIVITY LEVEL OF ADULTS OVER 50 YEARS-OLD

Matsudo, S.M., Araújo, T.L., Matsudo, V.K.

Physical Fitness Research Center from São Caetano do Sul CELAFISCS & Agita São Paulo Program, Brazil

Introduction: physical activity promotion in the community has been the main focus of the Agita São Paulo Program in the State of São Paulo Brazil since 1996. A regular evaluation of the PA level of the population has been performed since the beginning of the program.and has showed that after 5 years of intervention there was an increase of about 2%/yr in the walking involvement. Purpose: to analyze the evolution of physical activity (PA) level in males and females, over 50 years old from a community with a PA program intervention since 1996. Methods: sample comprised 1235 subjects, over 50 years old, men and women, 50 to 88 years-old (62.3+9.10 years-old). Subjects were selected from a randomized sample of population stratified by age, gender, and educational and socioeconomic status from the metropolitan region of São Paulo in the State of São Paulo, Brazil. They were interviewed each year from 1999 to 2005 at home by a trained professional using the IPAQ, 8th, short version. Subjects were classified as: Active: vigorous PA (VPA) performed at least 3d.wk-1,20 min per day; or moderate activity: 5d.wk-1; 30 min per day; or walking 150 min.wk-1; or an accumulation of 150 min.wk-1, 5 times per week of VPA, moderate PA (MPA) and/or walking; Very Active: those who performed VPA >5d.wk-1 and >30 or vigorous 3d.wk-1, 20 min per day plus moderate/walking: 5d.wk-1 30 min per day or 150 min.wk-1. Subjects below that recommendation were considered as Irregularly Active, and those who reported no PA at all were classified as Inactive. Statistical analysis used was Chi square test (X2) and the level of significance adopted was $p<.05$. Results: sample distribution (%) according to PA level from 1999 to 2005 was: a- Sedentary: 20.5 (1999); 25.2 (2002); 17.1 (2003); 14.2 (2004); 19.2 (2005); b-Irregularly Active: 30.0 (1999); 27.0 (2002); 28.2 (2003); 27.2 (2004); 30.6 (2005); c-Active: 42.3 (1999); 44.2 (2002); 50.0 (2003); 52.9 (2004); 45.9 (2005); d-Very Active: 7.3 (1999); 3.5 (2002); 4.7 (2003); 5.5 (2004); 4.3 (2005). Rates of inactive (sedentary) people varied from 14.2% to 25.2%. Considering the groups of active and very active as those who reached the PA recommendation for health, at least 47.7% to 58.4% of the sample through this period got the adequate PA level. Similar distribution was found according to gender. Statistical analysis showed no differences in the distribution of the PA level through the period of 6 years. Conclusion: although an increase in total PA level of the population (specially walking) has been found in this population as a result of the intervention done by Agita São Paulo Program, this increase seems not to be dependent of the population over 50 years-old. The PA profile of people over 50 remained stable during the 6-year period of community intervention.

BASELINE DATA FROM A 2 YEAR SCHOOL-BASED INTERVENTION IN RURAL NORWAY

Resaland, G.K., Mamen, A., Anderssen, S.A., Andersen, L.B.

Sogn & Fjordane University College, Norway

Introduction

256 nine - year - old children (4th grade) (age 9.3±0.3) will participate in a 2-year intervention study of 60 minutes daily physical activity in a rural school in Norway. The reported data are baseline data. According to the Norwegian Directorate for Health and Social Affairs the

fitness and physical activity levels of children in Norway are decreasing. Surveys that have been conducted on 9–15 year old Norwegian children have shown that the body weight has increased 3-4 kg in only 25 years (SEF, 2000). A decline in daily physical activity levels may be a factor contributing to the current obesity epidemic in the world (Saris et al, 2003). Since it is generally accepted that the onset of many chronic diseases lies in early childhood, preventive strategies should start as early as possible (Twisk, 2001). The natural institution where this could be done in Norway is the schools, where all children spend most of their day. The daily physical activity in the intervention will be activities that are fun, exciting, varied and full of play. The purpose of this abstract is to give baseline data and the association between fitness and HOMA score.

Methods

VO2peak was measured directly where the children ran on a treadmill until voluntary fatigue. After an overnight fast, intravenous blood samples were taken to analyse insulin, glucose, triglyceride, total cholesterol and HDL- cholesterol. Body weight was measured to the nearest 0.1 kg using a calibrated electronic scale with the children wearing light indoor clothing. 0.2 kg was subtracted from the result. Body height was measured to the nearest 0.1 cm, with the children standing in an upright position and the face fronted forward. Body mass index (BMI) was calculated as weight per squared height (kg•m-2). BMI were analyzed using the internationally accepted cut-points published by Cole et al (2000).

Results and conclusions

The main conclusions from the baseline data are that boys have significantly higher VO2peak than girls regardless of how it was expressed. The mean values (SD) for fitness were 55.7±7.0 for boys and 49.3±7.8 (ml (kg-1 min-1)) for girls. When using Cole et al's (2000) classification, 15 % of the boys and 25 % of the girls had a BMI score that is classified as overweight or obese. These differences may be due to genetic, behavioural or a combination of factors. Cardio-vascular fitness is recognised as an independent risk factor for CVD. Those belonging to the lowest (worst) quintile of fitness had a significant higher risk of belonging to the highest (worst) quintile of HOMA score ($p<0.05$) compared to the more fit children.

BODY COMPOSITION AS PREDICTOR OF MUSCLE STRENGHT. THE AVENA STUDY

Urzanqui, A. 1+2, González-Gross, M. 1+2, Barrios, L. 3, Ortega, F.B. 2, Valtueña, J. 1+2, Moreno, L.A. 4, García-Fuentes, M. 5, Benito, P.J. 1, Gutiérrez, A. 2

1 Univ. Politécnica Madrid, 2 Univ. Granada, 3 CSIC, 4 Univ. Zaragoza, 5 Univ. Cantabria, Spain, Spain

Introduction

Adolescence is a decisive period in human life in which important body composition changes occur. Increase of total body mass and its relative distribution are mainly related to physical fitness (strength, speed, flexibility and endurance among others), as well as to gender and pubertal development. The aim of this study was to assess the influence of body composition on physical strength in adolescents. The final aim is to obtain a formula to predict this quality in adolescents, together with the setting of standard values which would allow its interpretation.

Methods

A sample of 2477 adolescents (1194 females), aged 13 to 18.5 from the AVENA study was analysed on the left side of the body for the following anthropometric measurements: skinfold thickness (biceps, triceps, thigh and calf muscles, mm), circumferences (arm relaxed, arm flexed & tensed, thigh, and calf, cm), diameters (elbow, wrist and knee cm); also weight (kg) and height (m). The following parameters were calculated: BMI, arm and thigh muscle area and arm and thigh fat mass. Strength was assessed (for both hands and feet) by using three tests included in the Eurofit test battery: standing broad jump test (lower-limb maximal explosive strength), hand-grip test (maximal isometric handgrip strength), bent arm hang test (upper-limb endurance strength). The relationships between strength and body composition have been studied separately for arms and legs. Statistical analysis has been done with SPSS 13.01 for Windows by means of Principal Components based upon Pearson's Correlations and Categorical Principal Components by Optimal Scaling and Stepwise Linear Regression.

Results and Conclusions

Strength increases with age in both genders. There is a negative correlation between fat mass and body strength in all cases. Those parameters inversely related to lower-limb strength are thigh and calf skinfolds and leg fat area, and directly related are height, weight and knee diameter. Handgrip strength measured on the left side is highly related to strength in the right hand ($r= 0.92$; $p<0.01$). It is positively influenced by height, muscular arm area, wrist and elbow diameter, and negatively by biceps and triceps skinfolds and arm fat area. Upper-limb body strength is inversely related to biceps and triceps skinfolds and arm fat area, and directly related to arm muscle area, height, wrist and elbow diameter. In both sexes the difference between flexed-tensed and relaxed upper arm circumference is the best mark of strength. The levels of studied variables (strength and body composition measurements) vary significantly between age and gender groups, but the observed relationships between dependent and independent variables are maintained.

FUNDING

This study was funded by the Spanish Ministry of Health FIS nº 00/0015, CSD grants 05/UPB32/0, 109/UPB31/03 and 13/UPB20/04, the Spanish Ministry of Education (AP2003-2128), and grants from Panrico S.A., Madaus S.A. and Procter and Gamble S.A.

REVIEW OF SCIENTIFIC LITERATURE IN ADAPTED PHYSICAL ACTIVITY AND DISABILITY SPORT

Trost, T., Ciliga, D., Petrinovic- Zekan, L.

Faculty of Kinesiology, Croatia

INTRODUCTION

The term "disability sport" has become common in the last decade (DePauw et al, 1995). Disability sport is «meant to give equal weight to each word and disability is not meant as an adjective to Sport» (Doll-Tepper et al, 1997). On the other hand, the term "adapted physical activity" (APA) defines "a cross-disciplinary body of knowledge directed towards the identification and solution of individual differences in

physical activity". The aim of this study was to assess progress achieved in the study of disability sport and APA over five years and to find out and analyze the most common issues in the field of APA and Disability Sport research.

METHODS

Electronic search of journals was used. The databases used were: Academic Search Premier, Medline, ERIC, and MasterFILE Premier. Key words used in this search were adapted physical activity, disability, disability sport, sport for disabled, Special Olympics and Paralympics. Years of publications were constrained to 2000-2004. Only journal publications were included. Only articles published in english were processed. The found articles were divided into original scientific papers and reviews.

RESULTS

Electronic search of journals from 2000-2004 produced 225 publications. Original scientific papers made 83,74%, of the sample, the rest were review papers (16,26%). Among all electronically found publications, 34,66% investigated seven disability categories (amputations, spinal cord palsy, Down syndrome, mental retardation, visual impairments, development coordination disorders and deafness), 11,11% treated problems regarding APA education, while 43,11% were about disability sport. When no disabilities were specifically studied, or when the subjects in the study were not included in any kind of sport, papers were categorized as «other» (11,11%).

DISCUSSION/CONCLUSION

The majority of the papers classified as «APA education» were about supporting and limiting factors for the inclusion of children with physical disabilities in a regular full-time school program. A total of 25 papers in 5 years indicate the researchers' interest to improve the environment in which people with disability lives and to develop the teaching methods used in special schools. The Paralympics sports studied were wheelchair basketball, w. shot-putting, w. racing, w. volleyball, w. hand biking, swimming, running, discus throw and sailing, wile no paper about archery, bocce, equestrian, football 5-a-side, football 7-a-side, power lifting, table tennis, w. fencing, w. tennis or w. rugby were found. The need to increase the researchers' interest for the rest of the Paralympics sport is obvious, because the obtained results appear to be insufficient productivity to advance the field of disability sport significantly.

MUSCLE QUALITY: EFFECTS OF THREE DIFFERENT TRAINING PROGRAMS IN OVERWEIGHT WOMEN

Valamatos, M.J., Pinto, R., Carnero, E., Sardinha, L., Santos, P.

Faculty of Human Kinetics, Technical University of Lisbon, Portugal; Physical Education School, Federal University of Rio Grande do Sul (UFRGS), Brazil, Portugal

Introduction

Nowadays obesity is a worldwide problem. It is an epidemic, which grows quickly in the contemporary society, affecting children, youths and adults of both genders. Several factors can be associated with the development of obesity, such as the hipper-caloric diet and a less active lifestyle.

The regular practice of physical activity and the development of a more active lifestyle have been associated to efficient strategies of body weight loss. On this issue, doubts have been mentioned on the literature, namely related with the type, intensity and duration of the exercise (Volek, J.S. et al., 2005). Strength training has been accepted as a useful tool in body weight loss programs, when the main purpose is the increase of lean body mass and the resting metabolic rate (RMR) (Kraemer et al., 1999). Thus, the aim of this study was to compare the changes in the muscular quality of the thigh muscles of prê-menopause overweight women, submitted to three different training programs.

Methods

51 overweight women (40±7 years old, 1.61±0.05 m; 74.5 ±10.5 Kg; 28.8±3.7Kg/m2) were randomized distributed by 3 groups of training (Aerobic (AT), Strength (ST), Concurrent Training (aerobic and strength associated - CT) and Control Group(CG)). The training process lasted 24 weeks, twice a week. Intake habits were controlled before and after the study. All the subjects were evaluated for isometric maximal strength in a "leg press" equipment. Body composition was evaluated using a dual-energy x-ray absorptiometry (DXA). The statistical analysis included descriptive statistics and paired-samples T-test.

Results

The Table 1 presents the parameters of muscular strength and body composition before and after the training process,in Aerobic (AT), Strength (ST), Concurrent Training (CT) and Control Groups (CG)(**p<0.01)

Discussion/Conclusion

Body weight did not change significantly after the training process, suggesting that physical exercise without appropriate diet, probably, is not enough to have a positive impact on weight loss. Despite this fact, when we analysed body composition we could observe relevant changes. The results showed a significant increase of the fat free Mass (FFM) and a reduction of the fat mass (FM) in the different training groups. Additionally, we have observed an increase on muscle strength, in absolute and relative terms, in the ST and CT groups, without a significant increase of the thighs FFM.Together, these results can be seen as improvement of the muscular quality, and CT seams to be a good tool to achieve that purpose.

BONE MASS IS POSITIVELY ASSOCIATED WITH PHYSICAL ACTIVITY, MUSCLE STRENGTH, FITNESS AND LEAN BODY MASS IN SWISS SCHOOL CHILDREN [ISRCTN15360785]

Kriemler, S., Zahner, L., Puder, J.J., Roth, R., Schmid, M., Guldimann, R., Knöpfli, M., Rizzoli, R.

Institute of Sports and Sport Sciences, Switzerland

Background: More than every 3rd woman over 50 years suffers from osteoporosis. The impact of preventive measures on bone accretion is most pronounced during growth. We therefore looked for factors associated with higher bone mass in children and analysed the relationship between measures of physical activity (PA) and bone mineral density (BMD). Methods: Among 540 7-13 y old children (males and females) from randomly selected socio-ethnic diverse urban and rural public schools in Switzerland studied, 389 children had BMD and body composition measurements by dual energy x-ray absorptiometry (DXA). In 374 children physical activity was assessed by accelerometer. Vigorous PA was defined as the daily amount of time above 3000 counts/min. The independent association between BMD, PA, lower extremity strength (jump and reach), and aerobic fitness (20 m shuttle run) was assessed using partial correlation analyses. The association between low age- and gender adjusted BMD (Z-Score less than -1) with age, sex and pubertal stage, family history of osteoporosis, calcium intake, lean body mass (LBM), daily media use and all measures of PA was assessed using stepwise multiple logistic regression analyses. The amount of PA in children with low vs. high age- and gender adjusted BMD (Z-Score less than -1 and over +1, respectively) was compared by t-test. Results: The children were 9.2±2.2 yrs old (x±SD) with a LBM of 25.2 ± 6.7 kg and 23.5±6.0% body fat. BMD of the hip was 0.699±0.099 g*cm-2 and calcium intake 971±384 mg*d-1. Their daily PA was 599'390±167'322 counts*d-1 with 44.7±21.9 min spent in vigorous PA, in the jump and reach test they achieved 24.1±6.9 cm and in the shuttle run test they performed 5.7±2.2 laps. Independently of age, weight, height, sex, pubertal stage, calcium intake and family history of osteoporosis, total hip BMD was positively associated with more time spent in total and in vigorous PA (r=0.19 and 0.2, both p<0.01), strength (r=0.26, p<0.0001) and aerobic fitness (r=0.29, p<0.0001). On multiple logistic regression analyses, a low BMD of the hip was associated with male sex, older age and decreased LBM, strength and less vigorous PA (p<0.0001, n=274). Children with a high BMD spent 17% more time in daily PA compared to children with a low BMD (p<0.01). Conclusion: In Swiss children, higher BMD of the hip is independently associated with higher physical activity, muscle strength and fitness as well as LBM. Bone health improving interventions should therefore focus on increasing PA which also positively affects LBM, muscle strength and aerobic fitness.

ANTHROPOMETRIC AND FUNCTIONAL CHARACTERISTICS IN SCHOOL CHILDREN FROM BOLOGNA (ITALY)

Brasili, P., Merni, F., Ceciliani, A., Ventrella, A., Semprini, G., Toselli, S.

University of Bologna, Italy

Anthropometric and Functional Characteristics in School Children from Bologna (Italy)

Brasili P.1,Merni F.2,Ceciliani A. 3,Ventrella A.1,Semprini G. 2,Toselli S. 1

2Dep.Histology, Embryology and Applied Biology-University of Bologna, Italy;

3 Dep. Education- University of Bologna, Italy

Middle childhood appears fundamental in the development of strength and motor performance, with differences among specific skills. The purpose of this study is to evaluate the characteristics of Italian children in the context of growth, body composition and functional characteristics. The sample included 163 school children (97m,66f), from Bologna(Italy) aged 6-11y. This study is the first phase of a broader longitudinal project dealing with modifications in somatic and motor characteristics. The anthropometric dimensions included weight, height, sitting height, breadths, circumferences and skinfold thicknesses. Percentage fat was estimated with the procedures of Slaughter et al.(1988); fat-free mass(FFM) and fat mass(FM) were derived. Functional characteristics included lower back/upper thigh flexibility (sit and reach) and strength tests: hand grip, standing board jump, pinches and ball throwing. In addition, tests were performed in order to evaluate the dominant side of the body and the degree of "coordination" (eye-hand coordination with a tennis ball throw test and kinaesthetic differentiation trough weight estimation test).The growth status of children from Bologna is congruent with Italian standards (Cacciari et al., 2002). Males are fatter than females, but they generally show better motor performance. Only flexibility is higher in females. The results of stepwise multiple regression analysis for motor characteristics show that a substantial portion of the variance can be explained by somatic characteristics. Multivariate statistic allows to identify different cluster variables: one for anthropometric and one other for motor performance data. Height is the most correlated to motor tests variable and represent a link with both variable groups. The ball throwing test is the most correlated (test) with anthropometric data. Our results confirm the importance of the relationships between anthropometric characters and performance during growth.

HIGHER BMI IS ASSOCIATED WITH LOWER PHYSICAL FITNESS AND LONGER SICK LEAVES

Kyröläinen, H., Häkkinen, A., Kautiainen, H., Santtila, M., Pihlainen, K., Häkkinen, K.

University of Jyväskylä, Finland

It has been suggested that the changes in physical fitness and anthropometry can be explained by the western life style including reductions in physical activity and / or increased energy intake. Decreased muscle fitness, aerobic capacity and obesity have been shown to increase the risk factors for musculoskeletal injuries, coronary artery disease, hypertension, osteoporosis, certain cancers, type-2 diabetes and metabolic syndrome. These diseases cause sick leaves and, therefore, lost of many working hours. The purpose of the present study was to investigate changes in physical fitness and body mass index (BMI) over the years of 2001-2004, and their association with sick leaves.

7617 male workers participated in the present study. Their mean (±SD) age was 37±8 years (range 18-59 yr.), body height 1.80±0.06m and body mass 83.9±12.0 kg. The endurance performance was measured by 12-min running test or by bicycle ergometer test (estimated maximal oxygen uptake, VO2max). Muscle fitness tests consisted of push-ups, sit-ups, and repeated squats in 60 s, as well as maximal

grip strength. According to these physical fitness tests, the workers were divided to the five fitness index categories: scale from 1 (poor) to 5 (excellent). Body height and mass were measured to calculate BMI, and the relative amount of sick leave to working days and the duration of sick leaves were defined.

The mean (± SD) running distance during 12-min decreased from 2702 ± 330 m to 2656 ± 342 m ($p<0.001$) as compared to the years of 2001 and 2004. Respectively, VO2max decreased from 45.0 ± 8.1 ml/kg/min to 43.9 ± 8.0 ml/kg/min ($p<0.001$). The changes in muscle fitness was, however, minor: push-ups were averaged 31-32 repetitions (reps), sit-ups 34-35 reps and repeated squats 50-51 reps in 60 s. The mean hang grip results varied between 58 – 59 kg, while BMI increased from 24.3 ± 6.3 to 26.1 ± 3.3 ($p<0.001$). The mean fitness index was 3.8 (range 1.0-5.9). Lower fitness index in the year of 2004 was associated with higher BMI ($p<0.001$) and longer sick leaves ($p<0.001$). From those workers who belonged to the excellent fitness category, only 40 % had sick leaves lasting average 3 days, while from those workers who belonged to the poor category 60 % had sick leaves lasting 5 days.

The decreasing aerobic capacity together with increasing BMI values during the follow-up period of three years suggests that physical activity is low as compared to energy intake among the present workers. Furthermore, the number of sick leave days is higher among those workers with poor physical fitness. These results confirm earlier findings that sedentary persons with good fitness seem to show fewer diseases. Therefore, occupational health care system should concentrate to early prevention of life style health problems.

NET CALORIC COST IN THREE DIFFERENT PROTOCOLS – AEROBIC, STRENGTH, AND CONCURRENT TRAINING IN PRE MENOPAUSE OVERWEIGHT WOMEN

Pinto, R., Valamatos, M.J., Carnero, E., Santos, P., Sardinha, L., Rasoilo, J.

Faculty of Human Kinetics, Technical University of Lisbon, Portugal; Physical Education School, Federal University of Rio Grande do Sul (UFRGS), Brazil, Portugal

Introduction

Obesity and overweight have been focused as significant public health problems in some industrialized countries. Physical activity practice has an important role in the control of these epidemics. The caloric cost of some physical activities can affect significantly the daily energy expenditure and, consequently, knowledge of such costs may help in the management of weight loss program. The aim of our study was to compare the net caloric cost (kcal) of three training protocols in overweight women.

Methods

Thirteen overweight females (35±8 years old; body mass index-BMI 29.27 ± 3.59 kg/m2; fat free mass-FFM 44.84 ± 4.69 kg) performed three training protocols – aerobic (A), strength (S) and aerobic and strength associated (AS) in three different days. All the protocols were designed to have similar duration. The resting metabolic rate and exercise energy cost were assessed before and during each protocol, respectively, using an indirect calorimetry system (Cosmed K4b2). The gross caloric cost was estimated using a constant value of 5.05 kcal per liter of oxygen consumed (1). To relative analysis, the FFM was calculated using dual-energy x-ray absorptiometry (DXA). The statistical analysis included descriptive statistics and one-way Anova analyses of variance.

Results

The absolute and relative net caloric cost showed to be similar in A and AS protocols, but smaller ($p<0.001$) in the S protocol (Table 1).

Table1. Exercise time, absolute and relative to FFM net caloric cost of the three protocols.

Discussion/Conclusion

Based on the similitude of the metabolic impact induced by the A and the AS protocols, we can suggest that both strategies are effective for weight loss. However, taking into consideration that an AS type protocol can also have a positive impact on muscle strength and aerobic capacity it should be seen as a good choice.

In other words, the association of aerobic and strength, the so-called concurrent training, showed to be very effective to increment the energy expenditure during exercise sessions and can be an important training strategy to increase strength and muscular quality at the same time, both essentials qualities of the physical fitness.

LEISURE TIME PHYSICAL ACTIVITY AMONG NORWEGIAN YOUTH

Mamen, A., Aaberge, K.

Sogn og Fjordane University College, Norway

Introduction

There is increasing concern about the level of physical activity among children and adolescents today. Sport organisations report fewer youths as members, and recruitment to traditional organised sport activities are often difficult.

Methods

To quantify the degree of leisure time physical activity among Norwegian youth, we questioned 1272 boys and girls age 15 from Sogn og Fjordane County in western Norway (82% of the population) for their activity preferences and level of activity.

Results

Eighty three percent reported to be physical active in their leisure time and 49% are members of one or more sports clubs. Having fun was the most important reason for being active (82%), about 10% considered competitions to be an important reason for this. The most important reasons for not being active in their leisure time were injuries/illness, other activities and sport taking too much time. Unorganised activity was much more common among the respondents than organised sport, even for those who were members of sport clubs. Totally 8178 activity ticks were made, and 86% of these belonged to the unorganised type. The most popular unorganised activities were cycling, snowboard, cross-country skiing and football for the boys and cycling, swimming, cross-country skiing and snowboard for the girls. The most popular organised activities were football, volleyball, rifle shooting and handball (European type) for the boys. The girls had football, handball, dancing and volleyball as their most popular organised activities.

Conclusion

The unorganised leisure time activity among 15 yr old boys and girls in western Norway is substantial and mirrors partly the offers from organised sport. It seems that the youth wants both, so an important task for the society could be to try to fulfil these wishes, by giving the youth appropriate areas to activate them selves, and to give the sport clubs the means to improve their activity offers.

RIGID FOOT ORTHOSES AND POSTURAL STABILITY

Berger, L., Blanc, S.

Université de Savoie and Centre de podologie du Sport, France

Rigid foot orthoses and postural stability

L Berger*, S Blanc**

* Laboratoire de modélisation des activités sportives, Université de Savoie, Campus scientifique, 73376 Le Bourget du Lac Cedex

**Centre de Podologie du Sport, ZA Le parvis , 38500 Voiron, France

Introduction: Rigid foot orthoses are generally used by skiing racers. Indeed, the use of thermoudled orthoses allow a greater repartition of foot pressure. The aim of this study was to evaluate the impact of a thermoudled rigid orthoses on the body balance in expert and non expert subjects, respectively.

Methods : 10 international skiing racers (18 to 25 years) and 14 non expert subjects, never users orthose (22 to 36 years) participate to this experiment. Subjects had to realize a postural task, eyes closed, before (REF) and after the insert of the orthoses directly under the feet (O). The orthoses were in Podiafix® base Podialène® density 160 covers.

Undisturbed posture was quantified by using a force platform, through which the centre of pressure (CP) trajectories as a function of time an be measured. These trajectories are decomposed into antero-posterior (AP) and medio-lateral (ML) directions. The CP movments were then dissociated in two elementary superimposed components: the horizontal motions of the Centre of Gravity (CG) and the differences between the CP and the vertical projection of the CG (CP-CG).

Results :

Results showed a modification for ML parameters with orthoses.

A decrease of the median frequency of CG motions ($p < .05$) was observed for the non expert subjects, suggesting a change in body sway process.

In contrast, the amplitude of the CP-CG motions increase for the athletes ($p<.05$) corresponding to an increased acceleration communicated to the CG, and consequently, an increase of the neuro-muscular means. Moreover, an increased of the CP-CG median frequency suggested a change in the muscular stiffness and/or the muscular activity.

No significant difference were recorded in the AP direction for all motions and for the two populations.

Discussion conclusion

The better repartition of foot pressure allowed by thermoform orthoses seems to be differently used by the expert and non expert people. The expert group increase the neuro-muscular means used to control the posture whereas the non expert group probably do not take into account the increased tactile information.

WALKING AND BODY COMPOSITION: HOW MANY DAYS NEED TO CHANGE BODY COMPOSITION?

Jafari, A., Moradi, M., Salimi, A.

Islamic Azad University Research and Science Branch, Iran

PURPOSE: Scientific literature suggests at least 60 min of moderate-intensity physical activity may be necessary to maximize weight loss and prevent significant weight regain (John M Jakicic & Amy D Otto, 2005). For individuals constrained by a busy lifestyle, an exercise prescription that delivers benefits with the minimum investment of days is attractive. The purpose of the present study, therefore, was to comparing the effect of one, two and three days of brisk walking on some of the body composition factors in over weight sedentary females. METHODS: Thirty six sedentary Iranian females, aged 38.2± 4.4 yr (M±SD) were randomly assigned to three groups, 12 each, with following walking days per week: One day in the first group, two days in the second group and three days in the third group. Participants took 60 minutes of brisk walking with 50-70% VO2max for 12 week in the walking days. The walking was completed on a treadmill (T 9700 HRT, USA Fitness), which is capable for monitoring heart rates, so that the intensity of the walking can be controlled (e.g., if a participant was trained with at 140 beats/min heart rate (HR), we could adjust treadmill speed and elevation to keep HR at the targeted zone). Body weight, BMI, percent body fat, and waist and hip circumferences were measured before and after the intervention. All participants were asked not to change their eating habits during the intervention period, and food diaries were kept and monitored weekly. RESULTS: All participants completed the12-week program of exercise. Means (±SD) of pre-test weight, body fat, WHR, BMI in all groups were 69.15±9.7 kg, 32.71±4.6 percent, 0.82±0.065, 26.99±3.4 kg/m2, respectively. ANOVA test showed that there was significant difference among mean variables among three groups after the 12-week intervention. Tukey post-hoc tests showed that it was the third group differing from others. Follow-up paired t-test for the third group indicates the pre- and post-test means were statistically significant ($p<0.05$): Weight, body fat, WHR, and BMI (M±SD) 72/41±10.75kg, 33.10±4.2 percent, .80±.043, 26.73±3.35kg/m2 changed to 68.81±9.86 kg, 30.36±5.3 percent, .78±5.7, and 25.72±3.16 kg/m2) after the intervention. Only third group significantly reduced body weight, body mass index, and percentage body fat and waist circumference ($p < 0.05$). CONCLUSIONS: Brisk walking for 60 min one or two days a week for 12 weeks could not improve body composition of overweight females. This finding suggests that at least 3 days a week with 60 min of moderate-intensity physical activity is necessary to improve body composition. Many health benefits from physical activity can be achieved if duration and days of training is increased appropriately.

STUDY ON THE FACTORS AFFECTING IN ADOLESCENTS THE PEAK BONE MASS

Michiko, M., Noriko, M., Haruo, S.

Nara Women's University, Japan

There are two prophylactics to prevent osteoporosis, i.e. restraint of a bone mass and increase of the peak bone mass. The decrease of bone mass depend on the ageing process, but it is difficult prevented complement. Recently, the increase of peak bone mass is assumed to be important as an effective prophylactic. However, few studies have completed to be clear the lifestyle condition, including

nutrition and exercise, which influenced peak bone mass clearly. The purpose of this study was to identify the factors which influenced bone mass in adolescents.

Methods

The subjects who were followed up for three years in this research, were 128 junior high school students (67 boys and 61 girls, 11-14 years). Bone states of the os calicis were measure with quantitative ultrasound, using the Achilles ultrasonometer. Bone states were 'Stiffness' Index (SI) was used as a measure of bone states. %SI was used as index of an increase of SI for three years. Height(cm), body weight(kg), percent body fat(%) and grip strength were measured as indexes of physical fitness. The checklists of the daily lifestyle were composed of frequency about meal and exercise, and of histories of fracture and menarche. SPSS was used as statistical analysis.

Results and discussion

1) %SI was statistically increased in both boys and girls (paired-t-test: $p<0.001$).

The difference on the structure of factors was found between boys and girls by factor analysis. For the boys, the first factor was composed of 3 variables, i.e. fishes, meats, soybeans and vegetables. Also in the second factor, 3 variables, i.e. eggs, oils and fats, and in the third factor, 2 variables, history of fracture and exercise were included. Similarly, for the girls, in the first factor was composed of 3 variables, i.e. percent body fat, SI and appearance menarche. Also in the second factor, 1 variable, exercise, and in the third factor, 2 variables, soybeans and vegetables were included.

It was subjected that calcium and protein were important materials for bone, and exercise was important factor to increase bone mass by recruiting effective nutrition1). In addition, it was an interesting result that the soybeans variables was main Japanese food.

2) For the girls, it was suggested that SI was important factor to influenced %SI and the appearance menarche. Therefore, this result showed influence for female sex hormone secretion2).

THE ISSUE OF ALCOHOL AS A DOPING DRUG: DOSE-RESPONSE STUDIES USING A MOTORIC TEST BATTERY

Schulz, T., Pullmann, T., Bühlmeyer, K., Kornmayer, A., Spitzenpfeil, P., Michna, H.

Technical University Munich, Germany

Introduction

Alcohol is not only the most frequently consumed drug in the world, it is also the most common used drug among athletes. Some studies report in this connection that high consumption of alcohol is also strongly related to use of doping agents. The 2006 prohibited list of the WADA includes a passus to alcohol consumption: in competition it is illegal in certain sports but it exists no longer for (alpine) skiing. Nevertheless, in competition sports severe accidents are most common in alpine skiing. It is therefore that we checked the influence of different doses of alcohol in an appropriate motoric test battery in volunteers.

Methods

25 male students took part in the study, they were randomised in a control non-alcohol beer group (CG, n=12) and a normal beer (vol% 5,4%) group (AG, n=13). Beer was administered in a volume of 15x100ml/5 min for two times. Blood alcohol and breath alcohol levels were measured four times: pre-test (PRE), post first drinking (P1), post the second drinking (P2) and at the next morning after 8 hours (P3). Right after P1, P2 and P3 the probands performed a computer aided motoric test battery including: a 10m "grid-run" (rhythmic performance), a "tapping-test" (frequency abilities), a "shuttle-run" (agility), a "flashjump" and a "hand reaction test" (visuell reaction tests), a "match 6 test" (complex reaction and coordination), and a "MFT balance test" (balance). In addition, at each time-point of blood alcohol testing, the probands filled in a questionnaire regarding mood.

Results

At P1 average blood alcohol level of the AG was 0.55 promille, at P2 1.14 promille and at P3 0.14 promille. In regard to the rhythmic performance the grid-run showed differences between the groups after P1 and P2. The agility in the 26m shuttle-run showed no differences at P1 between groups. Instead, the AG improved the efficiency from PRE to P1. Tapping frequency revealed no differences between groups at P1 but between P2. In the AG frequency showed no differences between PRE and P1. Nevertheless, ground contact time of the left and right foot was enhanced in the AG and therefore showed an impaired tapping coefficient. The visuell reaction tests showed no differences between groups at P1 and P3; in the AG we found an improved reaction in the match 6 test from PRE to P3. Regarding the balance, we found no differences between PRE and P1 in AG but an enhancement of the balance ability from PRE to P3.

Discussion/Conclusion

In contrast to the ACSM position statement that consuming a large amount of alcohol limits skills that require reaction time, balance, accuracy or hand-eye coordination, we could only confirm this for blood alcohol levels of about 1.0 promille but not for 0.5 promille. Since alcohol may benefit performance psychologically by decreasing sensitivity to pain, increasing self-confidence, or removing psychological barriers to performance from our point of view alcohol must be on the prohibited list at least for alpine skiing.

PHYSICAL FITNESS AND QUALITY OF LIFE IN ELDERLY WOMEN – STUDENTS OF THE UNIVERSITY OF THE THIRD AGE AT WROCLAW UNIVERSITY IN POLAND

Dabrowska, G., Ignasiak, Z., Woźniewski, M., Żurek, G., Wnuk, W.

University School of Physical Education, U3A at Wroclaw University, Poland

Introduction. The society ageing occurs also considerable problem in Poland. Changes occurring in different of an ageing organism inevitably lead to involution of motor function Poland actively participates in European projects on geriatric care.

Geriatric prophylaxis in the University of the Third Age (U3A) at Wroclaw University aims at intellectual, mental and physical stimulation of the elderly students. U3A is active for 30 years.

The aim. The aim of this study is to present the organization of physical activity program in the U3A at the Wroclaw University in Poland and evaluation of physical fitness and quality of life in the elderly women – students.

Material and methods. 147 women, aged 60 – 86, students of the were included in the study. All tests were carried out at the Scientific Research Laboratory of the Dept. of Physiotherapy at the University School of Physical Education in Wroclaw. Physical fitness test according to K. Means modified to our purposes and suitable for measuring physical fitness and balance in the elderly. Life quality evaluation (Easy – Care). The average quality results in the Means test was 32,8 points (max 36).

Results. Our results point to a high level of fitness of students from U3A in Wroclaw comparing to average of their age. Physical activity of the elderly women – students U3A determined their health and life quality.

EFFECT OF VISUAL FEEDBACK ON MAINTENANCE OF HRTARGET DURING INDOOR CYCLING

Piacentini, M.F., Carminucci, R., Quinci, M.L., Capranica, L.

IUSM of Rome, Italy

Introduction

Indoor cycling is a popular fitness activity aiming at improving cardiovascular efficiency. Usually, experts and novices join the same lesson and no feedback is provided regarding their actual intensity. Previously it has been shown that during Spinning® participants remained on average 15% above the HR suggested by the instructor (HRtarget)(Piacentini et al., 2005). Recently, a new indoor cycling bike that includes a display on the handlebar has been developed. Participants can therefore visualize if their HR remains within HRtarget set by the instructor prior the lesson and eventually adjust their workload in order to remain in target. Thus, the aims of the present study were: 1) to study the effects of the visual feedback on the participant's ability to remain within the HRtarget; and 2) to evaluate the effect of indoor cycling experience in maintaining the HRtarget based only upon the rate of perceived exertion (RPE).

Methods

11 participants (age: 23.6±2.5 yrs; body mass: 70.7±14.3 kg; height: 175±8.1 cm) with different indoor cycling experience volunteered in the present study. They randomly performed the lesson with the new bike (Panatta Sport, Italy) with (F) and without (NF) visual feedback of their HR data on the display. During the F class they were able to adjust their workload in order to meet the displayed HRtarget, while during the NF class they tried to follow the indications of the instructor relying only on their RPE. Chi square test was used to evaluate differences ($p<0.05$) between cycling conditions in the participants' HR and RPE.

Results

A significant difference was found between F and NF lessons for the time spent exercising at HRtarget. Participants remained for 80% of the F lesson within their HRtarget, and were above only for 6% of the lesson. In the NF lesson participants spent only 34% of time within the suggested range and the majority (51%) of the class above their HRtarget. In particular during the F and NF lessons, novel practitioners exercised at their HRtarget for 86% and 41% of the total time, respectively, with the remaining time spent above the suggested HR. No difference was found for RPE between F and NF conditions relatively to levels of experience.

Discussion/Conclusions

The results of the present study show that during indoor cycling practitioners strongly rely on visual feedback to maintain their HRtarget. In agreement to the literature (Piacentini et al., 2005), during the NF class (i.e., condition similar to most indoor cycling classes administered in fitness centers), most of the time was spent at HR above the ranges suggested by the instructor, independently of level of expertise and RPE. Instead, visual feedback prevented participants, especially novel ones from exercising at intensities higher than suggested, thus meeting the training program and avoiding undue risks.

EVOLUTION OF THE SOMATOTYPE AND BODY COMPOSITION OF ADOLESCENT CLASSIC BALLET DANCERS

Sillero Quintana, M., García, A., Refoyo, I., Garrido, G.

Universidad Politécnica de Madrid, Spain

Classic ballet practice is compared, in terms of volume and intensity of training, with other sport disciplines as gymnastics. Furthermore, dancing requires keeping a strict body weight control, which could have a negative incidence in the normal growth and development of the young female dancers.

Our study tries to assess the longitudinal evolution of the somatotype and body composition on a group of dancers from the Public Dance School of Madrid aged between 11 and 14 years. The sample started with 23 female dancers aged 11.4 years (Ã± 0.9) and it finished, three years later, with 18 female dancers aged 13.5 years (Ã± 0.9). The half-yearly anthropometry allowed us to obtain the Heath-Carter somatotype and to estimate the percentage of body fat (%BF), besides providing us with the sum of 6 (S6) and sum of 4 (S4) skin-folds. Bone mineral density (BMD), bone mineral content (BMC) and %BF were obtained by DXA.

The height, weight and body mass index (BMI) averaged percentiles for our dancers were always higher than the 25 percentile for the Spanish girls of the same age. Other authors refer higher results in height and weight for older samples (1, 2). Anyway, the evolution along the three-years study forecasts that our dancers will reach these values.

Values of %BF obtained by DXA (19.0%; Ã± 5.1) were similar to others referred in literature (1). The BMD (0.936 gr/mm2 Ã± 0.061) values are still lower than others found for adult dancers (2,3) but they will evolves into these values when the dancers are older.

Pearson correlation coefficients between humeral (HW) and femoral widths (FW) and BMD were r (HW-BMD) = 0.572 (n = 56; $p<0.05$) and r (FW-BMD) = 0.439 (n = 56; $p<0.05$), and for the BMC, r (HW-BMC) = 0.678 (n = 56; $p<0.05$) y r (FW-BMC) = 0.645 (n = 56; $p<0.05$). Correlation between %BF by anthropometry and DXA was significant: r (%BFS6-DXA) = 0.793 (n = 56; $p<0.05$) and r (%BFS4-DXA) = 0.743 (n = 56; $p<0.05$). However, values of %BF obtained by DXA were higher than by anthropometric formulas. We suggest two formulas to estimate the %BF in ballet dancers from the S6 and S4 skinfolds.

It is essential that dance schools emphasises in body change evaluations during adolescence to compare the typology of the dancers with other actives or sedentary populations.

PERFORMANCE AND EXERTIONAL VARIATIONS DURING WALKING, RUNNING AND JUMPING ON TERRAINS OF VARYING COMPLIANCE

Davies, S.

Cape Peninsula University of Technology, South Africa

Introduction: This paper reviews three coordinated studies that investigated the effects of terrains of varying compliance (sand and a hard surface) during walking, running and jumping. The compliance of sand for each research objective was not significantly different and was verified by measurements using a rapid cone penetrometer.

Walking on sand: Fourteen adult males participated with a mean age of 34.6 years, who were 72.6 kg in mass, and 172.5 cm in stature. They walked at 3, 4, 5, 6 and 7 km.hr-1 on sand and grass surfaces. Physiological measures included heart rate, O2 uptake, CO2 exhalation, ventilation (VE), and relative oxygen uptake. Results indicated that there was a significant increase ($p<0.01$) in all physiological indices when walking on sand compared to grass at 3 to 7 km.hr-1, with the greatest disparity between the surfaces (ratio=1.63) in relative oxygen uptake at 5 km.hr-1.

Running on sand: Twenty adult male participants with a mean age of 27.7 years, who were 78.3 kg in mass, 179.1 cm in stature and 13.1% body fat. The Multi-Stage Fitness Test (MSFT) was the running protocol used on sand and grass surfaces. Two responses were evaluated namely heart rate and Ratings of Perceived Exertion. There was a significant ($p<0.05$) elevation in heart rate response by approximately 9% and an increased RPE of 17% when running on sand, and this resulted in an overall mean performance decrement of 37.3% in terms of MSFT shuttles (distance) completed.

Jumping on sand: Forty one male participants with a mean age of 20.4 years, who were 79.56 kg in mass, 178.03 in stature and 12.6% body fat. The mean vertical jump performance (VJP) achieved on sand was 49.0 cm, compared to 55.11 cm on a hard surface. The mean VJP on sand was 11.03% less than that achieved on a hard surface, which was significantly ($p<0.01$) less.

Conclusion: Sand appears to have a distinctive and significant effect on human performance during walking, running and jumping when compared to the same action performed on a hard (non-compliant) surface. Walking on sand increases physiological demand by as much as 63%, while running a predictive test of aerobic capacity (MSFT) resulted in a 37.3% decrease in distance-shuttles completed. Jumping on sand resulted in a mean 11.03% loss in performance compared to the same action on a hard surface.

LEVEL OF PHYSICAL FITNESS AMONG YOUNG TURKISH CYPRIOT POPULATION: ASSOCIATION OF PHYSICAL FITNESS WITH OBESITY IN 7425 EUROFIT TEST RESULTS OF JUNIOR SCHOOL CHILDREN

Ahmedov, S., Emiroglu, O., Atamtürk, H., Burgul, N., Tinazci, C.

Near East University, Cyprys

We aimed to assess epidemiology of obesity and its relation to physical fitness in prepubescent children of Cyprus. For this purpose 7425 junior school children (i.e. 78% of mentioned population), aged between 9 – 11 years old, were gathered from all 90 junior schools of North Cyprus and evaluated through application of EUROFIT Test Battery for the period between March – May 2005. The 12 tests, comprising EUROFIT, were height and weight measurements, test for skinfold thickness, flamingo balance test, plate tapping test, sit-and-reach test, standing broad jump test, test for handgrip strength, sit-up test, bend arm hang test, 10m x 5 sprint test and shuttle run test.

Statistical analysis of 7425 results allowed getting the following picture of physical fitness in Cyprus. The average rate of obese (> 95th percentile) children, identified by calculation of children's body mass indexes (BMI), was 13% with some age, gender and regional variations. Rural regions had significantly lower rate of overfats and better shuttle run performance in compare with urban population, which possibly witnessed in favor of better aerobic capacity of former group (t-test, $p < 0.05$).

Overall assessment of all test results for each participant through z-score revealed that in all age groups both boys and girls from rural region had higher overall physical performance in compare with urban areas, like for example Nicosia. Besides, the latter was the only region of North Cyprus, which test results were below the country's level.

BMI and physical performance data changed with age progression in girls. The rate of these group of children with excessive BMI decreased from 12.9% to 11.7% (for 9 & 11 years old girls respectively), whereas this parameter in boys has increased from 12.9% to 14.6%. Moreover, while regional differences of physical fitness level in girls have diminished with age progression, we didn't admit similar changes in boys.

In conclusion, age, gender and regional interrelation of BMI and EUROFIT test results indicated on impact of obesity on physical performance in children. Besides that decrease of obesity rate and positive changes in performance observed with age progression in prepubescent girls characterized them as more fruitful audience for management of childhood obesity in contrast to boys.

INFLUENCE OF BEHAVIOUR, LIFESTYLE AND SOCIAL COMPONENTS ON CARDIOVASCULAR DISEASE RISK FACTORS IN PARTICULAR THE METABOLIC SYNDROME (MTS) IN THE PRÄFORD COLLECTIVE

Kosminski, R., Predel, H.-G., Latsch, J.

German Sport University Cologne, Germany

Cardiovascular diseases (CVD) are the main cause of death in the Western developed nations and are often causally linked to lifestyle conditioned, cardiovascular risk factors (1). However, it is not sufficient to merely relate to the classical risk factors which collectively induce the metabolic syndrome (MTS). Increasingly the health influencing social components have to be considered. The objective of the study was to describe the interdependency of MTS, smoking and the social factors (education level) in the Präford study collective.

4.818 valid data records were available for the results of the study. These were collected within the framework of the Präford cohort study 2003-2004 from workers of the Ford factory AG and affiliated companies for the primary prevention of cardiovascular diseases. The data collection took place in accordance with the criteria of the NCEP-ATP-III (MTS1) as well as the criteria of the International Diabetes Federation (MTS2) (2). Smoking was defined by the status (smoker, ex-smoker, non-smoker) and by the number of daily smoked cigarettes as well as the amount of packets smoked per year (pack years). The education level was differentiated into a lower (secondary school),

medium (secondary modern school) and higher (grammar school) level. For comparison of the different components one factor analysis of variance was applied. With significant influences multiple mean value comparisons (according to Student-Newman-Keuls) for determination of differences between the groups were applied.

In terms of frequency of occurrence of MTS1 and MTS2, smokers (0.25±0.43 and 0.33±0.47; n=1609) differed significantly from non-smokers (0.17±0.37 and 0.24±0.43; n=1975) as well as ex-smokers (0.23±0.42 and 0.34±0.47; n=1038) from non-smokers (p=0,01). Subjects with higher education levels showed less inclination to MTS1/MTS2 (0.13±0.33/0.19±0.39; n=1358) than subjects with lower education levels (0.29±0.46/0.39±0.49; n=1605) (p=0,01). There were similar results for subjects with medium (0.19±0.4/0.28±0.45; n=1689) and low education levels and for subjects with medium and high education levels (p=0,01). Additionally subjects with higher education levels smoked significantly less (0.28±0.45; n=1339 vs. 0.38±0.48; n=1554 vs. 0.37±0.48; n=1636) and had fewer pack years (12.08±12.51; n=206 vs. 24.3±27.22; n=432 vs. 15.79±13.8; n=410) compared to subjects with lower education levels.

The results of the study demonstrated that the prevalence of smoking, the MTS1 and MTS2 as well as the risk constellation decreased with higher education level. Considering the respective prevalences the IDF criteria seem to be more progressive than the ATP-III criteria of the NCEP.

ANALYSIS OF THE MOST FREQUENT INJURIES IN KARATE ACCORDING TO THE RISK FACTORS AND THE LOCALIZATION

Gogl, A., Hilda, T., Dekany, M., Gyore, I., Pucsok, J.M , Nánai, F.

Semmelweis University, Hungary

In order to prevent sport injuries the knowledge of the risk factors and the mechanism of the injuries is essentially.

The aim of our studies was to clear up the prevalence and the risk factors of the karate injuries in a Hungarian karate population with a two years survey method.

The incidence of the injuries was analysed according to the risk factors (age, gender, BMI, training time, and skill level) and to the localization.

The data got in 201 athletes have been elaborated. The male/female rate was 145/56, the rate of injured/not injured athletes was 69/132. The greater part of the injuries (65.9%) occurred in training and 34.1% during competition.

The occurrence of injuries progressively increased with the age, skill level and training time. The most commonly injured regions were the lower extremity (38%), upper extremity (19%) and cranial region (19%). The cranially injured athletes had significantly higher BMI ($p<0.01$), body weight ($p<0.02$), skill level ($p<0.01$) and weekly training time ($p<0.01$).

The mouthguard was judged as an efficient protector of the teeth. The tibia padding should be modified to be effective.

The lesions caused by kicks in the cranial region were without exception fractures or other serious damages. The injuries of the attacker, independently of the region, were without exception the consequences of the inadequate techniques or failure of concentration.

AIRWAY SECRETION DURING EXERCISE IS IMPAIRED IN EXERCISE INDUCED ASTHMA AND IN CYSTIC FIBROSIS

Schmitt, L., Dehnert, C., Frese, F., Bärtsch, P., Mairbäurl, H.

University of Heidelberg, Germany

Airway lining fluid, mucus and the movement of cilia are important defense systems to trap particles contained in inspiratory air. The lining fluid also humidifies the air which is a requirement for alveolar gas exchange. Fluid secretion into the airways is driven by the secretion of Cl, whereas an increased reabsorption of Na would decrease the layer of the lining fluid and support its drying. A delicate balance between Cl-secretion and Na-reabsorption determines the ionic content of the lining fluid, modulates the osmolarity of the interstitial fluid and cell volume of surrounding cells. During exercise ventilation increases dramatically, which might cause drying of the airway surface, cell shrinkage, activation of mast cells and broncho-constriction. In susceptible individuals this can cause exercise induced asthma (EIA). In patients suffering from cystic fibrosis (CF) fluid secretion into the airways is impaired by a defective Cl-secretion which might enhance problems induced by exercise. The present study was therefore performed to test how airway secretion adjusts to the increased ventilation during exercise.

Healthy controls (CO; n=10), individuals with reported EIA (n=6) and patients with CF (n=10) were subjected to a maximal (50 W, 3 min steps) and sub-maximal ergometer test (basal lactate + 1mM, 30min) in a semi-supine position. Potentials across the nasal mucosa were determined as a measure of airway epithelial ion transport activity. Maximal workloads (W) and heart rates were 239±55 and 187±8 in CO, 196±46 and 178±15 in EIA, and 120±28 and 169±12 in CF; workloads and heart rates in sub-maximal tests were 129±64 and 133±13 in CO, 112±38 and 133±11 in EIA, and 64±9 and 128±8 in CF, respectively. Norepinephrine and epinephrine, which are known stimulators of Na- and Cl-transport in airway epithelium increased about 9- and 15-fold in maximal tests and only about 2-fold in sub-maximal exercise; there were no differences among groups. Nasal potentials (NP) at rest were about -18mV in CO and EIA but -54mV in CF, the amiloride-sensitive components representing Na-transport were about 6mV in CO and EIA but 22mV in CF. Cl-sensitive NP was about 15mV in CO but significantly lower in EIA (10mV) and CF (3mV). During maximal exercise total NP and Na-transport decreased significantly in CO and CF but not in EIA. Whereas in CO Cl-sensitive potentials increased during maximal exercise, no change was found in EIA and CF. No such changes were found in sub-maximal tests.

These results indicate that in healthy individuals fluid secretion is stimulated during intensive exercise. In contrast, in patients with EIA and CF these adjustments in Na- and Cl-transport during exercise are not seen are not seen. Therefore drying of the airways by a defective control of airway secretion might be involved in problems of ventilation at high intensity exercise. Knowledge of the might provide a basis for diagnosis and a more specific treatment.

RELATION OF THE OXIDATIVE DNA DAMAGE TO LYMPHOCYTOPENIA AFTER HIGH INTENSITY EXERCISE

Tanimura, Y., Shimizu, K., Yamauchi, R., Tanabe, K., Otsuki, T., Lemitsu, M., Maeda, S., Ajisaka, R.

Tsukuba University, Japan

Introduction: Post high intensity exercise lymphocytopenia is well documented (2), but the underlying mechanisms have not been fully elucidated. One possible mechanism is reactive oxygen species -induced DNA damage following high intensity exercise(3). Furthermore, lymphocyte apoptosis relating to the DNA damage may contribute to exercise-induced lymphocytopenia(1).

PURPOSE: The purpose of this study was to examine whether oxidative DNA damage can relate to lymphocytopenia after a bout of high intensity exercise, and the DNA damage is associated with apoptosis.

METHODS: Fifteen young healthy sedentary males (age 23.7± 1.5 yr, VO2max 43.1± 4.2ml/kg/min) exercised on a bicycle ergometer for 1h at 75% of their VO2max. Venous blood samples were taken at pre-exercise (Pre), and 0, 1, 2, 3, 4h of post-exercise (P0-P4). Lymphocyte counts, serum lipid peroxides concentration as a marker of acute oxidative stress, and serum cortisol concentration as an apoptosis inducing factor were measured. Single cell gel electrophoresis with the incorporation of the specific endnuclease (hOGG1) is a method to reveal an oxidative purine (8-OHdG)-sensitive sites contributed to most of post-exercise nucleotide oxidation. The oxidative DNA damage in lymphocyte was evaluated by the % DNA in tail whose intensity relative to the head reflects the number of DNA breaks. Moreover, after cell isolation, CD95 (Fas receptor) as a cell-based apoptosis marker was measured by flow cytometry. Data were analyzed using a repeated one way ANOVA.

RESULTS: Lymphocyte counts decreased significantly ($p<0.05$) at P1 (1983± 511 cell/μl), P2 (1785± 630 cell/μl), and P3 (1922± 550 cell/μl) compared to the Pre level (2444± 913 cell/μl). Serum lipid peroxides concentration significantly ($p<0.05$) increased approximately 1.6-fold at P2 (1.23± 4.3 nmol/ml). % DNA in tail as the oxidative DNA damage significantly increased from 42.6±11.1% at Pre to 54.3±12.8% at P3 ($p<0.05$). CD95 expression in lymphocyte significantly ($p<0.05$) increased during P2-P4, P2: 22.2±6.4%, P3: 22.5±7.6%, and P4: 22.2±9.6%, respectively. The serum cortisol concentrations decreased during P2-P4, P2: 15.2±4.5μg/dl, P3: 11.2±4.9μg/dl, and P4: 9.5±7.0μg/dl, respectively.

CONCLUSION: These results suggested that the oxidative DNA damage may in part account for lymphocytopenia after a bout of high intensity exercise. Further investigations are needed to elucidate whether lymphocyte apoptosis contributes to post high intensity exercise lymphocytopenia.

ANTROPOMETRICAL PREDICTORS OF CARDIAC PARAMETERS, VO2MAX AND MYOCARDIAL OXYGEN UPTAKE IN ELITE MALE BASKETBALL PLAYERS AND SEDENTARY CONTROLS

Popovic, D., Ostojic, M.C., Mazic, S., Stojiljkovic, S., Djordjevic-Dikic, A., Dikic, N., Mitrovic, D.

Medical Faculty Belgrade, Serbia and Montenegro

BACKGROUND: The degree of cardiac changes responsible for better work efficiency, which have been identified as the ¨athletes heart syndrome¨, is highly variable considering different kinds of physical activities. Only hypertrophied and dilated heart, of low heart rate, can perform better during vigorous physical activity. The aim of this study was to find best reasons, and consequently predictors, of morpho – functional changes of the athlete˜s heart.

METHOD: Subjects in this study were 35 elite male basketball players and 34 sedentary controls mached by age, BH, BW and BSA. Standard anthropometrical examination, standard echocardiographic method and ergospirometric maximal test on treadmill were used to assess cardiac parameters at rest; VO2 max and double product at rest and at maximal level of physical activity.

RESULTS: We obtained following parameters: LA, Ao, LA/Ao index, IVSd, PWTd, IVSd/PWTd ratio, LVd, LVs, RWT, LVM, FS, EF, TAFV, TPFV, Et, E, A and E/A index. All parameters were significantly higher in athletes, except LA, TAFV, E, A and E/A (not significantly different between groups), and LA/Ao, IVSd/PWTd, LVs (significantly lower in athletes). When indexed for LBM, the difference between groups in LVM, IVSd, PWTd and LVd was changed, but when indexed for BH, BSA, BMI remained unchanged. VO2max was significantly higher in athletes and its best predictor in both groups was LBM. Double product was lower in athletes at both levels of physical activity and its best predictor looking both groups together was LBM, but looking independently for athletes BW and for sedentary BH.

CONCLUSION: Better work efficiency of the heart in basketball players become from moderate dilatation and hypertrophy of the heart, lower HR and better systolic function of the heart. All examined morpho - functional changes of the heart are predominantly due to changes in LBM.

IMPACT OF CHRONIC ECCENTRIC EXERCISE ON MRF, MYOSTATIN AND MYH3 MRNA EXPRESSION IN HUMAN SKELETAL MUSCLE

Costa, A., Hissam, D., Zsolt, C., Hegyesi, H., Tihanyi, J.

Semmelweis University of Budapest, Faculty of Physical Education and Sport Sciences, Hungary

Existing evidence suggests that repeated-bouts of eccentric exercise on already damaged muscles do not affect or retard the recovery process. However the molecular mechanisms by which the skeletal muscle responds have not been yet investigated. The purpose of the present study was to investigate the expression of those genes responsible for satellite cell activation and therefore muscle fiber regeneration/hypertrophy (MH3, MyoD, myogenin, MYF5) combine with those responsible for satellite cells differentiation (p21) and hypertrophy suppression (myostatin) after a scheduled damage-induced exercise protocol.

Methods: Fourteen subjects, 9males and 5 females were recruited for this study with the following characteristics, standard deviations in parenthesis: age M=24,4years (3.8), weight M= 72,6kg (7.9), height 176cm (6.8). The exercise group (10 subjects randomly assigned) completed successfully the eccentric exercise, which consisted of (6sets of 15 rps) maximum voluntary eccentric contractions for six repeated days using a multicont isokinetic dynamometer. Three muscle biopsy (Bergstrom technique with suction) samples were obtained from each subject 1-week prior exercise, 1-hour post the first training session and at day-6 after the last training. Gene expression levels

were determined using real-time RT-PCR (reverse transcription-polymerase chain reaction) with GAPDH as an internal standard house-keeping gene.

Results: The mRNA expression of all myogenic regulatory factors investigating by this study (MYF5, MyoD, and Myogenin) was elevated one-hour post exercise 42%, 82% and 231% respectively, while after the last training session was increased by 97%, 201% and 174% respectively compare to the pre-exercise level expression. MH3 expression 1-hour post exercise was relatively unaffected while by the last training was increased 146%. In contrast myostatin mRNA expression was decreased 25% at both times measured comparing to pre-exercise level.

Conclusions: Our results suggest that skeletal muscle ability to respond in subsequent damage-induced eccentric bouts and thus avoiding further damage is at least partly mediated by molecular adaptations.

ACUTE EFFECTS OF EXERCISE TRAINING ON BLOOD PRESSURE IN PATIENTS WITH PREHYPERTENSION AND HYPERTENSION STAGE 1

Punter, E.

University of Innsbruck, Austria

Introduction: Hypertension (HTN), one of the most common medical disorders, is associated with an increased incidence of all-cause and cardiovascular disease mortality. Exercise programs that primarily involve endurance activity reduce blood pressure (BP) in adults with normal BP and those with HTN [1]. The aim of the study was to assess the acute effects of cross-country skiing on BP in persons with pre HTN and HTN stage 1.

Design: Subjects were five women (51.8±5.2 years, 164.2±3.7 cm, 74.8±10.9 kg) with pre HTN and HTN stage 1. Twenty-four hour BP was measured by Medi Tech Cardio tens 24-h system. During the awake hours (11am–10pm) the BP was measured each 45 min and during the night hours (10pm–7.30am) each hour. BP were recorded following exercise (Ex=60 min: 70–80% heart rate max) and during a non-Ex control day (C). On the Ex day, the subjects completed 60 minutes of cross-country skiing with a calculated intensity of 70%-80% of their maximal heart rate. On the C day the patients had a normal day with no exercise. The 24-h BP were compared between Ex and C days for magnitude of the BP reduction following cross-country skiing.

Results: In three subjects the BP decreased after the exercise. The mean systolic BP (SBP) at C day was 124.0±14.1 mmHg and the diastolic BP (DBP) 81.7±9.4 mmHg and decreased on E day to SBP 118.9±12.7 and DBP 76.5±9.6 mmHg. During the awake hours the SBP decreased by –5.8 mmHg and the DBP by –4.0 mmHg, in the night hours the SBP decreased by –4.3 mmHg and the DBP by –6.3 mmHg compared with the C day.

Discussion: Three out of five subjects are "Responders" and showed a decrease in BP following exercise. BP decreased in approximately 75% of individuals with HTN [2]. The "non responders" were the oldest and had the highest baseline BP values. Studies showed that the BP lowering effects of exercise are most pronounced in people with HTN with BP decreasing approximately 5–7 mmHg after an acute exercise session and is reduced for up to 22h after an endurance exercise [1]. Other results from a meta-analysis indicated the exercise effect with a decrease in SBP by 2.58 mmHg and DBP by 3.84 mmHg [3]. All these results are also reflected in this study. Not all people with HTN demonstrate postexercise HTN so definitive conclusions cannot be made at this time [1]. These results support and emphasise the recommendation that exercise training is an important initial or adjunctive step in the treatment of HTN.

RELATION BETWEEN ESTIMATES OF BODY FAT BY MEANS OF ANTHROPOMETRY, UNDERWATERWEIGHING AND BIO-ELECTRICAL IMPEDANCE AS MEASURED IN SPORTIVE YOUNG ADULTS

Deriemaeker, P., Clarys, P., Van Acker, A., Duquet, W.

Vrije Universiteit Brussel, Faculty of Physical Education and Physiotherapy, Belgium

Introduction

The underwaterweighing (UWW) as a method to measure the body composition is considered as a golden standard. Two other methods which are often applied in literature are the skinfold (SF) measurements and bioelectrical impedance (IMP). The objective of this study was to examine if the SF and bioelectrical IMP measures are valid to estimate the percentage body fat in sportive young people in comparison to UWW.

Methods

Thirty three (16 boys (20.8±1.2y, 73.1±8.1kg, 180.3±6.1cm and 17 girls (20.4±1.5y, 58.9±7.0kg and 167.6±3.2cm)) physical education or physiotherapy students participated. They participated in at least 10 hours sport per week. In this study bodyweight, body height, 10 SFs, 7 girths and biepicondylar humerus breadth were measured. For the measuring of the bioelectrical IMP a Tanita TBF-410 was used. In the method of the bioelectrical IMP we will examine two formulas, standard formula (IMPST) and a formula for athletes (IMPAT).

Results

For the males a significant difference was found between the IMPAT and the UWW. No difference was found between IMPST and UWW. Low correlations were found between the IMP measurements and the UWW. The correlations between UWW and anthropometric values were higher. By regression a formula was established using two anthropometric variables UWW=27.17+1.31*SF abdomen-0.71*calf girth (r=.82, r2=.67, SE=2.54). We found also a regression formula for our test group by means of the IMPSC in combination with age, length and weight. Low correlations were found between this combination and UWW. For the females higher correlations were found between the IMP measurements and UWW compared to the males. Two regression formulas were established: UWW=4.05+0.73*IMPST (r=.78, r2=.61, SE=3.44) and UWW=2.71+0.93*IMPAT (r=.74, r2=55, SE=3.73). For the prediction of UWW from anthropometric measurements we found a better estimation compared to the males. The hip girth (HIPG), SF thigh frontal (SFTHIGHF) and SF supra-iliac (SFSUPIL) gave the best predictions.

UWW=-39.5+0.51*HIPG+0.41*SFTHIGHF+0.31*SFSUPIL (r=.95, r2=.90, SE=1.87); UWW=-48.69+0.74*HIPG (r=.89, r2=.79, SE=2.51); UWW=-50.1+0.68*HIPG+0.37*SFTHIGHF (r=.93, r2=86, SE=2.12).

Conclusion

For the males we can conclude that UWW measurements corresponds more to anthropometric values then IMP measurements. For the females the correlations between UWW and IMP were higher but anthropometric values deliver still the strongest predictions for body fat as estimated with UWW. For our test group anthropometric measurements, which are cheap and easy in use, are the most accurate to estimates the fat percentage as estimated with the UWW.

THE EFFECT OF ACUTE PHYSICAL EXERCISE ON STEROIDHORMONE PROFILE AND CYCLOOXIGENASE ENZYME MEDIATORS AND OTHER METABOLIC PARAMETERS IN COMBAT SPORTS

Pucsok, J.M., Gyore, I., Hollósi, I., Soós, E., Horváth, I.

National institute for Sports Medicine, National Korányi Institute for Pulmonology and Pathophysiology, Hungary

A heterogenous group of 13 male and 16 female judoists, and 10-10 karate competitor male and female members of the hungarian national team participated in this study. The subjects completed a standardised maximal treadmill (Jaeger LE 580 C) exercise test. Capillary and urine samples were collected at the pre-and post exercise stages. The serum sample of 10-10 karate competitors was analysed using radio-immunoassay technique. The urine steroids were measured at the judo group, using a gas-chromatography, combined with mass-spectrometry (GC-MS) device. At the final stage of our study-design the judo group was measured for cyclooxigenase enyzme mediators from the exhaled breath condensate, while executing the above mentioned maximal exercise test. The purpose of this measurements was to determine the acute exercise induced changes in the concentration of cyclooxigenase enzyme mediators, prostaglandin E2 and tromboxane B2.

The concentration of anabolic hormones in the serum, such as testosterone, DHEA and androstendione have significantly changed. The concentration of the main catabolic hormone, cortisol increased in judo players, but not in the karate group. The results of our study supports, that elite judoists were in excellent physical condition. The hormonal response due to the catabolic/anabolic effects is balanced. The karate players demonstrated no significant increase in plasma cortisol level, the intensity of the treadmill test primarily strengthened the anabolic effects. We experienced no changes in catabolic effects. The changes of serum DHEA concentration is worth to note. We suggest, that the changes in the level of DHEA and the hormonal adaptation are important demonstrators of the improved physical capacity. The change in concentration of adrenal cortex originated DHEA is less known, compared to cortisol and testosterone on the effect of exercise. We found significant increase in both groups (judo, karate), which supports that DHEA has an important effect on the adaptation of physical exercise. The urine steroid profile showed a decrease in the level of inactive metabolites, androsterone and etiocholanolone in elite competitors. Among the analyzed hormones, we measured increase, although not significant, only in the concentration of DHEA and 11-beta-OH androsterone. This increase was negligible, so the level of 11-beta-OH androsterone eventually remained stabile throughout the exercise test. We suggest, that the elevated serum concentration of DHEA and the metabolism in the liver explains the higher concentration. The changes on the level of cyclooxigenase enzyme mediators are inversely related to exercise intensity. The changes in TXB2 are related to exercise intensity. We found, that physical activity has an effect on the level of PGE2 and TXB2 in the airways. We conclude, that these mediators have an important effect on the adaptation of the airways. The examination of biologically active substances - PGE2 and TXB2 - is a useful indicator of execise-induced airway adaptation.

AQUATIC EXERCISE PROGRAM-EFFECTS ON PHYSICAL FUNCTION IN PATIENTS WITH KNEE OSTEOARTHRITIS

Pais, S., Espanha, M., Santos, M., Alves, V., Silva, C.

Faculty of Human Kinetics, Technical University of Lisbon, Portugal, Portugal

Osteoarthritis (OA) is a joint disease which results of the degradation of the articular cartilage. The major symptoms are pain and physical disability1 namely in daily activities such as ascending and descending stairs and getting up from or sitting down on a chair, evolving both concentric an eccentric muscles actions. Non-pharmacological interventions such as exercise are frequent in the treatment of these patients2, although water is an excellent environment for these subjects to exercise there is little evidence of it's efficacy3.

A randomized clinical trail was carried out to compare the effects of a 6, 12 and 24 weeks aquatic exercise program on the physical function of patients with knee OA.Thirty subjects with knee OA were selected and observed by a rheumatologist, and randomly assigned to one of three groups of aquatic exercise: 6 weeks (G6; n=8; 66,7±6,04 yrs; 7F;1M;), 12 weeks (G12; n=11; 66,82±7,4yrs;7F;4M;) and 24 weeks (G24; n=11; 63,8±7,3; 8F;3M;). Physical function was assessed through three functional testes all preformed at subjects fastest speed. Time to ascend (TAS) and descend 12 steps (TDS)4 and time to sit and stand five consecutive times (CT)5 was measured before and after intervention.

The aquatic exercise program was performed, 3x wk. All exercises, specific for lower limb training were previously selected. Each session of 45' was organized with a 10' warm up; 5' of passive and dynamic flexibility exercises; 20' of dynamic and isometric strengthening exercises, in both closed and open kinetic chains and a 5' cool down period.

Although all groups decreased the time needed to perform the functional tests after intervention TAS (G6: -1,5%; G12: -19,3%; G24: -29,3%) TDS (G6: -2,3%; G12: -17,6; G24: -25,7%) and CT (G6: -19,6%: G12-30,8%; G24: -28,4%); in the G6 and G12 it was only significant for the CT ($p<0,01$; $p<0,001$). For G24 all three tests were significant (TAS $p<0,01$; TDS $p<0,001$; CT $p<0,01$). Between subjects differences were significant from 6 to 24 weeks of intervention ($p<0,05$). Aquatic exercise seems to improve physical function in OA patients independently of the duration of the intervention, demonstrating an appropriate selection of exercises, specially the strengthening one's, which were performed in similar condition of the functional tasks. However the magnitude of the results is strongly related to the duration of the program.

AGING EFFECTS IN ISOKINETIC STRENGTH IN ELDERLY WOMEN WITH AND WITHOUT KNEE OSTEOARTHRITIS

Espanha, M., Pais, S., Santos, M., Alves, V., Silva, C.

Faculty of Human Kinetics, Technical University of Lisbon, Portugal, Portugal

Osteoarthritis (OA) is the most prevalent joint disease and is a major cause of chronic pain and disability in the older population. Some of the risk factors of knee osteoarthritis in older adults1 are modifiable, such as obesity, muscle weakness and joint laxity. Quadriceps weakness is due not only to arthrogenous muscle inhibition, since findings show that it also occurs in women with no history of joint pain2. The purpose of this study was to compare isokinetic muscle strength in elderly women with knee OA and age matched healthy controls, and observe age influence. Measurements were done with a Biodex System III dynamometer to thirty women with knee osteoarthritis (GO; 64±7,2 yrs) and thirty healthy women (GH; 64±7,2 yrs). Diagnosis was done according to American College of Rheumatology criteria for knee OA3. The isokinetic knee flexion and extension strength (peak torque) and the ratio of hamstrings to quadriceps (H/Q) was assess at 60°/s in a C/C mode.

Knee extension and flexion strength was 40% and 35% lower (p<0.001) in OA subjects than in controls, respectively. Ratios of H/Q muscles did not differ between groups, however they were lower in OA patients (-11%). To analysis the effects of age, both OA and healthy groups were divided in three sub-groups: 50-59 yrs; 60-69 yrs; 70-79 yrs (n≈10). In healthy women significant peak torque differences were found in knee extensors between when comparing the group 50-59 yrs with the others two age groups (p<0.01), but not in the OA group. Ratio H/Q differences were observed only between OA age groups (p<0,05).

Women with knee OA have significantly lower extension and flexion muscle strength than controls, confirming previous findings2. Expected age decline in muscle strength was observed only in healthy controls, seeming to indicate that the muscle weakness observed in these patients is an outcome process of the disease not influenced by age. However the decrease in ratio H/Q observed only in OA age groups indicates a superior decline of the quadriceps strength, probably due to pain inhibition. This imbalance can compromise dynamic stability of the knee joint and contribute for acceleration of the OA process.

IS QUALITY OF LIFE REDUCED IN OBESE CHILDREN?

Keller-Marchand, L., Farpour-Lambert, N.J., Martin, X., Trigona, B., Schwitzgebel, V., Aggoun, Y., Beghetti, M.

University Hospital of Geneva, Switzerland

Is quality of life reduced in obese children ?

Keller-Marchand L1, Farpour-Lambert NJ1, Martin X1, Trigona B1, Schwitzgebel V2, Aggoun Y1, Beghetti M1.

1Pediatric Cardiology Unit; 2Pediatric Endocrinology and Diabetology Unit; Dept of Pediatrics, University Hospital of Geneva, Switzerland.

BACKGROUND: Childhood obesity is associated with poor quality of life, due to reduced psychosocial health, self-esteem and physical functioning. Physical activity is a major determinant of cardiovascular health and may also improve components of quality of life in this population. OBJECTIVE: To assess quality of life and physical activity in obese children. METHODS: Cross-sectional case control study including 41 obese prepubertal children and 41 lean controls aged 6 to 11 years (mean 9.0 ± 1.5 years). Both groups were matched for age, height and pubertal stage. Health-related quality of life was assessed by the Child Health Questionnaire. Other measures included: 7-day physical activity count by accelerometer; past 12-month physical activity level by questionnaire; body composition by DXA and anthropometrics. RESULTS: Quality of life total score (73.0 ± 10.9 vs 82.4 ± 7.3, p=0.001) was significantly lower in obese children compared to controls, especially psychosocial health, self-esteem, physical functioning, and impact on parental emotional well-being. Obese children had lower physical activity count (309.3 ± 42.4 vs 394.4 ± 99.5 cpm, p=0.04) and past 12-month physical activity (0.8 ± 1.3 vs 3.9 ± 3.2 hours/week, p=0.001) than controls, whereas body mass index (p=0.001) and percentage of body fat (p=0.001) were significantly increased. CONCLUSIONS: Our study demonstrates that quality of life is reduced in prepubertal obese children compared to lean controls, particularly psychosocial health and physical functioning. In addition, obese children are less physically active, suggesting decreased sports participation and physical conditioning. We conclude that obese children may benefit from adapted physical activity interventions to improve their quality of life and social integration.

SHAPE OF THE CORNEA AND VISUAL ACUITY OF ATHLETES

Jendrusch, G., Lingelbach, B., Dennhoven, P., Platen, P.

Ruhr-University Bochum / Institute of Optometry Aalen, Germany

It is well known that on average athletes show higher visual acuity than a representative selection of the whole population. It was proved in former studies that professional athletes (alpine skiing, soccer, table tennis, gliding flight etc.) normally have a visual acuity of more than 2 (= 40/20); in a few cases even visual acuity values higher than 3 (= 60/20) were found.

Every part of the visual system has to be perfect to obtain perfect vision. The cornea, the lens and all distances for the geometrical projection of the outer world onto the retina should be optimized.

PURPOSE: The purpose of the study was to determine the morphological conditions of the cornea which can lead to such a high visual acuity.

METHODS: In our experiments we determined the visual acuity of professional athletes, of students studying sports and of normal people. A total of 166 persons participated in these inquiries (63.3% male, 36.7% female). From overall 332 analyzed eyes 321 eyes could be evaluated.

Simultaneously we used an Oculus-Videokeratograph to get information about the shape of the cornea of each subject. With a software, especially designed for this experiment, we were able to analyze the shape of the cornea. The best fitting ellipsoid was determined and the deviations from this ellipsoid were fit in terms of Zernike-polynomials. These polynomials were used because each Zernike-polynomial correlates to a special aberration of the geometric optical projection.

RESULTS: The higher the visual acuity, the lower the amplitudes of the high-order aberrations. Especially the meridional polynomials like astigmatism or trefoil or four-lobe-aberrations are close to zero. The root mean square error (RMS) of the fit - which is an indicator for the amount of the total aberration of an optical system - was significantly lower with high acuity (correlation between RMS and visual acuity: r

= -0.20, p < 0.001). On an average the shape of the cornea was close to an ellipsoid with a shape-factor of 0.7 which is equivalent to a numerical eccentricity of about 0.55. Absolutely no correlation was found between shape-factor and visual acuity.

CONCLUSION: At first we only found very few people with extreme high acuity. All were professional athletes. Their corneae were nearly free of high-order polynomials and the shape was close to an ellipsoid with an eccentricity of about 0.55. A necessary but not sufficient condition for an excellent visual acuity - which plays a major role in numerous sports and field events - are low amplitudes of the high-order Zernike-polynomials in the shape of the cornea.

THE EFFECT OF INSPIRATORY MUSCLES TRAINING ON SPORT PERFORMANCE

Vasilescu, M., Rusu, L.

University of Craiova, Romania

Introduction. The results of specialty studies to the influence that training of the respiratory muscles has on the sport performance contradictory results: a part of the scientists indicate the positive influences, meanwhile others contest it. The aim of our study was to investigate the effects of inspiratory muscles training on aerobic performance of athletes.

Methods. Our study has included five aerobe trained athletes, mean age =20,3 years, with equal aerobic performance (VO2max = 50,5ml/Kg/min) and comparable respiratory function, who have been separated into two groups: group A for research (n=5), who undertaken an inspiratory muscles training with resistive loading at 75% of maximum inspiratory pressure, of 15 minutes beside the usual training and group B (n=5) has undertaken only usual training. The inspiratory muscles training session lasted for 6 weeks, four days a week.The ten athletes have made over the eight weeks the same type of aerobic training, at the beginning and the end of the eight week period there has been an evaluation of the aerobic capacity (VO2max) through the Astrand test at the cycloergometer Monark 828

Results and Conclusions. After the six training weeks, it has been noticed that the athletes of group A presented an mean increase of VO2max with 10,2% over the mean value of the B group subjects who did not undertake the muscles insiratory training . These results indicate the fact that the association of inspiratory muscles training with resistive loading to the classic aerobic training brings an outstanding improvement of aerobic performance.

PHYSICAL ACTIVITY LEVEL, RESTING EXPENDITURE ENERGY, FOOD INTAKE AND BMI ACCORDING TO BONE MINERAL DENSITY IN NON-SEDENTARY POS MENOPAUSAL WOMEN

Marin, R., Camargo, L., Matsudo, S.M., Telles, M., Lazzaretti-Castro, M., Matsudo, V.K.

Physical Fitness Research Center From São Caetano do Sul & Centro Universitário UniFMU & Endocrinology-Unifesp, Brazil

PURPOSE: compare and associate the physical activity level (PAL), resting expenditure energy (REE), food intake and body mass index (BMI), according to the bone mineral density status in pos menopausal women involved in a regular physical activity program. METHODOLOGY: sample was composed by 77 women aged 51 to 79 (68.7 ± 6.0 years old) who exercise (low impact aerobics), at least twice a week, 50 minutes per session during 8.1 ± 6.3 years. This sample is part of the Longitudinal Project of Aging and Physical Activity from São Caetano do Sul in São Paulo, Brazil. PAL was determined through International Physical Activity Questionnaire (IPAQ), 8th-short version, by interview. Subjects were classified in 3 groups according to the classification proposed by IPAQ: inactive (22.1%), minimally active (23.4%), and HEPA active (54.5%). PAL was calculated in total METs/week. A questionnaire of food frequency was applied to evaluate: a- calcium intake (dairy products and vegetables); and b- foods that limit calcium bioavailability (coffee, tea, chocolate, soft drinks and alcohol). REE was calculated using the Harrys Benedict´s protocol. BMD was evaluated with DEXA in femoral neck, proximal femur, lumbar spine (L1-L4), and trochanter. Osteopenia and osteoporosis diagnosis followed the WHO criterion. The statistical analysis used was the "t" Student Test for independent samples. Spearman Rho´s correlation was used to measure the association between BMD with PAL, REE, BMI and food intake. The level of significance adopted was p<0.05. RESULTS: the consumption of dairy, vegetables, coffee, tea, soft drink, and alcohol was not different between the normal BMD group and the osteopenia/osteoporosis group. It was noticed a significant difference (p<.05) on BMI and REE between the groups with normal bone density (BMI: 26.3 kg/m2; REE: 1279.6 kcal), and with osteopenia/osteoporosis (BMI: 27.4 kg/m2; REE:1233.6 kcal). However total PAL (2370.5 to 2885.5 METs/week) as well as calcium and limiting foods on calcium intake did not show any significant difference between both groups. Correlation values (r) between BMD and food intake (-0.01 to 0.33), PAL (0.01), BMI (-0.07), and REE (-0.06 to 0.08) were weak and no significant in both groups. CONCLUSION: patterns of physical activity, resting energy expenditure, body mass index and nutritional intake are very similar in non-sedentary pos menopausal women regardless their status of bone mineral density.

Supported CNPq 309481/2003-1.

BIOMECHANICAL COMPARISON OF THE TRACK START AND THE MODIFIED ONE-HANDED TRACK START IN COMPETITIVE SWIMMING: AN INTERVENTION STUDY

Galbraith, H., Scurr, J.

University of Portsmouth, United Kingdom

In competitive swimming, the fundamental goal is to cover a set distance in the least amount of time. The start is an area where small, yet significant gains can be made; some researchers have found that through consistent dive practice an elite swimmer can reduce their total race time by a minimum of 0.10 s. 1 At the elite and Olympic level this improvement could represent the time difference between a first and third place in a sprint event. 2,3 The purpose of this study was to modify the conventional track start diving technique and assess dive performance. Kinematic and kinetic effects of a swimming dive start intervention programme were examined using the conventional track start and the new one-handed track starting method in elite-level swimmers. Five male and seven female GB national qualifiers participated (mean age 16.7 ± 1.9 years, stretched stature 176.1 ± 8.8 cm, body mass 67.4 ± 7.9 kg) were assigned to a control group (n=6) or an intervention group (n=6) that learned the new one-handed dive technique. Swimmers underwent a 4-week intervention comprising 12 ± 3 thirty-minute training sessions led by the same coach to ensure consistency in coaching techniques, video feedback and training. Video cameras synchronised with an audible signal and timing suite captured temporal and kinematic data, and a portable force plate and load cell handrail mounted to a swim starting block collected force data over 3 trials of each technique. The performance criterion measure was time to 10 m [4.51s ± 0.45 track start (TS), 4.59s ± 0.41 one-handed track start (OHTS)], no significant differences

were found between the dive starts demonstrating the absence of a superior and preferred technique bias. A MANCOVA revealed that the type of dive conducted (F=7.682, 8, p = 0.000) affected several kinetic and kinematic variables including: vertical lower limb force (TS= 1.55 % BW, OHTS = 1.19% BW), flight distance (TS = 3.01 m, OHTS = 3.11 m), flight time (TS = 0.31 s, OHTS = 0.33 s) total time (TS = 0.97 s, OHTS = 1.03 s) and horizontal impulse (TS = 119.1 N•s-1, OHTS = 107.8 N•s-1). Although alterations in upper body technique had little effect on overall track start performance to 10 m, coaches should focus on the statistically significant dive performance variables including horizontal force and velocity at take-off, and time to 10 m during dive training sessions and they should guide athletes to choose the style that makes the best use of their respective strengths.

RED BLOOD CELL PARAMETERS IN PRE-PUBESCENT, PUBESCENT AND MATURE HIGHLY TRAINED FOOTBALL PLAYERS

Boyadjiev, N., Taralov, Z.

Medical University of Plovdiv, Bulgaria

Background - A suboptimal values of the haematological variables has often been recorded in young athletes involved in intense physical activity. There have even been reports of 'sports anemia' associated with intensive physical training(1,2). Our previous studies demonstrated lower values of red blood cell count (RBC), packed cell volume (HCT), haemoglobin concentration (HGB) in highly trained football players than in untrained controls of the same pubescent age(3).

The aim - To evaluate the haematological status of 2314 football players (15.11±2.89 yrs old) and to compare the results for pre-pubescent, pubescent and mature boys recruited in the study and also to relate the values obtained to the individulal aerobic functional capacity.

Methods - 2314 highly trained football players were included in the study. Their mean±SD age, weight, and BMI were: 15.11±2.89 yrs, 56.33±13.28 kg, and 19.62±2.58 kg/m2. The sportsmen were divided into three groups in accordance with their age: pre-pubescent group A (n=1178) - 13.22±1.05 yrs; pubescent group B (n=1029) – 16.57±1.04 yrs; and mature group C (n=107) – 24.30±3.78 yrs old. Venous blood samples were drawn from the cubital vein in standard conditions, and the RBC, HCT, HGB, mean corpuscular volume (MCV), white blood cell count (WBC) and platelet count (PLT) were measured. Each football player passed PWC 170-test.

Results – All haemathological variables in the groups were found in normal ranges, but the RBC was highest in group B (5.17±0.27 x 1012/l vs. 5.03±0.28 x 1012/l for group A, and 5.08±0.41 x 1012/l for group C). Group A demonstrated not only lowest values for the RBC, but also for the HGB (144.69±6.39 g/l vs. 149.06±6.02 g/l for group B, and 151.75±7.54 g/l for group C, P<0.001), and for HCT (0.437±0.02 vs. 0.451±0.02 for group B, and 0.451±0.03 for group C, P<0.001). The pre-pubescent football players (group A) had lower MCV (87.10±2.81 fl), than the players of group B (87.50±2.86 fl) and than the players from group C (88.06±2.95 fl). There was not difference in the WBC and PLT between pre-pubescent, pubescent and mature footballers. The mature players (C-group) demonstrated higher PWC/kg than pre-pubescent (20.64±2.34 vs. 19.25±2.36 kgm/min/kg), and than pubescent boys (19.76±2.69 kgm/min/kg). Significant correlations were obtained between the age and HGB, and between the age and HCT in groups A (0.19 and 0.19 respectively) and B (0.24 and 0.15 respectively). Good correlations were found between RBC and PWC/kg in all groups investigated.

Conclusions – Pre-pubescent highly trained football players have lower values of the red blood cell variables than pubescent and mature footballers, which correlates with lower aerobic working capacity.

THE INFLUENCE OF DIET EFFECT ON FREQUENCY, STRENGTH, AND PERIOD OF DIET IN KOREAN COLLEGE STUDENT'S

Hoseong, L., Youngho, S.

Dankook University, Korea, South

Although the exercise and dietetic treatment in the obesity are being clarified, in fact, a lot of problems exist in the diet action. Especially, frequency, strength, and period of exercise play an important role for diet effect. The objective of this study was to investigate the influence of diet effect on frequency, strength, and period of diet in male and female korean college student's. Data collection were surveyed by targeting in male and female college student's in the community, no disability in basic or instrumental activities of daily living and no cognitive impairment, and date used in this study recruited about 306 subjects including 65 males and 241 females. The collected data was analyzed with multiple regression analysis, and the result is as follows. First, the diet effect to the physical strength improvement was higher at practice period and practice frequency of diet, but not in the diet practice intensity. Second, the diet effect to the figure improvement was higher at practice period and practice frequency of diet, but not in the diet practice intensity. Third, the diet effect to the obesity improvement was higher at practice period and practice frequency of diet, but not in the diet practice intensity. Fourth, the diet effect to the well-balanced was higher at practice period and practice frequency of diet, but not in the diet practice intensity. Fifth, the diet effect to the confidence was higher at practice period and practice frequency of diet, but not in the diet practice intensity. These results suggest that diet practice contributed to the period and frequency than exercise intensity. Our results support the notion that constant and continued effort need to achieve the effect of diet.

FREQUENCY OF MUSCULOSKELETAL INJURIES IN TURKISH ROWERS

Koz, M., Ozkaya, C., Arslan, C., Yildiz, N.

Ankara University, Turkey

Rowing is increasingly popular in Turkey. There is a lack of information dealing with the profile of common injuries in Turkish rowers.The purpose of this study was to analyze all injuries occuring in a population of elite Turkish rowers to determine their frequency and location of injury.

A total 135 elite rowers (106 male, 29 female) participated in the study. Data were collected with a questionnaire named nordic questionnaire for the analysis of musculoskeletal symptoms during 2002-2003 race season. The injuries were classified according to the anatomical location of the injury, the mean time lost from employment or training due to injury, and the age of the rower. Correlations between incidence of injury and age, rowing experience, sex, weekly training hour, and boat type were determined by Chi-square test.

This study shows that the commonest site of injury in male are lumbar spine (54.7 %) knee (32.1 %), wrist/hands (26.4 %), shoulder (24.5 %) and ankle/foot (16.0 %). The commonest site of injury in female are lumbar spine (48.3 %), knee (37.9 %), wrist/hands (31.0 %), shoulder (24.1 %) and ankle/foot (10.3 %). The most frequent time lost from employment or training due to low back pain was 1-7 days (for male 20.8 % and for female 27.6 %). It has been determined that as long as chronological and training age increased, injury frequency had decreased significantly on all over regions ($p < 0,01$), and injury frequency of men has been detected as higher than that of women on the shoulder, wrist/hand, knee and ankle/foot areas($p < 0,01$). It has been found that there was a positive correlation between the boat type and the injury frequency($p < 0,01$). The highest frequency of injury has been observed in teh 4X class type rowers in all areas. It has also been found that there was a positive correlation between the weekly training hour and the frequency of injury. The more advanced training hour, the higher frequency of injury has been detected.

The present study suggests that there is a high incidence of injury in Turkish rowers, and that most injuries are low back pain and discomfort. This study also confirmed that low back injuries are a significant problem in rowers.

CUMULATIVE APPEARANCE OF DENGUE FEVER IN GERMAN PARTICIPANTS IN THE YOUTH TRACK AND FIELD WOLD CHAMPIONSHIPS IN JAMAICA 2002

Furian, T., Pfaff, G., Kimmig, P., Striegel, H., Niess, A.

Medical Clinic, Department of Sports Medicine, University of Tuebingen AND Baden-Wuerttemberg State Health Office, Epidemiology and Health Reporting, Stuttgart, Germany

The increasing international nature of sports, including youth athletics, results in more competitions in subtropical and tropical regions, with the corresponding health risks. After individual cases of Dengue Fever (DF) were diagnosed, all members of the German junior national team (n = 98) were asked to fill out a questionnaire regarding health problems and to send in a blood sample to be examined for DF-serology (quantitative IgM-titer). 76 persons completed the questionnaire (response rate 77.6%), 73 provided a blood sample, one who did not provide a serum specimen sent a written proof of respective laboratory results obtained from other laboratories (response rate 74.5%).

Most participants had used personal insect protection measures, such as mosquito nets and long clothing, or insect repellents. 27 participants reported having felt ill during the trip. After return, 25 persons experienced various symptoms.

Serologic evidence of DF was found in 10 participants (13.5 %), 6 females and 4 males. The prevalence of seropositive diagnoses did not differ significantly between athletes (5 out of 55 = 9.1%) and coaches (5 / 21 = 26.3%; p=0.2). Only in four cases was there at least a preliminary diagnosis of DF. Neither age, gender nor training volume influenced the risk of infection. DF led to a significant decrease in subjective athletic performance in the following 3 to 4 months.

The data of these follow-up examinations demonstrate that both good medical preparation and comprehensive care during competitions in countries with a high risk of tropical infectious diseases are very important. If international competitions take place in such regions, organizers and delegations should take measures to maintain the health of all participants including mosquito control programs.

EFFECTS OF SPONTANEOUS RUNNING ON SATELLITE CELLS IN RAT SKELETAL MUSCLE

Kurosaka, M., Naito, H., Ogura, Y., Kojima, A., Goto, K., Katamoto, S.

Juntendo University, Japan

Skeletal muscle satellite cells play an important role for muscle fiber regeneration and hypertrophy. It is well known that resistance training can increase the number of satellite cells with muscle hypertrophy. Recently, it has been reported that endurance training or an increased level of physical activity cause proliferation of satellite cells without muscle fiber hypertrophy. Therefore, the purpose of the present study was to examine the effects of the spontaneous running training on satellite cells in the skeletal muscle of rats.

Seventeen male Wistar rats (6 weeks old) were assigned to a control (CON) group (n = 5) or a training (TR) group (n = 12). Each rat in TR group was kept in a cage with a running wheel for eight weeks. All animals were fed standard rat chow and water ad libitum and maintained on a 12:12 h light-dark photoperiod in an environment-controlled room (22.0 ± 0.5?C, 55.0 ± 5.0% relative humidity). The daily running distance in TR group was recorded, and body weights in both groups were measured every week. After the training period, the right plantaris muscles in both groups were quickly removed under anesthesia, weighted and frozen with liquid nitrogen and stored at –85°C. Serial transverse sections (8μm thick) were made using a microtome at –20°C. Satellite cells were immunohistochemically stained, visualized and identified by using anti-Pax7 and anti-laminin antibody and DAPI. The number of muscle fibers, mean fiber area, myonuclei and satellite cells were measured. To determine the effects of endurance training, citrate synthase (CS) activity of the plantaris muscle was also measured as the oxidative capacity.

The mean running distance during the training period was 6570 ± 1773 m/day in TR group. Body weight was significantly lower in TR group than CON group (CON: 303.9 ± 16.1 g vs. TR: 259.5 ± 15.0 g). There was no difference in the muscle weight and mean muscle fiber area between CON and TR groups. CS activity (CON: 0.25 ± 0.01 μmol·min-1·mg protein-1 vs. TR: 0.30 ± 0.03 μmol·min-1·mg protein-1), the number of satellite cells (CON: 0.021 ± 0.004 vs. TR: 0.032 ± 0.007) and number of myonuclei (CON: 2.03 ± 0.14 vs. TR: 2.48 ± 0.40) per muscle fiber and the relative number of satellite cells (CON: 1.03 ± 0.17% vs. TR: 1.27 ± 0.15%) were significantly higher in TR group than CON group ($P < 0.05$). Furthermore, the relative number of satellite cells was positively correlated with running distance ($r = 0.61$, $P < 0.05$) as well as CS activity ($r = 0.49$, $P < 0.05$) in TR group.

It was concluded that the increased level of physical activity by spontaneous running induced proliferation of satellite cells without muscle fiber hypertrophy in the plantaris muscle of rat.

ACTIVATION PATTERN DIFFERS BETWEEN MONO- AND BI-ARTICULAR MUSCLES DURING A SUSTAINED CONTRACTION WITH EMG BIOFEEDBACK

Place, N., Martin, A., Duclay, J., Lepers, R.

INSERM ERM 207 Motricité-Plasticité, France

INTRODUCTION

Previous studies reported a different activation pattern for the bi-articular rectus femoris (RF) muscle compared to the mono-articular vastus lateralis (VL) and vastus medialis (VM) muscles during submaximal fatiguing isometric knee extension (Ebenbichler et al., 1998; Rochette et al., 2003). However, the activation strategy of the central nervous system during tasks where EMG is kept constant on different synergistic muscles has never been established.

The aim of the present study was to investigate time course of EMG activity for VL, VM and RF muscles during two tasks performed with an original EMG biofeedback either i) on vasti muscles or ii) on RF muscle.

METHODS

Thirteen subjects volunteered to participate to two experimental sessions. The protocol involved the measurement of 1) a maximal voluntary contraction with the knee extensor muscles (MVC); 2) a submaximal isometric fatiguing knee extension with a visual electromyographic (EMG) biofeedback set at i) 40% maximal EMG of vasti muscles (vasti task) or ii) 40% maximal EMG of RF muscle (RF task). All procedures were conducted on a Biodex isokinetic dynamometer at a knee angle of 75°. Surface EMG activity of VL, VM and RF muscles, torque and time to task failure were measured during the two tasks. EMG activity and torque was then expressed at every 10% of the endurance time. Maximal voluntary torque was measured before and after the fatiguing task.

RESULTS

Time to task failures were comparable for both tasks (173 ± 77 s for vasti task vs. 166 ± 105 s for RF task, $P>0.05$). MVC loss was similar for the two sessions (-27 ± 15% on average, $P<0.001$). Vasti EMG activity remained constant ($P>0.05$) for vasti muscles during the RF task but RF EMG activity decreased significantly ($P<0.001$) from 60% to 100% of endurance time during the vasti task (from 33.9 ± 2.9% maximal EMG at the beginning of the contraction to 23.3 ± 2.2% maximal EMG at task failure). Torque decreased ($P<0.001$) for both tasks (from 40.5 ± 0.7% MVC to 15.7 ± 1.4% MVC for the vasti task vs. from 41.4 ± 0.6% MVC to 23.4 ± 3.7% MVC for the RF task).

CONCLUSION

Present results clearly show a different activation pattern for the bi-articular RF muscle compared to the mono-articular VL and VM muscles during a sustained contraction performed with an EMG biofeedback. It seems that activating the bi-articular RF muscle is more strenuous for the central nervous system than the activation of the mono-articular vasti muscles.

NITRIC OXIDE SYNTHASE MEDIATES BONE STRENGTHENING EFFECT OF EXERCISE IN OVARIECTOMIZED RATS

Hung, W., Hsu, J.F., Lee, S.Y., Chang, C.K., Fang, J.L.

National Taiwan College of Physical Education, Taiwan

Bone strengthening effect of exercise on postmemoposal osteoporosis has been well documented, but the underlying mechanism remain controversial. Nitric Oxide synthase (NOS) expressed in bone tissues might be an important modulator in bone metabolism during exercise. The purpose of this study was to investigate whether NOS mediates the strengthening effect of exercise on estrogen deficient bone tissues in rats.

Fifty twelve-week old Spraque-Dawley rats were assigned randomly to one of the following five groups : (1) exercise (EX), (2) NOS inhibitor (NOS-I) + exercise, (3) sedentary control group (OC), (4) normal control group (N), and (5) baseline control group (B). All groups other than the B group were either bilateral ovariectomized or sham-ovariectomized. EX and NOS-I groups ran 4 days per week on a motor-driven treadmill. The intensity of exercise was gradually increased to 24 m/min at 0% grade for 60 min/day till the end of training period. L-NAME was administered to the NOS-I group at the dose of 30 mg each other day by gastrogavage for the entire study period. The rats were sacrificed after 12 weeks. Femurs and tibias were removed for cantilever or three point bending test, X-ray absorption, and NOS expression assays.

After twelve weeks of experiment period, exercise training increased bending moment of femur neck (EX：25.33±2.31, NOS-I：18.56±4.28, OC：20.46±4.89, N：22.93±4.12, B：16.01±4.50 kg-mm), maximal loading and stiffness of tibia (EX：18.72±1.56, NOS-I：15.57±1.93, OC：15.72±1.71, N：16.86±1.57, B：11.17±1.81 kg), and bone mineral density of femur neck (EX：0.70±0.05, NOS-I：0.63±0.02, OC：0.51±0.14, N：0.64±0.07, B：0.55±0.03 unit). The exercise effects were abolished by NOS inhibitor but bone density was not affected. NOS expression was dramatically increased in NOS-I group, possibly due to compensation.

RISK FOR THE HEALTH OF SOME OF THE USED SPEED GLUES FOR THE GLUING OF BLADES AND RUBBERS IN COMPETITIVE TABLE TENNIS

Porcar, C., Escoda, J., Riera, J., Drobnic, F.

Consorci Sanitari de Terrassa-Centre d'Alt Rendiment Esportiu, Spain

Speed glues for the gluing of blades and rubbers in competitive Table Tennis and its risk for health.

The international Federation of Tennis of Table will prohibit the use of speed glues that contain Volatile Organic Compounds (VOC) on 2007.

Such speed glues are being used approximately from 1970, with the purpose of providing greater speed and spin to the ball.

Recommendations and regulations for the use of these substances with the purpose of preventing acute effects and to protect the health of the workers exist in the labour world.

The risks for the health depends on the type of compound and of the exposure time.

In the composition of the three analyzed glues we found: butane, hexane, pentane, ciclopentane, heptane, ciclohexane, octane, and other similars in smaller amount. All of them are absorbed by inhalation and some by contact with the skin. The poisonous effects already mentioned are strictly controlled in labour environments.

Players are exposed to these volatile substances during the gluing, previous to each session of training, and throughout the time that each training session lasts.

The yearly health assessment of the Table Tennis players at CAR has been always correct. No alterations in the physical exploration have been detected, neither in the analyses of blood nor in electrocardiogram.

Nevertheless, we have found alterations in the respiratory functional tests, in form of some diminution of the respiratory volumes registered by spirometric test that correspond to a restrictive pattern. These alterations clinically are not related to pulmonary disease nor to bronchial hyperreactivity or previous clinical pathology history.

We have observed a diminution of the Forced Vital Capacity (FVC) in four of the eight players and the Forced Espiratory Volume in the first second (FEV1) in three of the eight players, comparing the assessments of 2005 with respect to the ones made in 2004. Indicating a worsening of the spirometric data.

We cannot statistically conclude that these alterations are secondary to the irritation of the upper respiratory produced by the VOC's inhalation. Research will continue, since the suspicion level is high.

LOW BACK PAIN IN ELITE AND SEMI-ELITE FOOTBALL: A CROSS-SECTIONAL SURVEY WITH NON-ATHLETIC CONTROLS

Hoskins, W., Pollard, H., Daff, C., Odell, A., Garbutt, P., McHardy, A., Hardy, K., Dragasevic, G.

Macquarie University, Australia

No study has investigated the levels and prevalence of low back pain (LBP) occurring in football players or at different levels of athletic play (elite and semi-elite).

PURPOSE: To document the levels and prevalence of LBP symptoms in Australian male elite and semi-elite level football players and to compare data with an age-matched non-athletic population. METHODS: Subjects were drawn from clubs playing in the national or international competition for elite players (n=271) and the highest level state competition for semi-elite players (n=360). Age matched controls were drawn from a convenience sample of university students and office workers (n=152). Subjects completed the validated and reliable Quadruple Visual Analogue Scale (VAS) and the McGill Pain Questionnaire (short form), along with a series of specific LBP questions regarding frequency and duration of symptoms, age of first onset LBP and aetiology. Group means were compared using descriptive statistics. RESULTS: There was a significant increased difference between controls and semi-elites and between semi-elites and elites for current VAS, VAS average and VAS at worst (all $p<0.01$) (controls 1/10 v semi-elites 2/10 v elites 3/10 for current and average VAS, controls 4/10 v seim-elites 5/10 v elites 6/10 for VAS at worst). The average pain profile was also clinically significant between controls and elites ($p<0.01$). There was a significant difference between controls and combined elite and semi-elites for VAS at best ($p<0.01$) (controls 0/10 v semi-elites and elites 1/10). There was a significant difference between controls and semi-elites combined compared with elites for levels of overall pain, sensory aspect of pain severity and total pain rating (all $p<0.01$). There was no difference between the age of first onset of LBP for any group (average age 17). 85% of elites, 65% of semi-elites and 53% of controls said their first ever episode or attack of LBP was due to athletic activities. The point prevalence of LBP was 69% for elites, 57% for semi-elites and 55% for controls. 93% of elites, 75% of semi-elites and 49% of controls said their current episode of LBP was due to athletic activities. 40% of elites, 31% of semi-elites and 17% of controls experience daily or weekly LBP. CONCLUSION: Footballers in Australia compared with age-matched controls have significantly higher levels and prevalence of LBP and this figure escalates significantly with level of play.

THE EFFECT OF SPORTS CHIROPRACTIC ON THE PREVENTION OF HAMSTRING INJURIES: A RANDOMIZED CONTROLLED TRIAL

Hoskins, W., Pollard, H.

Macquarie University, Australia

Hamstring injuries are the most prevalent and recurrent injury in Australian Rules football resulting in the most missed matches.

PURPOSE: To determine whether sports chiropractic involving manipulation and supporting soft tissue therapies to the spine, pelvis and lower extremity can prevent the occurrence of hamstring injuries in semi-elite Australian Rules footballers. METHODS: 59 male subjects (age range 18-27) were drawn from two semi-elite clubs and randomly allocated to an intervention (n=29) or control group (n=30) matched for age, low back pain, Knee Injury and Osteoarthirits Outcome Score and hamstring injury history. Treatment and scheduling for the intervention group was pragmatically determined. The minimum scheduling adhered to was 1 treatment per week for 6 weeks, 1 treatment per fortnight for 3 months and 1 treatment per month for the remainder of the season. Treatment began 6 weeks prior to round 1. The intervention and control group both continued to receive standard club medical management (including medication, surgery, manipulative physiotherapy, massage, strength and conditioning and rehabilitation) as directed by club staff. All medical staff were employed by the club and had no limitation in the number of treatments or the type of treatment they could render. This was independently administered without restriction or interference from the study authors. Injury was determined and recorded by club medical staff and defined as that which results in a missed match. Clinical parameters were recorded including mechanism of injury. Two-sample t-tests with 95% confidence intervals were used to assess the efficacy of the treatment with respect to the number of injuries and total amount of playing weeks lost. Survival analysis based on Kaplan-Meier curves and the logrank test were used to compare with respect to injury recurrence. RESULTS: At the end of season (24 matches/24 weeks) there was a significant difference between the intervention and control group for hamstring injury incidence (1 v 5 $p<0.05$), weeks missed due to hamstring injury (4 v 14 $p<0.05$), hamstring injury recurrence (0 v 2 $p<0.05$), total lower-limb muscle strain incidence (1 v 8 $p<0.05$), weeks missed due to total lower-limb muscle strain (4 v 21 $p<0.05$), non-contact knee injury incidence (1 v 7 $p<0.05$) and weeks missed due to non-contact knee injury (1 v 24 $p<0.05$). CONCLUSION: This study demonstrated significant prevention of hamstring injuries severe enough to result in loss of competition match play. Significant reduction in lower-limb muscle strains and non-contact knee injury was also observed.

SYNTHESIS OF MYOFIBRILLAR PROTEIN IN SKELETAL MUSCLE AND OF COLLAGEN IN TENDON OF PATIENTS WITH OSTEOARTHRITIS: RESPONSE TO EXERCISE

Petersen, S.G., Miller, B.F., Hansen, M., Holm, L., Kjær, M.

Bispebjerg Hospital, DK-2400 Copenhagen NV, Denmark

Physical activity leads to an increased protein synthesis in both muscle and tendon in healthy people of all ages, and this leads to both stronger skeletal muscle and more resistant connective tissue, which is important for joint-stabilisation. Likewise, in patients with osteoarthritis (OA) of the knee, physical training decreases symptoms and increases function, but the mechanism behind this is unknown, and it remains to be explored whether training leads to an increased synthesis of structural proteins of muscle and tendon in OA. We studied 8 elderly patients (50-70 years) with knee OA (symptoms and x-ray) and compared results with a healthy control group. Each patient performed 60 min of one-leg kicking at 67 % of W-max in a modified Krogh ergometer while the contra lateral resting leg acted as resting control. 24 hours after one-leg kicking, the patients met in the laboratory in a fasting state and had a stable isotope-infusion of 13C-leucine and 15N-proline in a brachial vein. During the infusion we collected blood samples, and after 4 hours of infusion, biopsies were taken bilaterally from both m. vastus lateralis and the patella-tendons. Analysis of 13C-leucine incorporation in the muscle biopsies demonstrated that the mean fractional synthesis rate (FSR) of myofibrillar protein in the resting leg was 0.07% h-1, whereas the mean FSR of the working leg was 1.0% h-1($p>0.05$). In healthy young controls, a similar mean FSR of the resting leg at 0.04% h-1 and a FSR of the working leg at 0.1% h-1 was found ($p>0.05$).

In contrast, in the tendon of OA-patients we found that the mean FSR was similar in the resting (0,09% h-1) and the working leg (0,09% h-1), indicating no response to exercise, whereas in the control group of younger men, mean resting FSR was 0,04% h-1 and working FSR was 0,08% h-1. Interestingly, the resting FSR for tendon collagen in OA was significantly higher than in controls ($p=0,029$). In conclusion, protein synthesis of skeletal muscle myofibrillar structures in elderly people with osteoarthritis seem to respond to exercise in a similar way that muscles of younger individuals do. In contrast to this, tendons of elderly people with osteoarthritis of the knee seem to have a significantly higher resting FSR than that of young people. Furthermore, protein synthesis in tendons of elderly with osteoarthritis does not respond to acute exercise. This study indicates that whereas protein synthesis of skeletal muscle is normal in OA patients, resting collagen synthesis rates of connective tissue (like tendon) is elevated in osteoarthritis patients.

EFFECTS OF TAURINE ON BLOOD LACTATE LEVEL WHICH WAS INCREASED BY RUNNING EXERCISE IN RATS

Shumpei, M., Tohru, T., Kazuyoshi, N., Hiroyasu, M., Takahiko, N., Yoshihisa, Y.

University of Tsukuba, Japan

To examine the effects of taurine on fatigue induced by running exercise with a treadmill, blood lactate and muscle lactate were measured.

Concentrations of blood lactate elevated in the twenty-, thirty- and forty-minutes' running groups as the duration of running exercise was prolonged. In the 30- and 40-minutes running groups were higher than the control group with statistical significance ($p<0.05$). Changes in concentrations of muscle lactate were'nt statistical significance in all the groups. However, concentrations of muscle lactate tended to elevate as the duration of running exercise was prolonged. Concentrations of blood lactate decreased in the 03, 1.0 and 3.0% taurine administration(14days) groups with 25minutes running exercise. Blood lactate decreased dose-dependently.

Taurine is considered to decrease blood lactatose and an index to indicate fatigue increased by running exercise.

EFFECTS OF SERIAL FATIGUING TASKS AND ACUTE RECOVERY ON INDICES OF VOLITIONAL AND MAGNETICALLY-EVOKED NEUROMUSCULAR PERFORMANCE OF THE KNEE FLEXORS IN FEMALES

Minshull, C.M., Walters-Edwards, M., Gleeson, N.P., Rees, D., Bailey, A.

Nottingham Trent University, United Kingdom

Optimal functioning of the knee flexors is paramount to the dynamic stabilisation of the knee (Rees, 1994). Team sports frequently require serial episodes of high-intensity fatiguing exercise (McInnes et al., 1995), which may be associated with greater decrements to neuromuscular performance and a prolonged recovery compared to single episodes of fatigue (Zhou, 1996). The effects on the physiologic capacity of the knee flexors to initiate muscle force under these circumstances are yet to be established.

Volitional and magnetically-evoked neuromuscular performance of the knee flexors of the preferred leg (females, n=20; 21.3 ± 2.3 yrs; 1.68 ± 0.06 m; 68.0 ± 6.3 kg [mean ± SD]) was assessed prior to and immediately following two treatment conditions: (i) a fatiguing intervention condition consisting of 4 bouts of 35-seconds maximal static exercise, (ii) a control condition consisting of no exercise. Recovery measures were obtained at 1, 3 and 6-minutes.

The intervention induced cumulative decreases to knee flexor volitional peak force of up to 15.9%; recovering to 96.6% of pre-exercise values following 6-minutes of rest (235.3 ± 54.7 N vs. 198.1 ± 38.4 N; $F[2.4, 44.8 GG] = 3.2$, $p < 0.05$). A 25.6% impairment to volitional electromechanical delay performance (55.3 ± 11.8 ms vs. 69.4 ± 24.5 ms; $F[4, 76] = 2.7$, $p < 0.05$) and a 10.0% improvement in magnetically-evoked electromechanical delay (EMDE) (24.5 ± 4.7 ms vs. 22.1 ± 5.0 ms; $F[2.6, 49.6 GG] = 3.18$, $p < 0.05$) following the first exercise bout were sustained throughout the remainder of the intervention and recovery. Magnetically-evoked peak twitch force was impaired (23.7%) following the fourth episode of fatigue (21.5 ± 13.6 N vs. 16.4 ± 14.7 N; $F[2.3, 44.5 GG] = 3.2$, $p < 0.05$) and did not recover by 6-minutes.

The fatigue-related impairments to the neuromuscular performance of the knee flexors suggest a prolonged decrease in capability to stabilise the knee joint following serial episodes of high-intensity exercise. However, quickened initiation of muscle force (EMDE) may represent a vital neuromuscular compensatory strategy to resist injury.

OPTIMISATION OF EXERCIES PERFORMANCE IN WHEELCHAIR RACING ATHLETES

Mueller, G.

Swiss Paraplegic Research, 6207 Nottwil, Switzerland

Wheelchair racing is a paralympic discipline where exercise performance is at the highest level in many categories. To win a medal at the paralympic games, athletes have to exercise and prepare for such competitions as able-bodied olympic athletes do.

However, spinal cord injured (SCI) athletes have additional problems to consider due to their impairment. Such problems may cause special or additional exercise training, supplementation, or other arrangements to be used in order to reach the highest possible exercise performance level.

Some of these additional problems are the absence of the sympathetic nervous system regulation in tetraplegic and high lesion paraplegic athletes, the absence of thermoregulation below the lesion level, the lower amount of active muscle mass which also affects respiratory muscles e.g. abdominals and in tetraplegic athletes even most expiratory muscles. This leads to an altered coenaesthesia which needs special attention throughout the whole training process.

In order to consider all these special needs and to concurrently improve individual exercise performance, we conducted several studies with junior and elite wheelchair racing athletes. Thus we developed and validated a new exercise test in order to improve training quality in junior wheelchair racing athletes. Furthermore, the effects of respiratory muscle endurance training on 10km time-trial performance in elite wheelchair racing athletes was investigated, as well as the influence of creatine supplementation on 800m all-out exercise performance. Results of the study about respiratory muscle endurance training showed significant improvements in respiratory muscle endurance in the training group, but failed to show significance in 10km time-trial performance, even if the training group showed a mean improvement of 3 min. Our current investigations focus on different tests to determine the individual maximal lactate steady state in wheelchair racing athletes in order to improve guidance of exercise training in this special group of athletes.

Outcomes of all these studies revealed that there are big inter-individual differences between athletes due to their varying types and levels of impairment. Lesion level for example plays a major role in exercise performance and due to only small numbers of athletes, large standard deviations occur in the results of scientific studies performed with SCI athletes. In general, due to the limited number and heterogeneity of wheelchair racing athletes, highly scientific studies are difficult to perform. Nevertheless, SCI individuals could benefit from such studies, and based on individual results each athlete would be able to decide which additional intervention may help to further improve personal exercise performance.

REPETITIVE HOPPING EXERCISE ALTERS THE SKELETAL MUSCLE ARCHITECTURE AND THE FASCICLE AND TENDON INTERACTION

Ishikawa, M., Vincent, M., Kanervo, M., Peltonen, J., Nicol, C., Chavet, P., Komi, P.V.

Neuromuscular Research Center, Finland

In human locomotion, the tendinous tissues (TT), such as tendons and aponeuroses, can play an important role for movement performance with regard to energy storage and its release (e.g. Fukunaga et al 2002). The recent ultrasonographic studies showed that the fascicles contract isometrically or shorten when the muscle-tendon unit (MTU) lengthens during the ground contact phase of walking, for example (e.g. Fukunaga et al 2002). This fascicle behavior, especially during the MTU lengthening phase, suggests that TT plays an important role as a mechanical buffer during human locomotion (Fukunaga et al 2002). On the other hand, it was suggested that repeated isometric contractions could alter the fascicle geometry (Maganaris et al 2002) and tendon properties (Kubo et al 2001). Therefore, it is important to consider how the repeated high intensity movements change the fascicle-TT interaction. This may have implications, especially for utilization of elastic energy during locomotion. Therefore, the purpose of the present study was to examine architectures and interaction between the fascicle and TT of the medial gastrocnemius (MG) and Soleus (SOL) muscles during human hopping exercises.

32 subjects underwent 15 repetitive hopping (two-legged hopping) with maximal efforts on a force plate followed by submaximal repetitive hopping (65% of the peak ground reaction force) until exhaustion. Ground reaction force and kinematics were recorded together with ultrasonographic scanning (96 images/sec) of MG and SOL during exercises. The subjects were asked to stop hopping and remain standing for 3-4 seconds to measure the muscle architectures before the exercise, after 15 maximal hops and during repetitive hopping after 50, 100, 250 and then at 250 hop intervals.

When measured during erect standing, the fascicle lengths of MG and SOL increased significantly and muscle-tendon junction of MG shifted proximally when hopping progressed. During the ground contact, after the rapid fascicle stretching (0-10% of the contact period), the MG fascicles shortened throughout the ground contact in the initial 50 hops. The SOL fascicles were stretched during the MTU lengthening. However, when hopping have advanced further (>500 hops), the stretching of the MG and SOL fascicles during the MTU lengthening increased and the estimated TT stretching decreased significantly.

The observed results demonstrate that the fascicle behavior of MG and SOL muscles and TT properties could vary with repetitive hopping. The increased fascicle stretching during exercise and the longer Achilles tendon at the standing position due to the repetitive hopping can influence the storage of elastic energy.

RELATIONSHIP BETWEEN ENDURANCE CAPACITY AND CHANGES IN SURFACE ELECTROMYOGRAM SPECTRUM ANALYSIS DURING SUSTAINED SUBMAXIMAL ISOMETRIC HIKING ACTIVITY

Boyas, S., Maïsetti, O., Guével, A.

University of Nantes, Nantes Atlantique Universities, France

Introduction

In dinghy sailing, hiking is a technical gesture allowing to reach the optimal speed of the boat. This position solicits several joints and mainly involves the anterior muscles of the trunk and lower limbs in an isometric contraction mode.

Several studies have shown that changes in sEMG parameters during isometric mono-articular submaximal contractions sustained until exhaustion were related to the endurance time (tlim) (1, 3). However, the relationship between tlim and changes in sEMG parameters has not been investigated yet during a sustained pluri-articular submaximal task.

The aim of this study was to examine whether the changes in sEMG parameters were related to the tlim of a submaximal pluri-articular task sustained until exhaustion.

Methods

Nine sailors regularly involved in hiking position (hikers) and 9 physical education students (controls) sustained a hiking position corresponding to 50% of their maximal hiking torque until exhaustion on a specific hiking ergometer reproducing actual hiking position. The electrical activity of main muscles [rectus abdominis (RA), rectus femoris (RF) and vastus lateralis (VL)] acting as synergists to maintain the hiking posture was recorded bilaterally. sEMG amplitude (RMS), MPF and relative power in the 6-30 Hz frequency band (FB1) were calculated.

Changes in sEMG parameters were assessed using the slope of linear regression and a regression-free index called area ratio (1). Changes were computed over the tlim and if significant, over time periods shorter than tlim. Relations between tlim and changes in sEMG were evaluated using Pearson correlations.

Results

Hikers were 45% less fatigable than controls ($p<0,01$). The most fatigable muscle was the RA, whatever the group (2). These results were illustrated by greater changes in RMS area ratio for controls (-1,06±0,80) compared to hikers (-0,34±0,24) and for RA (-1,18±1,37) compared to VL (-0,66±0,78) and RF (-0,31±0,35). Greatest changes in MPF area ratio were also obtained for the RA muscles (0,18±0,13) compared to RF (0,11±0,04) and VL (0,05±0,09). FB1 area ratio changes seemed to indicate that both RA (-0,26±0,38) and RF (-0,27±0,22) muscles were more solicited than VL (-0,04±0,14). No significant relation between tlim and sEMG changes computed over tlim was found whatever the statistical index (slope or area ratio), the muscle, the parameter or the group.

Discussion/Conclusion

These results contradict the literature indicating that relations between tlim and sEMG changes were greater using changes in the most fatigable muscle (3, 1). This may be due to the number of muscles and joints involved in pluri-articular tasks and to modifications in muscular activity patterns that can occur during fatigue (4).

BACKHANDSPRING PERFORMANCE MODEL BY CLUSTERS ANALYSIS

Penitente, G., Merni, F.

Faculty of exercise and sport sciences; University of Bologna, Italy

The backward handspring(BH) is a basic skill action used in the back tumbling passes on the floor exercise. It's also performed as a great deal on the beam and it represents the fundamental action of the Yurchenko vault elements. It was hypothesized that some BH biomechanical variables were significantly correlated and that they could identify the movement model. The aim of this work is to highlight the most important temporal, spatial (linear and angular), and kinematics relationships for this movement.

5 Italian female gymnasts aged 10 to 14,competing for 2 local clubs, performed several repetition of round-off(RO) and BH. Statistic analysis has been done on data extracted by the 3d trajectories of 46 markers displaced on the gymnast's body recorded by an optoelectronics system(Vicon 3000pixel;100Hz). The center of mass(COM) location was identified according to the Davis-Kadaba proceeding. The variables were selected from the technical evaluation rules and in reference to the specific literature[1-4]. Starting from two correlation matrixes, for the first(1) and second(2) flights(FL) phases' variables respectively, we have applied and then compared both the non-hierarchical and the hierarchical cluster analysis methods.

The results show that the 1FL phase's clusters are stronger than the 2FL ones and, that the clusters individualized with the two analysis methods are very similar.

For the 1FL there are 2 enough complex clusters. In the first the hip(h), knee(k) and ankle(a) ROIMP angles(A) are tightly correlated among them and, with the delta gathering and pushing's kA and, with the vertical velocity(Vz) at the ROIMP. The second cluster includes the aA takeoff(TKO) that is significant correlated to:

– the maximum gathering Ha

– the feet(F) SUPP time, the COM position versus the SUPP base both at the FIMP and TKO

– the ROIMP horizontal velocity(Vx)

– the gathering hA.

The 2 clusters that grouped the next variables are:

1. The COM vertical lift, the 1FL time and, the F TKO kA.

2. The FTKO hA, the FTKO Vz, the vertical COM pushing during the FSUPP phase.

The most important correlations for the 2FL are in the following clusters:

1. The 2FL time, the HTKO Vz; the 2FL space and the 2FL's COM vertical lift.

2. The HIMP hA, the HTKO aA and, the COM's vertical push space during HSUPP phase.

The results show that is possible describe a technical model for the BH through clusters analysis and,how both the biomechanical and technical variables, evaluated by judges, are correlated among them.

DIFFERENCE IN KINETIC VARIABLES ACCORDING TO SHOE TYPE DURING WALKING

Kwon, B.Y., Yi, K.-O.
Ewha woman's University, Korea, South

Purpose: The purpose of this study was to analyze force and pressure variables according to different shoes types during walking.
Methods: Subjects for this study consisted of three college-aged females who had never experienced pregnancy. Passive force variables were measured utilizing the Kistler Force Platform (9281B), while total pressure and pressure distribution was measured using the Pedar Insole system (V.654R, V.658L, novel, Germany). These variables included: maximum passive force, number of passive force peaks, maximum passive loading rate, maximum passive decay rate, passive impulse. Each subject used standard walking shoes, elevated forefoot walking shoes, round bottom walking shoes, and high heeled dress shoes (7cm). Statistical analysis was performed using SPSS 12.0 program with one-way ANOVA analysis and tukey post-hoc testing.
Results
There were significant differences in the following categories of passive force variables:
1. Maximum passive force between round bottom shoes and high heeled shoes(F=4.957, p<.05).
2. Number of passive force peaks between all shoes types and high heels(F=8.333, p<.01).
3. Maximum passive decay rate elevated forefoot shoes, round bottom shoes, standard walking shoes and high heels respectively (F=9.705, p<.01).
4. Passive impulse between round bottom shoes, standard walking shoes and high heels respectively (F=6.020, p<.05).
There were significant differences for pressure variables in the following categories:
1. Midfoot pressure between elevated forefoot walking shoes, high heels and round bottom walking shoes (F=7.048, p<.05).
2. Forefoot pressure between high heels and all other categories (F=45.869, p<.01).
3. Total mean pressure between elevated forefoot walking shoes and all other categories (F=20.994, p<.01).
Conclusion
Total mean pressure was highest for round bottomed shoes and high heels, while total mean pressure was the lowest for elevated forefoot walking shoes. There were significant differences between the high pressure and low pressure groups.
Elevate forefoot shoes had the lowest levels of decay rate, and total pressure. The structure of elevated forefoot shoes transfers these forces and pressures from the foot into the lower leg and higher. As a result, different muscles become engaged in gait, resulting in lower decay rate and pressure while walking. Future studies should incorporate the use of an EMG in order to quantitatively evaluate the degree to which different muscle groups are enacted according to shoe type.

SHORTENING-STRETCH CYCLE OF HUMAN PLANTAR FLEXORS IN VIVO: EFFECTS ON MOMENT GENERATION AND MUSCLE ARCHITECTURE

De Monte, G., Arampatzis, A.
German Sport University Cologne, Germany

It is accepted that following active muscle stretching or shortening, phenomena known as force enhancement and force depression can be present (1, 2, 3). In daily activities muscles do not undergo isolate shortening or lengthening contractions but rather shortening-stretch (SH-ST) or stretch-shortening (ST-SH). Reports state that the shortening induced force depression is unaffected by a previous stretch (4, 5). Oppositely, stretch induced force enhancement is affected in a dose dependent manner by a previous shortening (4, 5). However the available studies on force depression or force enhancement after a ST-SH or a SH-ST cycle were conducted on isolated cat muscles. Results on these phenomena in human skeletal muscles are not available in the literature. In addition the influence of the history dependent mechanical properties of the tendon and aponeurosis (i.e. creep) was not examined in these experiments. Therefore the purpose of this study was to examine the moment generation of the human plantar flexors and the architecture of the m. gastrocnemius med. (GM) during and after SH-ST cycles in vivo, and to verify the hypotheses that there is a moment enhancement after SH-ST cycles and that this might be influenced by muscle architectural changes.
Fourteen male volunteers participated in the study (Age: 30.7±5 years, height: 177.4±7 cm, body mass: 79.6±9 kg). The subjects performed a series of isometric-SH-ST-isometric plantar flexion contractions at two electro stimulation frequencies (85Hz, 30Hz), two movement amplitudes (15°, 25°) and three velocities (25°/s, 50°/s, and 100°/s). The corresponding ankle moments, kinematics and changes in muscle architecture were analysed at eight time intervals (B1 to B8). The effects of stimulation frequency, motion amplitude and velocity on torque enhancement were tested by a univariate ANOVA. The main effects were compared using a Bonferroni correction (α = 0.05). The results show an isometric ankle joint moment enhancement at steady state of about 2% after SH-ST cycles. Furthermore the enhancement found was independent of amplitude, velocity and stimulation frequency. Despite an "architectural steady state" after SH-ST cycles, the GM fascicle length was lower and the pennation angle higher (~2%) than in the initial isometric condition. Considering that the GM was tested in the ascending limb of its force-length relationship the results indicate that the moment enhancement found was underestimated. Concluding: We found an enhanced ankle joint moment after SH-ST cycles of similar amplitudes during maximal and submaximal stimulations. Moreover the observed moment enhancement underestimates the actual moment enhancement which has to overcome the adverse architectural changes.

ALLOMETRICAL ANALYSIS OF THE BALL KICKING PERFORMANCE IN MALE JUNIOR SOCCER PLAYERS

Teshima, T., Yumigeta, R., Tsunoda, N.

Kokushikan University, Japan

The purpose of this study was to clarify relative growth of the ball kicking performance to body height in male junior soccer players.

Eighty-seven male junior soccer players aged from 10 to 17 years were participated as subjects. Subjects were classified by nine body height groups for every 5cm. The anthropometric parameters for body height (BH), body weight (BW) and fat free mass (FFM) were measured in all the subjects. Each subjects were performed a warm-up routine including some stretching and kicking drills. All subjects were performed maximal ball kicking to measure maximal kicked ball distance (BD). Kicked ball velocity (BV) in the distance of 5m with the three ball kicking was measured by Radar Gun (Mizuno, Japan). Maximal swing velocity (SV) on ball kicking movement of the lower limb was obtained using a custom-made movement velocity measurement system of Speed Meter (VINE, Japan). Statistical analysis was used allometrical analysis method to relative development on ball kicking performances due to physical growth. Ball kicking performances (y) corresponding to body height (x) was plotted on double logarithmic graph to obtain allometric equation $y = bx^a$, where "a" is a developmental index and "b" is constant. Partial correlation coefficient between anthropometric data and ball kicking performances were analyzed. The level of significance was set at $p<0.05$.

The relationships between body height and ball kicking performances (BD, BV and SV) showed broken lines which has three phases with two critical points. The body heights corresponding to the first critical point were 150.3cm and 148.8cm for BD and BV, respectively. There is first critical point of body height corresponding to 146.3cm in SV. The index "a" for BD increased from 1.415 to 3.796 at first critical point. In BV, allometly index was changed from 0.777 to 2.1036. There was allometry index of SV increased from 0.199 to 2.251 at the first critical point. Above the second critical point, the index "a" decreased ball kicking performances respectively. And also, BH and FFM as anthropometric parameters were closely related to the ball kicking performances during rapidly developing from first to second critical point of body height.

In this study, Ball kicking performances were rapidly developed from about 150 to 170cm of body height. The age range corresponding to the first critical point was about 12-13 years old with chronological age. Generally, those ages were appeared adolescence growth spurt in almost boys. During this body height range from about 150 to 170cm, there was significant coefficient correlation between BH and FFM and ball kicking performances. And also, ball kicking performances were significantly developed than body height growth during this body height range. From these results, it was considered that ball kicking performance may be develop due to physical growth during adolescent growth spurt in male junior soccer players.

COMPERATIVE KINEMATIC ANALYSIS OF SIMILARITIES AND DIFFERENCES IN SERVE AND GROUNDSTROKES BETWEEN WHEELCHAIR AND STANDING TENNIS PLAYERS

Haudum, J., Wagner, H., Schwameder, H., Haudum, A.

University of Salzburg, Austria

Wheelchair tennis players (WTP) have different playing conditions compared to standing tennis players (TP) due to locomotion and injury. The purpose of this study was to clarify differences in EMG activity and shoulder angles between wheelchair and standing tennis players during tennis groundstrokes and serve.

5 male wheelchair tennis players (mean ITF ranking 41.5), and 3 male and one female able-bodied tennis players (Austrian National League) served as subjects.

Nine muscles (m. bizeps brachii, m. trizeps brachii, m. brachioradialis, m. anterior deltoid, m. posterior deltoid, m. pectoralis, m. trapezius, m. latissimus, m. external oblique) of the dominant side were studied using surface electromyography. The objective was to analyze the mean activation of these muscles engaged in the tennis movements: serve, backhand slice, and forehand topspin. The surface EMG was processed with IKE software.

Kinematic data was collected by eight cameras (Vicon System) keeping track of reflective markers placed on the trunk and arm. Data included shoulder angles of the dominant arm: anteversion, abduction and internal rotation of the humerus with respect to the thorax.

T-test was used for significance testing of the mean differences between WTP and TP (alpha = 0.05).

Results showed that in all movements normalized mean EMG activity of the nine muscles was not significantly different between WTP and TP.

Statistical analysis of kinematic data showed significant differences in the range of abduction ($p<0.001$) and anteversion ($p<0.001$) angles during all three movements, whereas results for the range of internal rotation angle did not show significant differences between WTP and TP ($p>0.05$) apart from the serve. WTP had a significantly greater range of shoulder anteversion, whereas the range of shoulder abduction was significantly lower than that of TP.

The findings of this study suggest several important points about joint motion. Although being in a lower sitting position, WTP have less abduction angles. Range of anteversion angle is, however, increased in WTP. This could be a strategy to find the best combination of anteversion and abduction angle producing the greatest consistency and accuracy in their strokes.

Different shoulder angles might be important findings for shoulder pathology and wheelchair tennis training skills, especially flexibility training.

CREATION OF A FREE COMPUTER SCIENCE INSTRUMENT FOR THE MEASUREMENT OF TEMPORARY EVENTS FROM CONTACT PLATFORMS NAMED CHRONOJUMP, AND ITS APPLICATION IN SPORT SCIENCES

de Blas, X.

FPCEE-Blanquerna, Universitat Ramon Lull, Spain

Time is the most used measure to value sport results. Time measurements must be taken with reliability, accuracy and independence of the observer, specially when the evaluands are very short. For this reason, when sport science universities need measuring tools, they usually buy expensive –unaffordable for students- technological instruments whose source code is not accessible, forcing the users to trust the manufacturing company's quality controls and preventing them from the desirable validation in all scientific scope.

The aim of this project is to provide a free GPL licenced application, which not only is freely downloaded from the Internet, but also facilitates the access to the source code and schemes of all its versions, both in software and hardware. This tool is made up of three parts: a contact platform, which is properly documented so that the user can build it; Chronopic chronometer based on the free microcrontroller Skypic; and Chronojump software, which captures the events in Chronopic, organises them in a database and manages all the information, allowing to analyse, graph and prepare reports.

A technological structure integrating some free softwares has been created. It includes: CVS for revision control, FTP for version distribution, SSH for secure changes submissions, Apache server for web publishing, Sendmail for mail lists, and Create_web_chronojump –designed ad-hoc- for document coordination and web translations; all integrated in the GNOME web development platform under the URL: http://gnome.org/projects/chronojump. In addition, contact has been established with the GNOME Translators Group in order to translate the program into as many languages as possible. As far as the execution environment of Chronojump is concerned, MONO development platform, Sqlite database manager and Nplot library are the main tools helping Chronojump to grow continuously with new features. Each new software module has been included after being gathered in the bibliography and/or requested by biomechanics or trainers, who are close to the development process in the aim of Extreme Programming methodology.

This new tool has been validated in four different ways: using a square waves generator, doing comparisons with an oscilloscope, doing comparisons with more expensive -and already validated- instruments, and through the exploration and study of the source code. The final product is a tool integrating Bosco tests well as any type of simple or repetitive jump, any kind of race and, before long, rhythms. It is a tool already used by training and health professionals, and university teachers, which, moreover, is also accessible to students, who can build the instrument with their own hands, at a very low expense, without violating any ethical or legal norms, with a high educative value and direct application to their professional scope.

SARCOLEMMAL EXCITABILITY AFTER ECCENTRIC EXERCISE IN MAN

Piitulainen, H., Komi, P.V., Avela, J.

Neuromuscular Research Center, University of Jyväskylä, Finland

INTRODUCTION: Intensive eccentric exercise results in a prolonged loss of muscle strength. The cause for this could be partly attributed to disturbances in excitation-contraction coupling (Warren et al. 2001). Any damage in the excitable membrane in muscle cell may be expected to lead to failure in sarcolemmal action potential (AP) propagation. Indeed, the sarcolemma has been found to be damaged after eccentric actions in animals (Komulainen et al. 1998), but not yet in humans (Yu et al. 2002). According to Warren et al. (2001) AP propagation is unaffected in animals after eccentric exercise. Juel et al. (2000) have reported the possibility of modified ion distribution across the sarcolemma after exercise in humans, which could result in reduced sarcolemmal excitability (Sejerstedt & Sjogaard 2000). The purpose of the present experiment was to examine if the sarcolemmal excitability is modified after intensive eccentric elbow flexor exercise in humans.

METHODS: In the exercise, subjects performed two sets of twenty maximal eccentric contractions with elbow flexors of right arm on a dynamometer (Komi et al. 2000). Supramaximal transcutaneous electrical stimulation (20 Hz, 30 sec.) was applied on the biceps brachii muscle of nine male subjects. The surface compound muscle action potential (M-wave) properties were analyzed and followed up to 48 h post exercise.

RESLUTS: The results indicated that the M-wave properties (area, peak to peak amplitude, root mean square and duration) were reduced when measured immediately post-exercise. However, this was not the case two days after the exercise, even though, subjects had clear symptoms of delayed-onset muscle soreness and the maximal voluntary isometric and eccentric torques were still depressed by 12.2 ± 9 % (mean ± SD) and 17.7 ± 9 %, respectively. Plasma concentrations of K+ and Ca2+ showed an acute post-exercise increase of 5.4 ± 5.4 % and 1.7 ± 2.1 %, respectively, suggesting an acute loss of normal ion distribution across the sarcolemma. The ion concentrations were returned to normal one hour after the exercise and remained this level the rest of the experiment.

DISCUSSION: In conclusion, these findings suggest that the eccentric exercise may decrease the sarcolemmal excitability acutely, which seems to be related to increased sarcolemmal permeability. However, the disturbance of sarcolemmal excitability is not the major factor in eccentric exercise induced prolonged loss of muscle strength.

ANALYSIS OF TWO JUMP TESTS AND THEIR LANDING PHASES IN A GROUP OF SCHOOL AGED CHILDREN

Rubio, J.A., Abián, J., Alegre, L.M., Lara, A.J., Sordo, S., Aguado, X.

University of Castilla-La Mancha, Spain

Introduction:

The aim of this study was to analyse ground reaction forces during the landing phases of two jump tests, and their relationships with the values of the push off phase in a group of school-aged children.

Methods:

Fourteen children from the same primary school [7 boys (height 137.5 ± 2.1 cm; weight 35.15 ± 4.33 Kg, age 9 years) and 7 girls (height 135.7 ± 3.9 cm; weight 34.99 ± 4.50 Kg, age 9 years)] volunteered for the study. They performed two jump tests: an Abalakov test (ABK, vertical jump with an arm swing) and a countermovement jump (CMJ) on a force platform. During the push off phase of the jumps the peak power was analysed. There were also analysed the jump height and the following variables during the landing phases: the first and second maximum vertical forces (F1, F2), the time at which these values occurred (T1, T2), the height difference of the centre of gravity between the end of the push off phase and the contact of the feet (HL), the trajectory of the centre of gravity during the landing (Lr) and the

time elapsed from the feet contact until the vertical forces reach the subject's weight for the first time after the landing movement (TBW). Anthropometric variables were measured: height, body mass, percent body fat and fat free mass (FFM).

Results:

The mean values of F2 were 8.47 ± 2.33 BW (range: 6.27 -12.06 BW) and 7.49 ± 2.93 BW (range: 3.27 -13.97 BW) in ABK and CMJ, respectively. In the CMJ test, T2 correlated significantly with F2 (r = -0.70; p< 0.01) and Lr (r = 0.67; p< 0.05), and there were significant correlations between F2 and HL (r = 0.70; p<0.05). In the ABK test, there were significant correlations between T2 and F2 (r = -0.65; p< 0.05), T2 and Lr (r = 0.68; p< 0.05), and F2 and HL (r = 0.70; p<0.05). There were no significant relationships between F2 and jump height or peak power, either in the CMJ or in the ABK test.

Discussion/ conclusion:

The results of the present study show that the participants who were able to delay F2, that is, to increase T2, obtained lower values of F2 during the landing, and, at the same time, lowered more their centre of gravity in the two tests during the landing. These characteristics are compatible with a proper landing technique. The delay of F2 could be achieved with a greater plantarflexion at the moment of the first contact of the feet, combined with greater activation of the plantarflexors. The softest landings, observed in few participants, are not frequent, maybe because few physical education teachers or coaches teach how to perform a landing with proper technique. The lack of relationships between jump heights and F2 values showed that, in the sample studied, F2 did not depend on the landing height; therefore landing technique would be the main factor in decreasing vertical ground reaction forces during landings.

Further studies should focus on the design and application of an intervention programme to teach a proper landing technique among school aged children.

REGIONAL DIFFERENCES OF SEMITENDINOSUS MUSCLE CONTRACTION BEHAVIORS DURING ISOMETRIC KNEE FLEXION

Kubota, J., Torii, S., Fukubayashi, T.

Graduate School of Human Sciences, Japan

The semitendinosus muscle (ST) has a tendinous intersection (TI) within the muscle berry. The TI is a complicated three-dimensional tendinous structure and connects the fibers of the two regions (proximal, distal), which are innervated via two branches from the tibial part of the sciatic nerve: one above and one below the TI. The exact function of the TI is unclear. The purpose of this study was to characterize changes of the TI shape of the ST during isometric knee flexion. Furthermore, we investigated the fascicle and sarcomere length of proximal and distal regions of the TI.

This study examined 16 healthy young male volunteers who performed an isometric knee flexion task. The muscle thickness, the magnitude of displacements of two points (superficial point, apex point) and TI angle (superficial angle, apex angle, deep angle) were determined using real-time B-mode ultrasonography. Moreover, the ST was dissected in two human cadavers. The fascicle and the sarcomere lengths of proximal and distal regions were measured.

The angles between the superficial fascia and short leg of TI (superficial angle) and between the short leg and long leg of TI (apex angle) increased significantly with increasing isometric torque (P<0.05), but no significant change was observed in the angle between the long leg of the TI and deep fascia (deep angle). The superficial angle increased from 27.3±9.0 degrees to 32.6±8.0 degrees and the apex angle from 53.1±13.2 degrees to 59.5±11.1 degrees. The displacement of the superficial point at 100% ramp maximum, 8.2±3.4 mm, was significantly greater than that of the apex point, 5.9±3.1 mm. Difference in fascicle length was observed. The fascicles of the proximal region were longer than that of the distal region. Sarcomere lengths were approximately equal.

This study indicated that the shortening behavior of the muscle fascicles was different at the superficial region and at the mid region of the ST during isometric knee flexion. Although the prime factor which affected the difference in the displacements of the superficial and the mid regions was not clarified, the regional heterogeneity of the fascicle length suggests that muscle contraction behaviors could be regionally different in the ST.

Recent studies demonstrated that the contractile force transmission from the muscle fibers was not solely to the MTJ, but also to the lateral fibers within the muscle. The ending architecture of the muscle fibers near the TI is similar to the architecture of the MTJ. Consequently, it is assumed that the function of TI is to participate in lateral force transmission.

These results indicate that the contraction behaviors in the ST differ near the muscle rim and at the muscle center, and around the superficial layer and deep layer. The TI might have a role in strain sharing behavior.

KINETIC DIFFERENCES BETWEEN MEN AND WOMEN IN SIX LANDING SITUATIONS

Abián, J., Alegre, L.M., Lara, A.J., Aguado, X.

University of Castilla-La Mancha, Spain

Introduction: Landings have been reported to be the main cause of injury in some sports. Two thirds of the anterior cruciate ligament injuries happen during the landing from a jump, and this fact is particularly important in women, because they have specific characteristics that increase the risk of injury during drop landings. The aim of this study was to analyse and compare the vertical ground reaction forces in six different landing situations between men and women.

Methods: Fifteen young women (age = 18.8 ± 1.0 yr, height = 164.8 ± 7.1 cm, weight = 60.53 ± 5.66 Kg) and men (age 22.1 ± 2.3 yr, height 176.6 ± 6.2 cm, weight 72.11 ± 6.21 kg) all of them physically active and university students, volunteered for the study. The force-time data from six different landing situations were recorded by a piezoelectric force platform: four of them from an elevated surface at 0.75 m from the ground (perform a soft landing with the use of upper extremities, perform a soft landing without upper extremities, just before a drop jump and after a sudden start) and two from the ground level [landing after a counter-movement jump (CMJ) and after a drop jump (DJ)].

Results: There were significant negative correlations between the jump heights in CMJ and DJ, and F2 in the landings from 0.75 m (r = -0.56 and 0.54, respectively, P < 0.001). There were only significant differences in F2 between men and women in the landings from 0.75 m, with greater F2 values in the females (P < 0.05). The contribution of the upper extremities reduced F2 by 13.5% in women and 10.3% in men. When comparing F2 among the six landing tests, there were significant differences in the women's group only (P < 0.05).

Conclusions: The decrease in F2 with the use of the upper extremities during the landing is not always possible during a sport competition, but reduces the impact forces and consequently, the risk of injury. There were no differences in the landings from ground level between men and women. However, the significant differences appeared when the landings were performed from 0.75 m. It seems that the explosive force of our participants would be more important in the landings from 0.75 m, while in the landings after jumps a good technique would be more relevant to achieve lower values of F2. Further studies should analyse kinematics and electromyography synchronised with the ground reaction forces, in order to achieve deeper understanding of these differences.

FATIGUE AFTER ECCENTRIC CONTRACTIONS IS MUSCLE LENGTH DEPENDENT

Desbrosses, K., Babault, N., Meyer, J.P., Pousson, M.

INRS Nancy, France

It is well established that repeated maximal eccentric contractions induce a decline in the torque production capacity. Recently, McHugh (2004) demonstrated that this fatigue was length dependent during eccentric exercises and may be primarily attributed to peripheral factors. However, central contribution is not clearly described (e.g., Prasartwuth et al., 2005). So, the present study was designed to investigate fatigue mechanisms responsible for the muscle length dependency observed after repeated maximal eccentric contractions of the quadriceps femoris muscle group.

Twelve subjects performed, three weeks apart, two eccentric fatiguing sessions of the quadriceps muscles. Each session was conducted with a given range of motion, randomly presented: from 20° to 60° (SL, for short muscle lengths) or 80° to 120° (LL, for long muscle lengths) (0°, maximal knee extension). Fatiguing exercises consisted in maximal eccentric contractions (45°/s) repeated until a 40% torque decline. Before and immediately after each fatiguing exercise, maximal voluntary torque (MVT), activation level (AL, estimated by means of the twitch interpolation technique) and peak doublet torque (Pd) were assessed. All measurements were carried out during eccentric actions at 40° for SL and 100° for LL. Muscle soreness was evaluated with the CR-10 Borg scale (Borg, 1982) during five days after the fatiguing sessions.

To reach the 40% torque decline, 165.1 ± 78.2 (mean ± SD) and 74.8 ± 31.8 contractions were required for SL and LL, respectively. Decline in post-fatigue MVT was significantly ($P<0.05$) greater for LL (-27.9 ± 15.9%) as compared to SL (-8.7 ± 8.9%) whereas AL similarly decreased for both conditions (mean AL decreases: -9.4 ± 9.5%, $P<0.05$). For LL, Pd significantly declined (-23.9 ± 15.7%) while it was potentiated for SL (+16.2 ± 15.5%). Soreness significantly increased immediately after SL and LL fatiguing contractions and was maintained during the 3 following days for LL.

Our results demonstrated a greater torque reduction after eccentric contractions performed at long muscle lengths (LL). The lack of difference in AL between SL and LL exclude the contribution of central factors to the eccentric fatigue dependency on muscle length. Therefore, this dependency would primarily be peripheral in origin as shown by the Pd reduction for LL as compared with SL. Additionally, the persisting muscle soreness for LL suggests the presence of greater muscle damages. In contrast, the Pd increase for SL could likely result from an improved Ca2+ myofilament sensitivity at short muscle lengths. We can conclude that peripheral factors (contractile apparatus alterations) may be at the origin of the fatigue dependency on muscle length after eccentric contractions.

INTER-SUBJECTS RUNNING DYNAMIC SIMILARITIES IN MEN AND WOMEN

Delattre, N., Lafortune, M.A., Moretto, P.

Faculté des Sciences du Sport et de l'Education Physique, France

The aim of this study is to test the validity of Froude number (NFr) or Strouhal number (Str) to determine inter-subjects similar running patterns.

Twenty male and eighteen female subjects ran barefoot on a runway equipped with a Kistler force platform sampled at 1 kHz and covered by an EVA foam. The running tests were performed in three experimental conditions. C0:all subjects ran at the same absolute velocity V=3.5 m.s-1; C1: the velocity was determined from the NFr; C2: the stride frequency was determined from Str. NFr and Str were determined to ensure that the mean velocity and mean step frequency were identical through the three conditions. The vertical ground reaction force (Fz) is analysed to check the contact time (CT); the active peak (Peak); the time to active peak; the loading rate between 10 and 90% of Fz peak; and the vertical impulse (Iz). Similarity ratios (k) were computed from each kinetic and anthropometric parameter in respect with the fundamental dimensions of length [L], mass [M], and time [T]. k ratios resulted from a paired subjects combination, which allows to proceed to 190 combinations in men and 153 in women. A r=0.7 ($r^2=0.5$) correlation value between anthropometric ratios and kinetic ratios has been considered for the analysis and enabled us to identify the running similarities between subjects.

The use of Str (C2) allowed obtaining the best correlations between anthropometric and kinetic parameters i.e. the best dynamic similarities. In men, 3 similarities are obtained with Str (C2) and with Nfr (C1), versus 2 similarities observed under C0. With a mean correlation reaching r=0.86, the C2 condition appeared the best one to obtain similarities, while r=0.78 under C0 and r=0.73 under C1. In women, 2 similarities are obtained in each experimental condition. However, similarities obtained with Str are qualitatively the best (r=0.91) while r=0.90 under C0 and r=0.89 under C1.

The study of similarities showed an interest in using the Str for the determination of similar dynamic running conditions. However, the sight of results showed that men and women's locomotor patterns significantly differ. Similarities in men are principally linked to CT, suggesting that men's pattern is mainly organised in accordance with time dimension. Likewise, women's pattern are principally organised in relation to the mass. This difference in the pattern organisation is probably due to leg stiffness differences between genders.

Thus, it appears that the determination of similar dynamic running conditions needs to be specified. Indeed, it seems interesting to take the difference of leg stiffness due to genders into account. The simultaneous use of NFr and Str could bring better results in this way.

Future investigations should be conducted to determine inter-subjects similar dynamic running conditions from dimensionless numbers taking the leg stiffness into account.

MEAN POWER FREQUENCY LINEARLY DECREASE DURING 100 M MAXIMUM CRAWL SWIMMING

Stirn, I., Strojnik, V., Jarm, T., Vizintin, T., Kapus, V., Sarabon, N.

University of Ljubljana, Slovenia

INTRODUCTION

During sustained isometric and dynamic contractions power spectrum of the detected EMG signal compresses and mean power frequency (MNF) shifts towards lower frequencies. The validity of the MNF decrease during dynamic contractions has been tested with isometric contraction (2) and with the use of peak torque as a criterion variable (1). At the beginning of the fatiguing task the MNF decrease is linear, latter the MNF value approaches a plateau where no further decrease is observed (1,3). This may be connected to the lowest limit of muscle fatigue as expressed in an EMG signal. The purpose of the study was to evaluate the MNF decrease during 100 m crawl swimming at a maximum effort level.

METHODS

Eleven competitive swimmers (22.0 ± 2.9 years of age) were involved in the study. EMG signals from m. pectoralis major (PM), m. latissimus dorsi (LD) and m. triceps brachii (TB) were collected. Bipolar Ag-AgCl skin electrodes (9 mm diameter, Hellige, Freiburg, Germany) with inter electrode distance of 20 mm, were used. The cables from the electrodes were fixed to a coaxial cable connected to the telemetric EMG transmitter (Biotel 88, Glonner, Munchen, Germany) which was carried above the swimmer during swimming. For every muscle an envelope of generalized energy was calculated using a sliding 250 ms window. For every stroke and muscle an active part of the stroke was then extracted, defined as the part of the signal where EMG energy was greater than 50% of the maximum energy within the stroke in question. From the extracted segment we calculated the power spectral density (PSD) estimate and its mean frequency (MNF). A linear model was fitted to the scattergram of MNF values belonging to individual strokes for each muscle. We used this model to estimate values of MNF at the time of the first and the final stroke within every swimming session.

RESULTS AND DISSCUSION

MNF linearly decreased during swimming in all observed muscles. The greatest decrease of MNF was detected in TB (from 103.4±8.4 to 78.3±11.3 Hz, eq. 25.1±8.9 %), followed by LD (95.0±7.2-70±10.5 Hz, eq. 22.8 ± 8.8 %) and PM (88,0 ±17.3-67,8±10.7 eq. 20.2 ± 11.3 %). The differences between the decrements were not statistically significant.

The plateau of stabilized MNF was not observed in any of the analyzed muscles. We believe that if subject continued to swim with relative maximum velocity, MNF would decrease further finally reaching a plateau. The muscle first reaching the plateau could possibly limit the performance most and might need analytical training.

KINEMATICS CHARACTERISTICS OF SNOWSHOEING UNDER DIFFERENT RUNNING SPEED

Luk, T. C., Fung, L., Leung, M. L.

Hong Kong Baptist University, Hong Kong

Snowshoeing is one of popular sports and it became the top 20 participatory sports in US. Recently, snowshoeing has become an official event in Special Olympics. The idea of Special Olympics considered that snowshoe racing could help athletes enhance their fitness level during the winter months through a full body workout. Literature founding indicated that snowshoeing at a self-pace for 30 minutes provides sufficient intensity to improve the cardiovascular endurance. However, limited study was found in the literature about the biomechanical analysis of snowshoeing.

Moreover, the arrangement of venue became another problem in training or competition. Snow track may difficult to find in some countries or seasons. Sometimes, grassland or sand course may be employed for training or competition purpose instead of using snow course. Therefore, the purpose of this study was to identify the kinematics characteristics of snowshoeing on sand under different running velocity in elite Hong Kong mentally handicapped athletes.

Four athletes participated in this study. All the subjects were asked to perform the snowshoe running on sand with their maximal speed at a outdoor beach volleyball court for 5 laps. A 3CCD digital camcorder with 50Hz filming rate was located 14 meters away from the subject and the shutter speed was set at 1000Hz. A section of running motion at the first and fifth lap was video recorded. Kinematics parameters such as single leg support time, flight time, stride frequency, velocity of CG, vertical displacement of CG, cycle length, stride length, thigh and knee angle under different running velocities were measured. The repeated t-test was employed to examine the difference of the kinematics parameters between different velocities in snowshoeing.

When compared with over-ground running gait, snowshoeing found similar kinematics characteristics in changing of running velocity. The results of present study found that the stride frequency decrease as the snowshoeing velocity decreased. Moreover, both cycle length and stride length were significantly decreased when snowshoeing from high to slow velocity. When compared the CG oscillation in over-ground and snowshoe running, snowshoeing seems to have large vertical CG oscillation at given speed which may cause more energy expenditure.

The changing of kinematics parameters on snowshoeing on sand in different running speed showed similar finding when compared with changing velocity in over-ground running. However, the requirement of technique, such as thigh angle, for snowshoeing on sand seems higher than over-ground running at given speed. Further study should be conducted such as biomechanical comparison of snowshoeing technique on sand, grassland and snow course. Such information could be helpful for athletes, coaches in training program design and technique improvement under different training condition.

RESEARCHES OF STROKE PARAMETERS IN PARALIMPIC SWIMMING IN TEST WITH INCREASING INTENSITY

Petriaev, A., Kleshnev, I.

St.-Petersburg Research Institute of Physical culture, Russia

It is known that the average velocity of swimming on distance is determined by two its components: stroke rate and stroke length. It is very actual to find their optimal correlation. There are several different ways of resolution of this problem. As the planning of swimmer's preparing must emanate from the purposes of his activity – achieving results on main competitions – so the search for rational correla-

tion of stroke rate and length on distances is realized from the analyse of swimmer's. Another way is to find an optimal correlation using special testing of athlete increasing velocity and rate. These ways are very useful in classical swimming and they are described enough, but in paralimpic swimming, due to different degree of athletes' disability, generalized data of analysis of competition activity are approximate. The purpose of the research was to value influence of intensity increase to the parameters of stroke rate and length in depending on character of disease.

In the investigate took part 16 Paralympics national level athletes (S3-S13) women 20,1±4,6 years; stature 165,4 ±8,3 cm, mass 50,3±4,2 kg; men 24,5±7,4 years; stature 177,1±6,2 cm; mass 67,4±10,5 kg.

Athletes swam 6х50 m with increasing intensity. Stroke rate (SR), stroke length (SL), average velocity (v) were determined by video recorder. Heart rate (HR) was determined by Polar 810.

Studying the velocity range, that was showed in the test, it is possible to say that this range for women was 1,01±0,21 m/s (low intensity) to 1,32±0,25 m/s (high intensity). For men it was from 0,99±0,22 m/s (low intensity) to 1,38±0,34 m/s (high intensity).

Change of SR in test for women was from 35,0±20,7 cycles/min (low intensity) to 55,9±27,5 cycles/min (high intensity). For men it changed from 35,9±21,4 cycles/min (low intensity) to 52,6±10,5 cycles/min (high intensity). The dynamics of SL in swimming with different intensity for women was 2,00±0,73 m/cycle (low intensity) to 1,63±0,68 m/cycle (high intensity), for men it was from 2,01±1,01 m/cycle (low intensity) to 1,57±0,35 m/cycle (high intensity). The average pulse after a special test was 183,5±6,8 1/min for woman and 170±22,7 1/min for men.

The interconnection between: SR and SL; HR and v; SL and v; SR and v; SR and HR; SL and HR were determined on the basis of received data.

The analysis of results showed that the structures of special and technical preparedness of paralimpic swimmers have wide individual differences, that is connected with particularities of disability, which impose essential individual sport technique.

Its particularities do not allow to use the basis predications of forming sport techniques, which were developed for healthy athletes. For improving the technical skills of sportsman with limited possibilities it is necessary to have an individual biomechanical analysis of athlete's technique, individual analysis of special preparedness, and to develop an individual model of sport technique on the basis of it.

ENERGETICALLY OPTIMAL AND PREFERRED BICYCLING SPEEDS

Belli, A., Kram, R.

University of Saint Etienne, France

Introduction.

Humans and other animals prefer to locomote at the speeds that minimize the gross metabolic energy cost per distance travelled (1, 2). Is the same true for solo human bicycling? The optimal speed for bicycle racers is obviously the fastest that they can sustain. But for most of us, bicycling is either a form of transportation, a mode of moderate aerobic exercise or just plain fun. Our goal was to calculate the speeds that minimize the metabolic cost per distance for racing and recreational bicyclists. We then compared the energetically optimal speed to the preferred speeds of recreational bicyclists.

Methods.

The mechanical power output for bicycling (Pmec in W) at a constant velocity over level pavement through still air can be well approximated by equation 1:

Pmec = a.V + b.V3;

where a (in N) and b (in N.m-2.s-2) are rolling and aerodynamic resistance coefficients respectively and V is velocity in m.s-1. The coefficient of aerodynamic resistance varies with the size, shape and posture of the rider (3). We selected values from the literature (4) for an average sized rider using a racing bicycle with the dropped handlebar posture (a=2.8, b=0.193) and a recreational bicycle with a forward leaning trunk posture (a=5.8, b=0.271). Plotting metabolic power consumption (Pmet in W) vs Pmec yields a positive linear relationship (equation 2):

Pmet = Pmet0 + Pmech.n-1;

where Pmet0 is the intercept rate of energy consumption at zero power output and n is the muscular efficiency. Values of n =0.238, Pmet0 = 143.5 J (taking 20.1 J/mlO2 for the energetic equivalent of oxygen consumption), were also selected from the literature (5). Combining equation 1 and 2 and dividing by V in order to calculate the metabolic cost per distance (C, J.m-1) gives:

C = Pmet0.V-1 + a.n-1 + b.n-1.V2 (equation 3)

Finally, the optimal velocity (Vopt in m.s-1) that minimizes C (Cmin) was obtained by setting the first derivative of equation 3 equal to zero.

Results and discussion.

Vopt and corresponding Cmin were 4.46 m.s-1 and 60.1 J.m-1 respectively for a racing bicyclist and 3.98 m.s-1 and 78.5 J.m-1 respectively for a recreational bicyclist. Since bicycle time trial races involve speeds greater than 11;m.s-1, clearly racing bicyclists prefer to minimize time rather than minimizing metabolic energy cost per distance. However recreational/commuting bicyclists average 4.9 to 5.6 m.s-1on unobstructed bike paths (6) which is close to Vopt.

BIOMECHANICAL MONITORING OF SCHOOLCHILDREN'S BODY KINETICS DURING PHYSICAL EDUCATION

Kashuba, V.

National University of Physical Education and Sports of Ukraine, Ukraine

Introduction. There is a necessity of the constant control of human organism condition at natural development and perfection of human motor function in complex modern conditions of his biological and social interaction with an environment [3]. The human body kinetics

term characterizes a condition of motor function, feature of a structure and the spatial organization of human body, biodynamics and a statics of the support-motional apparatus in physical culture and sports & pedagogical practice. However the human body thus is considered not as a point or system of points and as complete macroscopical object. We studied movements of its separate parts and elements which mechanical condition essentially depends on entry conditions of measurement in [1].

Methods: biomechanical analysis.

Results. We developed the "BioVideo" software for the biomechanical videocomputer analysis of movements, the «Torso» software for the dynamics of biogeometrical structure formation of child's bearing and «BigFoot» software for child's foot support-spring properties during the biomechanical control [2]. «BioVideo» consists of four modules:

The construction module.

The point coordinates module.

The calculation of movement characteristics module.

The biokinematic scheme of movement module.

The construction module was purposed for drawing up of scheme model of researched dynamic object. Model may include the points of child's total body or his separate bioparts or biolinks, for example, only the low or upper extremity, etc. «BioVideo» modules determine not only kinematic, but also dynamic characteristics of movement. The «BioVideo» program complex provides definition biomechanical characteristics of center of mass (CM) bioparts and general CM of child's body, and also the phase analysis of movement.

Discussion. As the «BioVideo» program complex is created for work with the equipment available to us, for example with analog or digital videocameras, naturally, coordinates of point should be marked manually, instead of an automatic mode which is provided, for example, with the ELITE Biomech and Qualisys special reflective markers of infra-red light.

Conclusions. The pedagogical experiments have shown, that the use of «BioVideo» as the technology of biomechanical monitoring of schoolchildren's body kinetics allows to estimate objectively a level of their physical development and to make corrections to physical education process on the basis of received data.

THE EFFECTS OF AGING ON FUNCTION OF THE TRICEPS SURAE MUSCLE GROUP DURING FATIGUING ISOMETRIC CONTRACTIONS

Walsh, M. 1, Mademli, L. 2, Arampatzis, A. 2

1 Miami University, 2 German Sports University in Cologne, Germany, United States

Knowledge about the effect of aging on muscle activation during fatigue is important to understand muscle-tendon function. Wolfe's law suggests that muscles will adapt to loading they encounter regularly. Since the muscles of the body are loaded differently it seems reasonable that they would adapt diferently. Since the triceps surae muscle group is involved in locomotion it is important we understand the effects of aging on those muscles. Therefore the purpose of this study is to examine functional differences between young and old subjects in the triceps surae muscles during a submaximum isometric fatiguing contraction. Our hypothesis: age related differences observed during fatigue will be muscle dependent.

Methods

14 elderly, 65.2(3.6) yr; 175.7 (5.4) cm; 76.2 (8.8) Kg, and 12 young males, 30.4 (7.1) yr; 178.6 (6.3) cm; 78.7 (6.3) Kg, participated in this study. A maximum voluntary isometric plantarflexion (MVC) was performed on a dynamometer (Biodex Medical Systems. Inc. USA) (ankle and hip angle 90°, knee 180°). The fatiguing protocol was a sustained isometric contraction at 40% of the MVC. Inverse dynamic analysis and center of pressure calculations to calculate the actual joint moment were performed as reported by previously (Arampatzis et al. 2004). Electrodes recorded the electric activity of the gastrocnemius medialis (GM) and lateralis (GL), soleus (SOL) and tibialis anterior (TA) muscles. For the independent variables an age by independent variable 2 way ANOVA with repeated measures was performed with follow up T-tests.

Results

The time to fatigue was greater for the older subjects. Results of the 2 way ANOVA showed increasing normalized RMS values of both GM and SOL for both groups during the fatigue trial. A significant group by fatigue interaction effect ($p = .032$) for the SOL indicated that the differences between the young and older subjects varied as a function of fatigue. The effects of fatigue for the SOL-MD showed an age group x fatigue interaction with younger subjects showing a greater decrease in SOL-MD during the fatiguing contraction than older subjects.

Discussion

The results indicate that there are functional differences of the triceps surae muscle group between age groups during sub-maximal contractions to fatigue. The normalized GM and GL RMS patterns were similar between subject groups while the soleus values are visibly, yet not significant ($p=0,68$) higher for the older subjects throughout the entire fatiguing task. An increase RMS and a decrease MD were found for both groups. The new finding here is the age x fatigue interaction. Thus, there are age related neuromuscular changes, but they do not occur to the same extent in all muscles.

Changes in the step width, step length, and step frequency

of the world's top sprinters during a 100 m race

Akira Ito1, Masaki Ishikawa2, Juha Isolehto2, Paavo V. Komi2

1Sport Biomechanics Laboratory, OsakaUniversity of Health and Sport Sciences, Japan

2Neuromuscular Research Center, University of Jyvaskyla, Finland

The purpose of this study is to clarify the changes in the step width, step length, and step frequency of the world's top sprinters during a 100 m race and provide coaches and sprinters with useful step data.

The subjects were 18 male sprinters who participated in the heats of the 10th World Championships in Athletics held in Helsinki, Finland. They were divided into two groups based on race timing: the high performance group (HG; 10.12–10.32 s) and the low performance group (LG; 10.40–10.9 s). We set up two video cameras in the auditorium to record the spot at which the foot came into contact with the surface of the track during the starting dash and the sprint with full stride (approximately 60 m from the starting line). The x-y coordinates of the runners' foot prints on the track were calculated by the two-dimensional direct linear transformation method (DLT method).

The step length was observed to increase with the sprint speed ($p < 0.001$) in both groups; further, the step length of HG was longer than that of LG in the starting dash and the full stride (0.12 ± 0.03 m, $p < 0.003$). The step frequency was maintained at almost the same level (4.56 ± 0.16 steps / s) in the starting dash and the full stride, and no difference was observed between the groups. Although there was no difference in the step width, it decreased in both groups from 0.39 ± 0.07 m in the 1st step of the starting dash to 0.17 ± 0.04 m in the full stride ($p < 0.001$). These results suggest that sprinters change their step length and step width according to the change in acceleration of the sprint running speed.

The results obtained suggest the following conclusions: (1) Sprinters should not be forced to have a higher step frequency in the starting dash. (2) They should attempt a longer step length from the 1st step of the starting dash. (3) They should maintain adequate step width not only in the starting dash but also in the full stride.

AGE AND SEX DIFFERENCES IN THE SPEED OF ARM RECIPROCAL MOVEMENTS

Latecka, B., Warchalewska, M., Lapszo, J.

Academy of Physical Education and Sport in Gdansk, Poland

INTRODUCTION: Reciprocal arm-reaching movements are a basic form of daily human motor behavior. These movements consist of a target reaching movement and a returning movement back to the starting position. The purpose of this research was to test age and gender differences in the speeds of initiating and performing the movements with the right and left hand. 21 young subjects (11 males, 10 females – av. age 23) and 22 elderly subjects (10 males, 12 females – av. age 72) participated in the research. METHOD: The psychomotor efficiency timer developed by Lapszo (2002) was used in conjunction with a measurement station to test the reciprocal movements. The measurement station consisted of 6 tactile sensors (one starting position and 5 target sensors). The range of the tested movements was 25 cm. The movements were performed in the horizontal plane separately with the right and left hand in 3 series of 10 movements. The movements were stimulated by light and sound in the sensors. The average movement initiation time (MIT) and the total time (MTT) was measured for all the tested movements. MIT was measured (in milliseconds) from the instant the target location presented itself (light in the sensor) to the instant the starting position sensor was released; MTT was measured to the instant the target sensor was touched. RESULTS AND DISCUSSION:. Three-way ANOVA (age x sex x hand) was used to analyze the results. The research showed up differences between young and elderly subjects ($P0 < 0.0002$; Ho hypothesis), and between young and elderly female subjects ($P0 < 0.006$), with respect to both times (MIT, MTT) and both hands. Elderly male subjects were slower than young males to initiate movements ($P0 < 0.02$), but the total time (MTT) for the movements of the right and left hands was the same in these groups. Young male and female subjects performed reciprocal orientation movements with the right and left hand with the same speed, but elderly males performed right-hand movements faster ($P0 < 0.03$) than elderly females. Elderly subjects initiated movements on the average 22 % more slowly than younger subjects. Elderly subjects were also much slower than young subjects to perform (MTT) right-hand (29 %) and left-hand (30 %) movements. This finding endorse Welford's (1988) research results, which showed a 30 % longer movement time (MT) in older than in young adults. The age differences with respect to MTT are greater in the female (41 %) than in the male (18 %) group. This research has shown that ageing prolongs the initiation (MIT) and total (MTT) time, but that the age differences in these times are larger in the female than in the male groups.

AGE AND SEX DIFFERENCES IN SPEED OF LOCOMOTION AND ROTATION MOVEMENTS

Latecka, B., Warchalewska, M., Lapszo, J.

Academy of Physical Education and Sport in Gdansk, Poland

INTODUCTION: Locomotion and rotation movements are very important forms of human motor behavior. The process of ageing brings about changes in our muscles (Lexell, 1995) and brain (Alexander, 1994). The purpose of this research was to test how such changes affect the human psychomotor system with respect to balance control and arm and leg coordination. 23 elderly subjects (9 males, 14 females – av. age 74 years) and 23 young subjects (10 males, 13 females – av. age 23.5 years) participated in the study. METHOD: A psychomotor timer (Lapszo, 2002) was used in conjunction with a measurement station to test locomotion and rotation movements. The locomotion station consisted of two tactile sensors located 3.5 m (locomotion) and 0.5 m (rotation) from each other. In the locomotion task, subjects were asked to walk as quickly as possible between the sensors (3 trials). The rotation task consisted of 3 complete turns through 360 degrees to the right and left. The result of these measurements was expressed as the average of 3 trials each of locomotion time (LT), right-hand rotation movement time (RRT) and left-hand rotation movement time (LRT), measured in seconds (accurate to 1 ms) from the instant the sensors were released to the instant the sensors were touched with both hand. RESULTS AND DISCUSSION: Two-way (age x sex) and three-way (age x sex x direction) ANOVA was used to analyze the respective differences in locomotion and rotation movement speeds. The analysis showed that the speed of locomotion was higher (47 %) in the young than in the elderly subjects ($P0 < 0.005$; Ho hypothesis). Elderly male subjects walked 19 % faster than elderly female subjects ($P0 < 0.04$) but 65 % more slowly than young male subjects ($P0 < 0.005$); in the same task elderly female subjects walked 96 % more slowly than young female subjects ($P0 < 0.002$). Young subjects turned to the right ($P0 < 0.001$) and left ($P0 < 0.001$) more quickly than elderly subjects (55 % and 57 % respectively). The differences in the speed of rotation movements between groups of the same sex correspond to the age differences.

Elderly males and females perform rotation movements with the same speed. No differences were found in the speed of locomotion and rotation movements between young male and female subjects. The analysis leads to the conclusion that ageing slows locomotion and rotation movements to a high degree.

DIFFERENCES IN SPRINTING SPEED KINEMATICS DURING GROWTH

Tomazin, K., Dolenec, A., Skof, B., Coh, M.

University of Ljubljana, Faculty of Sport, Slovenia

Introduction

Sprinting speed, like other short-burst activities, increased significantly during growth (Asmussen, 1973). Sprinting speed is defined by strides frequency and strides length. Both of them mainly depend on force developed by hip, knee and ankle extensors during the contact time, neuromuscular coordination and morphological characteristics of the subject. Especially morphological characteristics changed significantly during growth and maturation, influencing the maximal sprinting performance. There is a paucity of information concerning growth influence on strides length and stride frequency during the sprinting. Therefore the present study was designed to examine the differences in kinematic parameters during maximal sprinting performance during growth, controlling for variation in body mass and leg length.

Methods

The subject sample consisted of two groups. The first group (A) included 37 girls (10.4±0.5 y.a., 34.7±4.6 kg, 142.9±5.8 cm), the second group (B) included 30 girls (8.5±0.5 y.a., 30.0±3.7 kg, 133.3±5.9 cm). Subjects performed 20 meters with flying start. Maximal speed (vmax), contact time during take off (CT) and stride flight time (FT) were measured during 20 meters segment with Opto-track system (Microgate, Italia). Average stride frequency (SF) and stride length (SL) over measured distance were calculated. Anthropometric variables were measured according to EUROFIT (1983). Descriptive statistics for measured parameters were calculated for each group. ANCOVA were performed to assess the differences in maximal speed kinematic parameters between groups, controlling for variations in body mass and leg length. Statistical significance was accepted with 5% alpha error.

Results

The maximal running speed increased from 5.6±0.4 m/s for the group B to 6.03±0.43 m/s for the older group A ($P<0.001$). It is interesting to note that stride length increased as well from 145.3±9.2 cm for the group B to the 160.0±11.6 cm for the group A ($P<0.001$), on the other hand contact time (0.149±0.4 s - group A, 0.148±0.1 - group B) and stride frequency (3.8±0.3 s-1 – group A, 3.9±0.3 s-1 group B) remained almost unchanged during the maximal speed test.

Discussion/Conclusion

Increased sprinting speed during growth was mainly due to changes in stride length, rather then strides frequency. Stride frequency depends on the functioning of the central nervous system and is to a large extent genetically predetermined (Mero et al., 1992), on the other hand we could probably concluded that also stride length were not affected only with quantitative but also qualitative neuromuscular changes during growth.

A KINEMATICS AND A ONE-DIMENSIONAL COMPARISON OF PERFORMANCE FACTORS BETWEEN THE SPLIT JUMP AND THE SPLIT JUMP WITH THROW AND CATCH OF THE BALL IN RHYTHMIC GYMNASTICS

Mkaouer, B. 1, Jemni, M. 2, Amara, S.M. 1, Abahnini, K. 1, Agrebi, B. 1, Tabka, Z. 3, Feki, Y. 4

1 ISSport et Educ. Physique, Ksar Saïd/TN, 2 SSD Anglia Ruskin Univ. Cambridge/UK, 3 Fac. Méd. Sousse/TN, 4 Mini Jeunesse Sport et EP/TN, Tunisia

Purpose: This exploratory study sought to compare some execution factors particularly force; speed and flexibility during a split jump with and without throw and catch of the ball in Rhythmic Gymnastics (RG).

Method: Five female rhythmic gymnasts (13.8 ± 1.3 yrs; 1.58 ± 0.07 m; 46.59 ± 8.23 kg) from the Tunisian Junior National Team agreed to participate.

Test took lace in the gym during normal training session. A two-dimensional kinematics' analysis (Sony DCR PC 105E camera), associated with a one-dimensional force analysis (Kitsler force platform 500Hz) were performed to assess two skills: a split jump (SJ) and a split jump with throw and catch of the ball (SJth-c). Athletes performed ten trials of each skill in order to assess reproducibility. Only the best four trials were analysed and compared. Gymnasts were equipped with three markers: one on the hips (at 56% of the height) and two on the ankles to assess legs' split angular velocity. The geometrical centre of the ball was also considered.

Data were collected using AviStep & Regressi software: Horizontal force (Fx), vertical force (Fy), horizontal velocity (Vi), vertical velocity (Vy), take-off time (tc).

Non parametric one way ANOVA test (Friedman) was performed to assess the repeated measurements. The U test of Wilcoxon was applied to compare the two skills. The level of significance was set at 0.05.

Results: The reproducibility study did not show any significant variation of the performance factors. All gymnasts were able to repeat the same skill with or without apparatus. Meanwhile, performance factors were significantly different between (SJ) and (SJth-c).

Apart from the (Vy) and the angular velocity of the split which were significantly higher during the (SJth-c), all the other components of the same skill were significantly less than those measured during the (SJ) ($p < 0.05$). [1.6 ± 0.1 m/s vs 1.5 ± 0.2 m/s for the (Vy) and 963.4 ± 11.2 deg/s vs 803.3 ± 20.3 deg/s for the angular velocity of the split respectively for the (SJth-c) and (SJ)].

Peak power was significantly lower [1480.4 ± 217.9 W vs 1606.7 ± 291.6 W respectively for (SJth-c) and (SJ)]. Force was also significantly lower [924.8 ± 82.2 N vs 1032.3 ± 125.6 N respectively for (SJth-c) and (SJ)]. Vertical displacement was significantly lower [0.382 ± 0.02 m vs 0.4 ± 0.03 m respectively for (SJth-c) and (SJ)]. ($p < 0.05$).

Conclusion: The (SJth-c) is a double tasks' skill which requires focus on the ball as well as high level of technique and fitness. This study shows that performance factors of the (SJth-c) are lower than the (SJ). Arm's contribution in throwing and catching the ball may have prohibited force, velocity and flexibility. Particular attention in developing related components to these factors may enhance performance.

KINEMATIC ADJUSTMENTS IN THE BASKETBALL JUMP SHOT AGAINST A PASSIVE OPPONENT IN YOUNG BASKETBALL PLAYERS

Ignjatovic, A., Stankovic, R.

Faculty of Physical Education, Serbia and Montenegro

The jump shot is distinguished as the most important of all the shooting actions and have also been analyzed under different conditions. Many drills for young basketball players are consisted from a jump shot over the passive opponent (passive opponent is just standing with his hands raised high above his head). During one training session in this study shooting accuracy from a foul throw line was decreased from 62% to 42% in the present of a passive opponent. The participants of this study were 10 young 15-years old players who are members of regional champions at theirs age in season 2005/2006 in Serbia. The participants were shooting until each player had performed 15 successful jump shots in both conditions (with and without opponent). Ten successive shot by each player (five with and four without opposition) were selected for analysis.

Two-dimensional video techniques (50 Hz) were used to obtain images of basketball jump shot from two different conditions. 23 dependent variables that have been studied extensively in the literature were selected for analyze. The release angle of the ball increased from 43.32 +/-5.3 to 45.58 +/- 3.8. This mean release angle of the ball in this study was similar to results of Rojas et al., (2000.) and smaller then 48 found in the studies carried out by Satern (1988), and Miller and Bartlett (1996). The velocity of ball release increased from 6.45 +/- 0.2 to 6.49 =/- 0.2, and this mean value was similar to data reported by Rojas et al(2000) 6.33 m/s-1,and Walters et al. (1990) had between 6.6 and 6.9 m/s-1.and by Miller and Bartlett (1996) who reported values of around 6.2 m/s-1. The height the ball reached at release was higher when shooting against an opponent than without an opponent. this could be related to the greater release angle. Higher height reached by the CG is opposite of results of Rojas et al. (2000) and this could be explain by the different protocol of studies. In this study the opponents are not trying to block the shot so the players are shooting without a fear of blocking. But neither of these differences was significantly different. Only statistically significantly different between the two situations in this study was found between the angles of shoulder and hip at take off position. This could be explained by close present of an opponent 30 cm distanced from the place where the players are executing the jumps shots so the players can't perform tehnic as they used when nobody was in front of them.

MECHANICAL DETERMINANTS OF THE JUMPER'S KNEE

Bisseling, R., Hof, A., Bredeweg, S., Diercks, R., Mulder, T.

University Center for Sport, Movement and Health Groningen, Netherlands

In volleyball jump serve, spike, and block are the volleyball players' skills to perform offensive and defensive jumps. To avoid injury, the kinetic energy generated from the jump should be absorbed properly by the extensor mechanism during landing. Repetitive high intensity loads during the jump-landing sequence can traumatize the quadriceps tendon. Among high level volleyball players, the most frequent injury is patellar tendinopathy (jumper's knee) with a prevalence of 40% to 50% (1).

To accommodate the impact during landing, lower extremity kinematics before and during impact phase influence the loads around the joints. By using joint moments of force and joint kinematics of the lower extremity, landing mechanics can be described, which contribute to neutralization of the kinetic energy from the jump. Differences in impact accommodation strategies, used by volleyball players could lead to get insight into the causal determinants of the jumper's knee. Besides landing mechanics, some evidence exists that the jump itself could give information to the causal mechanisms of jumper's knee in volleyball (1, 3). Still, no definite answer is known.

The main question to answer is why some volleyball players suffer from a jumper's knee and others do not, while training intensity and frequency are the same? By identifying etiological factors to get insight in the injury mechanism, preventive measures can be developed (2).

In the search for the potential role of the lower extremity dynamics related to the development of jumper's knee, twenty-seven well trained male volleyball players participated in this study. All subjects were diagnosed by a sport physician, who determined the diagnosis patellar tendinopathy or no patellar tendinopathy. The severity of symptoms of patellar tendinopathy was measured by the VISA-score. Together with the patellar tendinopathy diagnosis, subjects were classified in three groups. 1. healthy subjects, 2. jumper's knee patients with pain during the experiments and 3. jumper's knee patients without pain during the experiments. A three dimensional dynamical analysis was carried out to determine differences in effect of drop jump height on landing strategies used by the volleyball players, to find differences in the jump and landing dynamics during a countermovement jump, and to find differences in the jump and landing dynamics during the execution of a spike jump. These results could lead to a better insight into the developmental characteristics of the jumper's knee.

THE INFLUENCE OF ARTICULAR SURFACE GEOMETRY OF FEMORAL CONDYLES ON CONTACT PRESSURE DISTRIBUTION

Boulti, V., Gigis, P.

Aristotel University of Thessaloniki, Greece

The objective of this study is to determine the changes of the load on the femoral condyles, depended on the geometry of the articular surfaces. On this purpose MRI scans of 18 individuals (6 females, 12 males) were used (age 41.55±12.8 years, min 17 max 63 years). The subjects had no complains about chronic pain of the knee joint and underwent the MRI scan after an acute injury which did not affect the articular surface. The distance between the slices was 2.5mm. They were digitized and by the use of a computer program (TableCurve3D) the best fitting equation was found. The accuracy ranged between 0.99 and 0.97. In respective parts of the surfaces the applied load was compared. The applied force was assumed to be of the same magnitude and direction in all cases. The force was resolved in three components (normal and tangent to the articular surface). The resolution is a function of the angles formed between the tangent plane and the direction of the applied force. The analysis revealed an increase up to 8% of the normal component in respective parts of the articular surface, which indicates that the cartilage is more loaded. The results of this study can be applied on the prediction of the degeneration of the articular surface.

ELECTROMYOGRAPHIC ANALYSIS OF THE DOMINANT UPPER LIMB DURING THE GOLF SWING

Pezarat-Correia, P., Cabri, J., Fernandes, O., Sousa, J.P.

Faculty of Human Movement, Technical University of Lisbon, Portugal

Purpose: The identification of neuromuscular patterns is an important cue for the management of muscular development, skill improvement and injury prevention. The main purpose of the present study was to characterize muscular coordination patterns in the dominant upper limb in the different phases of golf swing in experienced golfers.

Methods: Three low-handicap golfers (handicap lower than five) performed six full swing movements with a pitch iron. Surface electromyography (EMG) was recorded from 12 muscles: anterior (AD), middle (MD) and posterior (PD) deltoids, pectoralis major (PM), latissimus dorsi (LD), infraspinatus (IS), vastus lateralis (VL) and long portion (LP) of triceps brachii, biceps brachii (BB), brachioradialis (BR), wrist flexors (WF), and wrist extensors (WE). The EMG signals were sampled at 1000 Hz, full wave rectified, low pass filtered (second order Butterworth filter at 12 Hz) and normalized using the EMG of the maximal voluntary contraction (MVC) as a reference. In synchrony with the EMG signals, a three axis accelerometer fixed at the back of the golf club head informed about ball contact time (BC). Mean EMG value was calculated separately during each phase: backswing (BS), downswing (DS) and the first 500 ms of the follow-through (FT). For the movement analysis and phase delimitation the swing was filmed with four high speed video cameras (300 Hz). The recording of EMG and cinematic data was performed with a SIMI system (SIMI Motion, Munich, Germany).

Results: The average of normalized values of all muscles of the dominant arm in the three subjects, showed that the DS exhibited the highest muscular activity (28,8% of the EMG of the MVC) compared with the FT (19,9%) and the BS (15,7%). The elbow flexors (BB – 26%, BR – 45%) and the wrist extensors (WE – 26%) presented the strongest activation during the BS to promote elbow flexion and hand extension, and silenced before the DS initiation. During the DS the shoulder adductors (LD – 53%, PM – 38%) and the elbow extensors (LP – 50%, VL – 47%) presented the highest EMG activation. These muscles were activated at the beginning of the DS but the shoulder adductors peaked earlier. The AD peaked 70 ms before the BC and its activation may contribute to the arm internal rotation during the acceleration phase. The WF peaked during or just after the BC to accelerate hand flexion. The shoulder abductors (AD – 34%, MD – 14%) and the wrist flexors (36%) showed the highest activity during the FT. The posterior and middle deltoids showed low activity in all the phases (less then 20%).

Conclusions: The results demonstrated that the most active muscles during the golf swing were the shoulder adductors and the elbow extensors, and that the downswing was the phase where muscles from the dominant upper limb presented stronger activation. The EMG patterns we found can help to design training programs to improve strength and flexibility and to reduce injury risk in the golfer's upper limb.

THE PROCESSES BY WHICH PERCEIVED TEACHER BEHAVIOR IN PHYSICAL EDUCATION PROMOTES LEISURE TIME PHYSICAL ACTIVITY BEHAVIOR: A TRANS-CONTEXTUAL MODEL

Pihu, M., Hein, V., Koka, A.

Tartu University, Estonia

Introduction

Recently, trans-contextual model on the basis of self-determination theory and the theory of planned behavior was developed by Hagger et al. (2003) to investigate the determinants of the intentional physical activity behavior among adolescents. The trans-contextual models allow to investigate the processes by which motivation for physical activity in a PE context is transferred into a leisure-time physical activity context. The roles of perceived autonomy support from teachers, parents and peers in this model have been determined. The aim of this study was to test whether the other factors such as the students' perception that they are taught by teachers to use the learning strategy and students' perception of the teacher's positive feedback will fit to the trans-contextual model of motivation characterizing the intentional physical activity behavior.

Methods

The participants were 404 (126 boys and 278 girls) students. A three-wave prospective design was used. At the first occasion of data collection (time 1), self-report measures of perceived positive teacher feedback (Koka & Hein, 2005), use of strategies (Solmon & Lee, 1997) and the perceived locus of causality in a PE context were administered. One week later (time 2), a second questionnaire containing measures of attitude and intention (components of the theory of planned behavior) and perceived locus of causality in a leisure-time physical activity context was administered. After four weeks, self-reported physical activity behavior was measured at a third point in time (time 3) using the Leisure-Time Exercise Questionnaire (Hagger et al., 2003) A structural equation modeling was used for studying the hypothesized model.

Results

The values of fit indexes CFI =.91; RMSR=.07; RMSEA=.078 (CI .072 - .083) confirmed the hypothesized model. The effects of the perceived use of learning strategy and positive feedback on perceived locus of causality in a leisure-time physical activity context were mediated via the perceived locus of causality in a PE context. All together, the observed components of the model accounted for 58 % of the variance in physical activity behavior.

Discussion/Conclusions

Incorporating the components of the perceived teacher behavior to the trans-contextual model of the intentional physical activity behavior explained higher amount of the variance in physical activity than the previous models (e.g., Hagger et al., 2003).

The teachers should be acknowledged that students' perception of their positive feedback and that they teach students to use the learning strategy play an important role in forming the motivation in leisure-time physical activity context, which in turn influences intentional physical activity behavior.

THE DYNAMICS OF THE BIMANUAL COORDINATION AND THE CONCOMITANT ATTENTIONAL COST AFTER A SPECIFIC BILATERAL FATIGUE PROTOCOL

Murian, A., Deschamps, T.

JE 2438 , France

Especially interesting for the understanding of sport performance, fatiguing muscular activity is well documented. Vuillerme et al. (2002) found that after calf muscle fatigue, the subjects' posture was more variable and the associated attentional cost increased. Supported by dynamical approach to motor control, numerous studies have focused on the main principles by which the degrees of freedom problem overcame. First, studies on the influence of attention while performing bimanual coordination demonstrated that the more the movement variability, the more the central load (Monno et al., 2000). Secondly, it has been showed that peripheral constraints such as biomechanical factors altered the coordination variability but not the central load (Temprado et al., 2001). Thus the current study emphasized the influence of a specific bilateral arm fatigue protocol on the stability of bimanual coordination and associated attentional cost.

Ten volunteers participated in two sessions differentiated by the muscular activity preceding the 40 s coordination trials. In the "endurance" session (ES), bimanual coordination trials were preceding by an endurance time (T1) requiring to oscillate as long as possible both joysticks with added resistance, at a 1,5 Hz paced frequency. Then the participants had to carry out in anti-phase coordination trials (2 frequencies : 1.75 Hz and 2.25 Hz), with and without resistance, in a simple or double (reaction time task) task design. At the end, a second endurance time (T2) was performed. The "control" session (CS) replicated the same procedure, except the T1.

The standard deviation of relative phase, the absolute constant error (i.e. the absolute difference between the required and the performed coordination), and RT were classically analysed. The analysis of endurance times revealed that T2ES was shorter than T1 and T2CS. Results failed to reveal any effect of the T1 on the coordination variability and RT. However, absolute constant error was greater in the ES compared to the CS ($F1, 9 = 7.89$; $p < .05$).

Though our results did not reveal any effect of fatigue (evidenced by the significant difference between endurance times) on coordination stability and attentional cost, they showed that subjects were less accurate to maintain the anti-phase coordination pattern during the ES. It would be in line with the results of Temprado et al. (2001) who demonstrated that peripheral muscular constraints did affect the coordination but not the concomitant attentional cost. Nevertheless, analyses of the actual frequencies demonstrated that the subjects were not able to maintain the higher frequency when fatigued. To this consideration, current analyses are necessary for capturing the coordination dynamics according to the trials duration and the respect of frequency.

PATTERNS OF PROTOTYPES IN SPORTING BEHAVIOR

Keresztes, N., Piko, B.

University of Szeged and Semmelweis University, Budapest, Hungary

A number of studies suggest that individuals have clear social images of the type of people who take part in different health risk behaviors. The role of these prototypes in youth's health risks behaviors has already been investigated while the relationship between these images and preventive health behaviors such as physical activity is a less investigated field of research.

Our data were collected in 2005 among 14-21-year-old students at the Southern Plain Region of Hungary (n=548) using self-administered questionnaire. Items measured youth's health behaviors, social images, anxiety and their attitudes (social comparison, altruism, rationalism, and competitiveness).

We hypothesize that there may be important differences in the structure of these images in the light of sociodemographics and youth's attitudes.

This study points out that the prototypes of sporting behavior reflect very clear social images similarly to health risk behaviors. Using factor analyses, three social image factors have been isolated: a factor of "positive, personality-associated image", a "positive, health and sports-related image", and a "negative image" factor. These factors are related to sociodemographics and youth's attitudes in different ways.

Based on these findings social images of preventive health behaviors should get more attention in future research.

ATTRIBUTIONS ACROSS TIME: CONTROLLABILITY AND GENERALISABILITY ATTRIBUTIONS ON EFFICACY EXPECTATIONS IN SPORT

Coffee, P., Rees, T.

University of Exeter, Exeter, EX1 2LU, UK, United Kingdom

Rees, Ingledew, and Hardy (2005) proposed that in sport psychology, attribution research should focus on the main effects of controllability attributions, together with interactive effects of controllability and stability, globality, and universality attributions upon an outcome such as expectations. Additionally, Biddle (1999) recommended investigation into the consistency of attributions across time. In the present study, data were collected at three time points. At Time 1 (day 1), participants (n = 117 elite athletes, mean age 25.77, SD 8.45 years) completed a measure of attributions immediately after performance. At Time 2 (day 4) participants were asked to reflect on their performance at Time 1 and then complete a measure of attributions. At Time 3 (day 8), participants completed a 7-item measure of efficacy expectations relating to their up-coming performance. Hierarchical regression analyses revealed that immediately after more successful performances (Time 1), participants had higher subsequent efficacy expectations (Time 3) when they viewed the cause of performance as controllable (R square = .17, p = .00) and/or universal (R square change = .13, p = .01). Upon reflection (Time 2), an interaction (R square change = .09, p = .03) demonstrated that participants had higher subsequent efficacy expectations when they viewed the cause of performance as controllable and universal. Immediately after less successful performances, participants had higher subsequent efficacy expectations when they viewed the cause of performance as controllable (R square = .11, p = .01); an interaction (R square change = .05, p = .04) demonstrated that participants had higher subsequent efficacy expectations when they viewed the cause of performance as controllable and stable. Upon reflection, participants had higher subsequent efficacy expectations when they viewed the cause of performance as controllable (R square = .06, p = .04) and/or stable (R square change = .10, p = .01). Based upon this study, immediately after more successful performances, applied practitioners should encourage athletes to perceive control over the causes of performance; upon reflection, athletes should be encouraged to perceive any uncontrollability over the causes of performance as common to all people. Immediately after less successful performances, athletes should be encouraged to perceive control over causes of performance, especially when causes are perceived to recur in the future; upon reflection, athletes should still be encouraged to perceive control over the causes of performance.

RISK-TAKING, PERSONALITY AND MOOD - ARE QUESTIONNAIRES IN TOUCH WITH REALITY?

Jüngling, S., Kleinert, J.

Institute of Psychology, Germany

Introduction: The willingness to take risks is an important variable in sport science. It is not confined to extreme settings in risky sports. Willingness to take risks can also be of significance to explain accidents at each individual physical activity. Current research often uses questionnaires to collect data of risk perception and risk taking behavior. These instruments deal with theoretical statements and are usually personality-orientated. The variable of risk-taking as a result of situational assessment is often neglected in questionnaires. It can thus be assumed that the risk-behavior of a person depends on personality as well as on situational factors. The present study deals with reality-orientated measuring of risk acceptance in physically dangerous situations. The coherence between risk acceptance in a (real and virtual) physically risky test-situation on the one hand and stable and unstable psychological factors on the other hand are to be analysed.

Method: Two reality-oriented methods measuring risk-taking were developed: (1) a „blind-jumping-test" (real risk) and (2) a virtual „jumping-situation" (virtual risk). Test (1): The blindfolded subjects climb sideways up a wooden ramp as high as they dare, to a height of their choice, from where they think they might be able to jump still blindfolded. The height and speed of the climb are recorded. In test (2) the subjects are shown the video of a person climbing sideways up a sloping wall. The participants are to put themselves into the position of that person and to point out the highest level from where they think they might be able to jump. Following that the video is started by the blindfolded subjects a second time. They have to point out the spot which corresponds to the former estimate of the jump-off spot. The current study involved a group of 70 persons active in sports (34 male, 36 female) between the ages of 20 and 36 years. The subjects were divided into two groups, each group taking part in one of the two risk-tests. Each person was to carry out the test twice, with an interval of approximately 45 minutes. Between the tests they were physically or mentally stressed. The perceived physical state and the mood state were measured every time before a risk-test. Additionally, a few days after the test, the subjects had to fill in questionnaires concerning stable personality factors (e.g. sensation seeking).

Results: We found some significant but moderate correlations between psychological factors and the results of our risk-tests. In case of the virtual test-situation these correlations appear more often. This indicates that questionnaires have only weak or moderate relationships to risk taking in ecologically valid settings. The closer this setting is to reality the less marked this relationship appears to be. In addition findings suggest that especially psycho-social variables (e.g. self-confidence) are connected to the behavior in a physically risky test-situation.

TYPES OF PHYSICAL ACTIVITY AND PHYSICAL SELF CONCEPT IN OLDER ADULTS

Ouaghlani, M., Bertsch, J.

Université Paris Sud, France

Introduction: To date, few studies have been done to highlight the relation between aging and Physical Self Concept. Only a small amount of research exploring self esteem has been conducted and they have shown that as individual grow older, self esteem is likely to be affected (McAuley & al, 1997). Several types of exercise are effective in changing physical self perception in older adults, but there is most evidence to support aerobic exercise rather than other types of exercise (Netz & al, 2005). Thus, the purpose of this study was to examine the relationships between PSC and types of physical activity according to the age.

Method: 120 subjects represented two age groups: 60 young adults (M=23.7 years) and 60 older adults (M=69.2 years) who completed two questionnaires. The first one examined the physical self concept (PSDQ, Marsh et al, 1994). The second one measured the physical

activity (QUANTAP, Vuillemin & al, 2000). Each age group was divided into 3 groups of practice: sedentary, fitness (running, swimming, cycling, and walking), and specialised (petanque, bowling, golf, archery, and fencing).

Result: There was a large effect of age, F (1,108) =1429.2, p<.0001. The average of the older PSC responses (M Old = 3.02) was smaller than that of the young (M Young = 4.54). The group effect, F(2,108)=873.7, p<.0001, revealed that the score of PSC was lower for the sedentary group (M Sedentary=2.69) than specialised group (M Specialised=3.89) and fitness group (M Fitness=4.74). The 2Age X 3Group interaction was significant, F (2, 108) = 8.1, p<.0005. Scheffé post hoc analysis showed that, regardless of the age, the highest score of PSC was for the fitness group and the lowest one was for sedentary group.

Discussion: Regardless of the age, fitness groups get very high score of PSC, followed by specialised groups. It seems to be somewhat logical insofar as it has been deduced that aerobic training was most beneficial for psychological well being in older adults (Netz & al, 2005). The gender difference grew larger with age. It is fairly consistent with some studies on body satisfaction (Bruchon-Schweitzer, 1984).

GOAL ORIENTATION AND MAINTAINING PARTICIPATION WITHIN COMPETITIVE YOUTH SPORT

Konttinen, N., Laakso, L., Toskala, A.

KIHU - Research Institute for Olympic Sports, Finland

Past research on goal orientation has suggested that task orientation more often than ego orientation protects the athlete from disappointments and a lack of motivation (Duda, 1989). The purpose of the present study was to gain additional insights into this issue focusing on the relationship between goal orientation and continued involvement in competitive youth sport. The participants for the study were 3255 Finnish junior level athletes representing three different sports, ice hockey, floorball, and track and field. The participants ranged in age between 14 and 15 years (mean and S.D: age 14.90 and 0.29 years). Goal orientation was examined using the Finnish version of the Perception of Success Questionnaire, or POSQ (Liukkonen, 1998; Roberts, Treasure, & Balague, 1998). A longitudinal follow-up design was applied to provide a better understanding of the relation of motivational orientation to persistence in sporting context. Persistence, indicated by having a valid competition licence, was recorded one (Persistence 1) and three (Persistence 2) years after completing the initial questionnaire. The dependence of persistence on task and ego orientation, sport and gender was studied with forward stepwise logistic regression. For both the Persistence 1 and Persistence 2, the final regression equations contained Task orientation and Sport main effects and Task orientation by Gender interaction. The fit of the models were statistically significant for Persistence 1 and Persistence 2, Chi square = 115.200, df = 4, p = .000; Chi square = 76.800, df = 4, p = .000, respectively. The Sport main effect reflected differences between sports. One year after the initial data collection phase, 74.3 per cent of the ice hockey players, 52.0 per cent of the floorball players, and 43.5 per cent of the track and field athletes still held their competition licence. After three years, the corresponding figures were 41.8, 35.9 and 23.9, respectively. Task orientation by Gender interaction implicated that task orientation predicted both Persistence 1 and Persistence 2 better among boys than among girls. The prediction for maintaining participation, based on the regression equations, was correct in 72.7 per cent of cases for Persistence 1 and in 55.6 per cent of cases for Persistence 2. Even though the success of prediction was far from perfect, it was better than the predictions based on the actual drop-out rates. Taken together, it appears that the present findings support the results from previous studies, demonstrating that task orientation is related to continued involvement in competitive sport over the time span of three years, despite of several other factors affecting the persistence in sport among young athletes.

MASS CAMPAIGN "GERMANY IS MOVING!" 2005 - ACHIEVEMENTS AND STUMBLING BLOCKS DURING THE FIRST YEAR

Neß W., Brehm, W., Wagner, P., Sygusch R., Bös, K., Tittlbach S.

University of Bayreuth; University of Karlsruhe, Germany

The German health insurance company Barmer jointly initiated the health campaign Germany is moving! (Deutschland bewegt sich!) with the media partners Bild am Sonntag and ZDF. The German Gymnastics Federation (DTB) is a partner in terms of the realisation of the initiative. Tests for the campaign were developed by the University of Bayreuth as well as the University of Karlsruhe in the year 2005. Among other things, the cooperation with the universi-ties shall assure that intervention units are developed and evaluated for the campaign. On the one hand, these units provide comparative levels of physical performance and thus establish the basis for a bonus system for preventive successful behaviour. On the other hand, the units allow for an initiation of change in the test participants' behaviour of inactivity to more activity.

The three developed intervention units are based on a four-staged concept of behavioural change: Deliberation (reflecting to be physically active); preparation (preparing to be physically active); implementation (trying out some physical activities); habilitation (stabilising the physical activities). Each unit contains a fitness test for assessing or for objectively identifying the fitness level of adults as well as for a follow-up consultation on the next step of change to more physical sportive activity. The intervention units are usually carried out by DTB helpers. Amongst others, the intervention unit Test 1 (for Preparing and Trying Out) was deployed during a city tour through 19 major cities in Germany in the year 2005. Additionally, in the final two cities a survey on the demographic structure and fitness level of the participants

as well as an evaluation of the process was conducted. Overall, 5,636 evaluated surveys from the intervention unit Test 1 are available. Nonetheless, during the practical implementation of the intervention unit Test 1 & Consultation a number of serious problems un-folded.

The initiation of behavioural change appears to be possible with the help of the campaign intervention units. However, this implies unperturbed cooperation and accurate execution of the intervention measures. The objective to collect nationwide data on comparative levels of physical performance in order to establish the basis for a bonus system for preventive successful behaviour could not be accomplished yet. Hence, for the year 2006, improvements are planned in the following areas: a) a more selective engagement of the target group containing the risk factor lack of exercise, b) an improvement in the implementation of the test, c) the preparation and application of a standardised consultation concept for the systematic evaluation and exploitation of behavioural effects, and d) a more intense usage of potential behavioural effects on behalf of the cooperation partners, in particular on the part of the DTB.

A LONGITUDINAL STUDY OF SPORT IDENTITY AS A MEDIATOR OF CHILDREN'S PARTICIPATION IN SPORT

Lau, P.W., Fox, K.R., Cheung, M. W.

Hong Kong Baptist University, Hong Kong

Sport identity has been a core construct in explaining sport participation of individuals in the past decades (Brettschneider & Heim, 1997; Brewer, Van Raalte & Linder, 1993; Lau, Fox, & Cheung, 2004; Theodorakis, 1994). These studies have demonstrated the positive relationships between sport identity and individuals' sport involvement. Since all the previous studies in sport identity were cross sectional, it would be valuable to investigate the longitudinal changes of sport identity and sport participation. The purposes of this study were to examine (a) the relationships between sport identity and sport participation in children using the 3-year longitudinal data, (b) the longitudinal changes of all constructs, and (c) test the preliminary sport participation model. Participants were 238 boys and 231 girls aged 12 to 15 from a secondary school. A series of established questionnaires was conducted to the participants including the Task and Ego Orientation in Sport Questionnaire, Self-Regulation Questionnaire, Sport Competence Subscale from Physical Self-Perception Profile and Perceived Importance Profile, and Athletic Identity Measurement Scale to assess psychosocial variables. In addition, socio-environmental questionnaires were developed for the study to assess the influence of parents, peers, school and accessibility.

Correlation results showed that sport identity was significantly associated with sport participation of children in year 1 ($r = .37$, $p < .01$) and year 3 ($r = .36$, $p < .01$). MANOVA contrast analysis found that only task orientation, Relative Autonomy Index (RAI), school influence, peer influence and accessibility had significant changes after two years period. Finally, structural equation modeling indicated that the model was consistently a good fit of the data (year 1: CFI = .994, Standardized RMR = .027; year 3: CFI = .976, Standardised RMR = .038). These results demonstrated that children's sport participation could be explained by the sport identity model.

THE EVOLUTION OF THE AFFECTIVE DEMAND IN THE COACH-ATHLETE RELATIONSHIP

Huguet, S.

University of Luton, United Kingdom

Lots of researches on the coach-athlete relationship have focused on the social interaction (Carron, 1977 Jowett, 2000) or the leadership (Chelladurai, 1978; Cote et al., 1995), rather than the affective process. However, this relationship may sometimes lead the coach to face an affective demand that he/she is not prepare to handle.

Therefore, the psychoanalysis approach proposed to analyse the unconscious affective process in the coach-athlete relationship through the concept of transference initially developed by Freud (1922). The concept of transference helps to understand that previous relationships with significant others may have consequences on the next relationships. A previous research (Huguet, Labridy, 2004) had already concluded that the coach might be a substitute or come as a replacement of a parent's figure.

This study aims to analyse the affective process behind the coach-athlete relationship and how the affective demand evolve from childhood to adulthood depending on the athlete's family structure.

We interviewed 14 high level tennis players (7 males and 7 females ranged from 13 to 29 years old). We had between 3 and 4 interviews with each player that were transcribed verbatim. A thematic analysis was then designed according to the psychoanalytical theories on the relationships of the subject with the others and how he/she structured his/her identity within his/her family and what were the relationship with the coach since the beginning.

As the result of this study was case study, it is not possible to develop all the 14 case studies in depth in this part.

However, these case series show similarities in terms of structure between athletes. The affective demands towards the coach evolve depending on whether the athlete has decided that the primary motivation to compete is the desire to play for him/her or whether he/she remains dependant on the parent or coach's desire.

The beginning of practising often means that the child is dependant upon his/her parent's desire. The fact that he/she playing for fun as well at this stage may explain why the coach is not a significant figure for the player. During adolescence, the athlete is either still pursuing sport on a parent's desire or on the coach's desire as they experience more identification and idealisation phenomenon. Therefore there is a transference process that may put the coach in a parent's substitute position.

When the player becomes professional, there are two options: he/she is still not fulfilling his/her own desire to compete sport and that often leads to a series of unexplained injuries or bad performances. Or the athlete finds his/her own signification of practicing sport and do not require the coach to fill his/her affective demand anymore.

The coach has to be aware of the unconscious mechanisms that happen in the relationship as that would help him/her to understand the affective demand of the athlete. This demand will vary according to the athlete's previous relationship with parents and significant others.

ARE SPORT INJURIES RELATED TO AFFECTIVE PRIMING?

Fries, U., Hoffmann, A., Würth, S., Alfermann, A.

University of Leipzig, Germany

Introduction

The study "Attention and risk of injury (Az. VF 07/10/01/2005-2006)" is supported by the Federal Department of Sport Science to deliver a contribution to the understanding of causes of sport injuries. On the basis of Kleinert's Stress-Injury-Modell (2002) it has been examined to what extend former experiences of injuries influence attentional processes in terms of negative priming and so, abet (re-) injuries. It is assumed that acute experiences of injuries stay fixed in the athlete's memory. Activated by subliminal presented pictures with high risk of injury (negative prime) these reminiscence could affect the following motoric Reactions and increas the number of errors (and so the risk of injury). This effect should be even higher in stressful situations.

Method

For the study in hand we won over one female and one male team of each sport: Basketball, Handball and Hockey. In a choice-reactiontime-experiment the influence of primes of different emotions on the athletes' reactions has been examined. Based on an expert-rating 60 photos were chosen for each sport to reflect positive mood, neutral mood and negative mood combined with high risk of injury and used as primes. Coloured chequered patterns provided target and non-target. Reactiontime and percentage correct were measures of performance.

The control condition was without distracting influences. In the experimental condition stress was generated with typical noises recorded at competitions of each sport.

Results

The results are to be presented and discussed in reference to the following questions: Do primes with high risk of injury impact the speed or accuracy of reaction? If yes, is this effect more eminent for athletes with experiences of injuries? Does stress augment this effect?

CAN SIGNIFICANT OTHER'S BEHAVIOUR INFLUENCE OUR WAY OF THINKING? THE EFFECTS OF POSITIVE AND NEGATIVE BEHAVIOUR ON AUTOMATIC THOUGHTS DURING A TENNIS STROKE

Zourbanos, N., Theodorakis, Y., Hatzigeorgiadis, A.

University of Thessaly, Trikala, Greece

Cognitive-behaviour theories have been based on the premise that a person's thinking can affect emotions and behaviour (Meichenbaum, 1977). Considering the importance of thoughts and their significant role on behaviour and emotions, it would be interesting to examine the extent to which behaviour of significant others affects individuals' thoughts (Mead, 1964). The present study examined the influence of instructor's behaviour on participant's negative self talk (worry). Sixty physical education students participated in the study. The experimental task was to execute forehand drives (4 sets of 10 repeats) in a tennis court using the Broer-Miller Forehand-Backhand Drive test. Participants, after performing a baseline trial (B) were assigned into two groups; positive instructor's approach (PIA) and negative instructor's approach (NIA). Each group was tested under two more conditions, which were counterbalanced, within a two-week period; with time pressure (TP) and without time pressure (NTP). During the execution of these trials, participants in the PIA group were provided with positive reinforcement from the instructor, whereas participants in the NIA group received negative criticism. The effectiveness of the group manipulation (instructor's approach) was evaluated with the Coaching Behaviour Questionnaire (CBQ). In addition, participants completed the Automatic Self-Talk Questionnaire for Sports (ASTQS), from which only the worry dimension was used. Independent sample t-tests showed that there were no differences between the groups in performance and worry for the initial assessment, $t(38) = .43$, $p = .67$ and $t(38) = -.46$, $p = .65$, respectively. Correlation analysis showed that there were negative relationships between performance and worry in all conditions (ranging from -.25 to -.44). Therefore, two mixed model ANOVAs, with group as an independent factor (PIA, NIA), condition as a dependent factor (B-TP, B-NTP), and performance as covariate (to control for effects of performance on worry) were calculated to test for differences in the patterns of worry between the two groups. Regarding the TP condition, the analysis revealed a significant group x condition interaction effect, $F(1,37) = 5.04$, $p < .05$. Follow-up paired samples t-tests showed that worries for the NIA remained stable, whereas for the PIA decreased significantly. Regarding the NTP condition, a similar pattern was identified, however the interaction effect only approached significance $F(1,37) = 3.68$, $p = .06$. The results of the study provide support for the importance of instructor's behaviour and verbalizations on individuals' thought patterns and especially worry.

EVIDENCE ON THE VALIDITY OF THE AUTOMATIC SELF-TALK QUESTIONNAIRE FOR SPORTS (ASTQS): A PRELIMINARY ANALYSIS ON NEGATIVE SELF-TALK

Zourbanos, N., Hatzigeorgiadis, A., Theodorakis, Y., Chroni S.

University of Thessaly, Trikala, Greece

Interest in self-talk research in sports has been increasing the last decade. Although some answers regarding the phenomenon of self-talk have been revealed (Hardy, 2006), still many remain unanswered. An aspect that has not received much attention is the conceptualization of the structure of athletes' internal dialogue. This research aimed to construct an instrument to assess athlete's automatic self-talk during training and competition. The present investigation focuses on athletes' automatic negative self-talk. At the first stage of the investigation, row data (negative self-talk) were collected through open-ended questionnaires from a sample of 355 athletes representing a wide variety of sports. Athletes' responses were then screened by the authors to eliminate redundant items. An initial pool of 62 items was cull. Following Dunn, Bouffard, and Rogers' (1999) recommendations item-content relevance analysis was conducted. This resulted in a pool of 44 items which were retained to be further processed. In the next stage of the investigation these items were submitted to exploratory factor analysis. Athletes from a wide variety of sports completed the prospective instrument (N = 337). Athletes were asked to indicate how frequently they experience the listed thoughts during training or competition. Principal components analysis was conducted to identify the number of factors to be interpreted. The analysis supported the existence of three factors. Subsequently, a forced three-

factor solution using oblique rotation was applied. Items with loadings below .30 and items with similar loadings on more than one factor were eliminated, leaving a total of 19 items. The three factors accounted for 56,77% of the variance. The first factor was labeled worry, the second factor was labeled somatic fatigue, and the third factor was labeled disengagement. These factors appeared to reflect the structure of Hatzigeorgiadis and Biddle's (2000) Thought Occurrence Questionnaire for Sport, apart from factor somatic fatigue which was made up of items revolving body disturbs caused by exhaustion. The reliability of the instrument was tested through the internal consistency of the subscales. Cronbach's Alpha coefficients ranged between .74 and .88. The results of this study suggest that ANSTQS demonstrates promise as a measure of athletes' negative self-talk.

FACTORS UNDERLYING PARTICIPATION MOTIVATION OF YOUTH HOCKEY PLAYERS WITHIN A CLUB SETTING. A COMPARATIVE STUDY

Campbell, R., Lloyd, S.

Stranmillis University College , United Kingdom

Background: Sports clubs are increasingly reliant on youth sections for recruitment and development of future adult players (Sports Council Northern Ireland, 1996). In order to optimise the quality of experience for children it is vital to discover what motivates young people to participate in particular sports (Irish Sports Council, 2003).

Objectives: To compare the reasons for club sport participation in field hockey by females across three age groups (9&10, 11&12, 13&14 yrs). To assess coaches understanding of children's motivation for participation.

Methods: An adapted version of Gill et al's (1983) Participation Motivation Questionnaire was used to assess subjects' (n=60) motives for participation. Further descriptive data was obtained in an attempt to understand how sessions could be improved. Qualitative information was obtained from the coaches via interviews. Chi square was used to examine if differences in motives across year groups were significant.

Results: Questionnaire responses indicated that key motivating factors vary with age. Across the groups, 'fitness' and 'skill development' were found to have significant differences. Several non significant trends were highlighted. The children also identified a range of areas in which sessions could be improved. However, these were not considered to be barriers to participation. Responses from interviews indicated that coaches understand their players' needs with the programmes offered reflecting this.

Conclusions: This study gives those involved in youth sport an awareness of the main participation motives of children involved in field hockey in a club setting. This child centred approach will benefit the future of clubs' development as well as returning many benefits in terms of the health and well being of our future adult population (SCNI, 1996). The small sample size within this study means results should be considered exploratory in nature, with a more in depth study being required to strengthen findings.

A NEW CONCEPT "THE HEART SINK ATHLETE"

Rogers, R., Worth, N., Mahoney, C.

University of Wolverhampton , United Kingdom

There are certain athletes whose usual frequent appearance makes the medical staff's "hearts sink". This is a phenomenon that many Sports clinicians and sports scientists experience, however to our knowledge there is no mention of it in the literature. The "Heart Sink Athlete" is a new phase taken from a known phenomena experienced in General Practice, the "Heart Sink Patient". These are patients who give the doctor and staff a feeling of "heartsink" every time they consult. These patients evoke an overwhelming mixture of exasperation, defeat and sometimes plain dislike that causes the heart to sink when they consult. In other words the term refers to the clinician's emotions which are triggered by certain patients. The term "Heart Sink" can be viewed as a politically incorrect judgment made about a patient. It can however also be seen as the honest appraisal, by a mindful professional, of his or her own response to a particular patient /athlete. This alternative view allows us to move from blame to understanding, and involves accepting that the negative feelings experienced are the product of the interaction between patient and professional. Many heart sink athletes have medical records which can be 10 times thicker than those of the average athlete. In addition many athletes present with unexplained chronic pain. Some athletes can also be described as malingerers. This could be as a result that they are "not good enough". It is also common for athletes to experience an increased tendency to be injured when they are not performing well or the team is not winning. Ever wonder why the treatment room is less busy when a team is winning? Most of these athletes have been seen by several specialists and have scores of laboratory tests and imaging examinations. The difficulty in managing these athletes often arises because they have been given different explanations for the same condition, this may leave them confused and frustrated. These feeling can be projected in the consultation and as a result create a problem between the clinician and athlete. In addition each new clinician has to familiarize himself with the ever growing set of notes, or adopt an unsatisfactory temporizing measure, e.g. sending patients for x-rays or putting them on placebo.

This presentation will discuss the, profile, problems, differential diagnosis and possible management of these athletes.

MENTAL SUPPORT OF THE TRANSITION PERIOD- SPORTPSYCHOLOGICAL PREPARATION OF HUNGARIAN HANDBALL JUNIOR TEAM

Lénárt, Á., Gyömbér, N.

Semmelweis University, Faculty of Physical Education and Sport Sciences, Hungary

Introduction.

The youngmaking process of the hungarian man handball team, which achieved the fourth place in the Olympic Games in Athens, 2004, became neccessary. Having aimed to reach the same mental preparation level with juniors, that we had been able to manage with the Olympic players before. The goal of the new team is the participation on the World Championship (2007, Germany), and qualification for the next Olympic Games.

Methods.

Steps were worked out according to the following.

1. Tests, statusmeasurement, exploration (n=18) and discussions with coaches. Applied tests: ACSI-28/2, CSAI-2, Lüscher, Wartegg, TOPS, Sociometry.

2. The preparatory course (duration 4 weeks, two hours a day) contained autogenic and mental training, goal setting, cognitive techniques, self- confidence development, attentionfocusing, communication skills improvement and team building. Parallelly individual sessions were held (about five hours a day).

3. During this period they adapted the acquired methods, after it, the effectiveness of this preparation has been evaluated (retest).

4. Individual work, in form of consulting were also available during the World Championship.

Results.

Concluding the results of the first testing, the team in respect of practice strategies initially owned good level of goal-setting (also the same among competition strategies) and imagery. However the ability of relaxation and activation needed considerable development, which is the same in the case of automaticity, considering competition strategies (TOPS).

According to ACSI-28/2, beneficial values could be found, in the respect of the following cooperation. The level of cognitive and somatic anxiety were approximately the same, and they showed a good level of self-confidence, which suggested optimistic attitude. After retesting, there were significant difference ($p<0,01$) in all factors, both among practice and competition strategies (goal-setting, emotional control, automaticity, relaxation, self-talk, imagery, attentional control, activation and negative thinking). This can be unequivocally explained with those basic psychological techniques, what they acquired during preparation.

We can consider positive, that making up to the World Championship all competition and practice strategies had improved.

There was also significant difference in self-confidence ($p<0,05$, CSAI-2) and peak performance ($p<0,01$, ACSI-28/2), which can be consider as a really good value before the championship. Furthermore team cohesion and conflict- management also improved.

The team has finally won bronz medal.

Conclusions.

The best six players were chosen into the national team. Joining they could perform, in psychological meaning, as high level as the others, thus creating a new and homogenous team. This is expressly beneficial in respect of the long run cooperation (Beijing, 2008), because this way juniors can be also the part of a physically and psychologically integrated work, that is absolutely necessary for the future successes.

ANALYZING EXPERT BASEBALL COACHES' STRATEGY FOR SUBJECTIVE KNOWLEDGE

Nagayama, T., Kitamura, K., Saito, S.

Tohoku University, Japan

Physical tacit knowledge is subjective knowledge. Tacit knowledge refers to the highly subjective insights, intuitions and hunches (Nonaka, 1991), and the accumulated skills and experience (Leroy and Ramanantsoa, 1997). In addition, it is difficult to be formalized, organized (Kim, 1993). Physical tacit knowledge is an important topic, when we research motor learning. But there are a few studies that clarified physical tacit knowledge in motor learning. Therefore, the purpose of this study was to investigate expert coaches' strategy for the transformation of physical tacit knowledge into explicit knowledge during baseball pitching training. Three expert coaches and five players served as the participants for this study. 30 training sessions where coaches instructed players in physical tacit knowledge of baseball pitching skills were observed and recorded. In-depth interview was conducted with each coach and player stimulated recall by VTR every training session. Interviews were focused on coaches' strategy for externalizing their personal knowledge. Interview transcripts were divided into 56 meaning units. These meaning units were regrouped into three categories which were crucial for a way to make the tacit dimension of their knowledge explicit. Three categories emerged from the analysis consisted of 1) comprehension of player's body experience, 2) externalizing internal imagery, and 3) enhancement of kinesthetic sensitivity. Results showed that expert baseball coach tried to comprehend players' body experience and instructed them in coach's internal imagery by figurative languages which brought out some kinesthetic sensitivities which were essential for skill acquisition. As a result, players could comprehend physical tacit knowledge by which he/she linked some kinesthetic sensitivities they had already experienced. And it was most important coaches' work to make players sensitive their kinesthetic sensitivities during training. Expert coaches gave players the reference so that players could pay attention to their kinesthetic sensitivities. The reference allowed players adjusting their performance to internal imagery consisted of some kinesthetic sensitivities. It was difficult for coaches to externalize their physical tacit knowledge, because physical tacit knowledge was subjective knowledge. However, expert baseball coaches always tried to transform physical tacit knowledge into explicit knowledge by means of figurative languages and make players sensitive their kinesthetic sensitivities by the reference.

A QUALITATIVE ANALYSIS OF THE ATHLETE-COACH RELATIONSHIP OF PROFESSIONAL SOCCER TEAM IN BRAZIL

Kitamura, K., Nagayama, T., Saito, S.

Tohoku University, Japan

This study provided an in-depth description of the dynamics of the athlete-coach relationship indicating that the coach-athlete relationship as a suitable psychological climate provide both chances to develop adaptive person and performance accomplishment. Jowett, & Ntoumanis (2003) indicate that Closeness, Co-orientation and Complementarity are salient components of the coach-athlete relationship. The purpose of this study was to describe an in-depth description of the athlete-coach relationship in professional soccer team in Brazil taking into account their coaching philosophy in relation to coaching expertise development. Ten coaches (four coaches, four physical coaches, two goalkeeper coaches) from four categories (professional B, U-19, U-17, and U-15) and thirty two athletes from each category served as participants for this study.

In-depth open-ended interviews were used to gather data on ten coaches and thirty two athletes from four categories. Participated observation was also used to describe a detailed atmosphere during the practice. The interviews were systematically transcribed verbatim from the integrated circuit recorder immediately after the completion of each interview, and a total of 188 meaning units were extracted from the data set. The data was decontextualized using an inductive procedure for analyzing unstructured qualitative data. The inductive analysis process resulted in regrouping these interview transcripts into three categories: (reliability, commitment, and mutual supporting), and six properties (having feelings of sympathy, respecting, understanding, helping substantially, share the goal, commitment to the attainment of the goal, motivating, providing positive feedback, and communication).

This study found significant agreement between the suitable psychological climate on how the athletes and coaches evaluated their mutual supporting activities in relation to performance enhancement of soccer players and how this suitable psychological climate between the athletes and coaches affected their development in the professional soccer team in Brazil. The strong relationship between reliability, commitment, and mutual supporting indicates that a desirable interpersonal relationship direct athletes to commit to deliberate practice as a way of overcoming the constraints for performance enhancement.

Results showed that the athlete-coach relationship is a very dynamic, multifaceted, interpersonal phenomenon. Successful coaches construct the relationship with athletes in a manner that maximizes athletes' commitment to daily effortful practice.

PERCEIVING PATTERNS IN DYNAMIC ACTION SEQUENCES: IDENTIFYING THE CRITICAL INFORMATION UNDERLYING ANTICIPATION SKILL IN SOCCER

North, J.S., Williams, A.M., Hodges, N.J., Ward, P., Ericsson, K.A.

Liverpool John Moores University, United Kingdom

Anticipation is essential to top-level performance in sport. Pattern recognition is thought to be an essential component of anticipation (Williams et al., in press). We examined the processing mechanisms employed by skilled (n = 11) and less-skilled (n = 15) players when recognising complex, dynamic soccer sequences. Also, we considered the relationship between pattern recognition and anticipation performance. In an anticipation phase, players viewed filmed action sequences from a defender's perspective and anticipated an opponent's pass destination. In a subsequent recognition phase, players identified whether or not each sequence was presented during the anticipation phase. During recognition some sequences were presented in point-light rather than film format, removing superficial display features and maintaining relational information between players. Visual search behaviours were assessed. Skilled players were expected to demonstrate superior recognition performance than less-skilled players, particularly for point-light sequences. If pattern recognition is an essential component of anticipation, performance on these tests was predicted to be correlated and the processing strategies not to differ.

Skilled players (M = 64.3%, SD = 6.29) were better at anticipating pass destination than their less-skilled peers (M = 55.7%, SD = 3.85). Moreover, skilled players (M = 58.0%, SD = 12.9) were more accurate than less-skilled participants (M = 52.0%, SD = 16.3) in recognising patterns of play. This skill advantage was maintained when clips were presented in point-light format. Skilled performers develop elaborate task-specific knowledge structures providing an advantage when making such perceptual judgments (Ericsson & Kintsch, 1995). Performance on anticipation and recognition tests were not correlated. Visual search behaviours during anticipation and recognition differed markedly, implying that contrasting perceptual-cognitive mechanisms underpin performance on these two tasks. Participants employed more fixations (M = 1.3 vs. 1.1) of shorter duration (M = 683.0 vs. 978.0 ms) and spent more time fixating areas other than the ball (37.0 vs. 25.6%) when attempting to anticipate rather than recognise patterns of play. In conclusion, skilled performers make use of relational information between players and associated higher-order strategic knowledge to detect meaningful patterns of play. However, pattern recognition may not be an essential component of anticipation performance, but rather a related by-product of exposure to the task domain. Findings have implications for the development of training programmes to enhance perceptual-cognitive skill in sport.

A QUALITATIVE ANALYSIS OF VALUE ORIENTATIONS OF UNIVERSITY INSTRUCTORS: A CASE STUDY

Sarac, L.

Middle East Technical University, Turkey

Introduction: In the typical teaching-learning environment, teachers make curricular decisions. These curricular decisions often include the questions such as what should be taught to whom, when, how, and why? Curriculum theorists states that, teachers' curricular decisions constructed on their set of educational beliefs (Ennis, Chen & Ross, 1992). In physical education area, five value orientations have defined as affecting teachers' educational decisions: Disciplinary Mastery (DM), Learning Process (LP), Self-Actualization (SA), Social Reconstruction/Social Responsibility (SR), and Ecological Integration (EI) (Bain & Ennis, 1995).

Purpose: The purpose of this case study was to find out the impact of physical education instructors' value systems on their curricula by examining 2 physical education instructors' curriculum content and implementation.
Method: The value profiles of 8 physical education instructors were determined by using Value Orientation Inventory (VOI). Then, 2 instructors were selected by using criterion (having different value priorities) type of sampling. According to the results derived from the VOI, one of the instructors (Cem) was founded as SR oriented and the other (Berfin) was DM oriented. In order to collect data on reflection of value orientations 2 instructors and their students were interviewed. Additionally, instructors' behaviors during actual teaching setting were observed, and their verbal behaviors were recorded by tape recorder. Observational data were collected based on the physical context, lesson content and structure, classroom management, activities, etc. Coding categories and the themes was constructed according to the literature (Ennis & Chen, 1993).
Results: In the current study Berfin was a DM oriented instructor mainly focusing on the development of psychomotor and cognitive behaviors necessary to be successful in skill related and fitness activities. However, it was clearly observed in the SR oriented teachers' class session that he was focusing on teaching SR oriented concepts such as self responsibility, respect to social orders, classroom rules. In general, it was founded by the class observations that the each instructor reflects their value profiles in their lessons. Also, instructors were consistent with their value profiles during formal interviews. Additionally, students' perspectives on their instructors teaching environment revealed that both DM oriented and SR oriented instructor reflected their value orientations in their classes.
Conclusion: In order to provide maximum learning, curriculum developers consider some factors such as learner, society, nature of the content etc. Teachers' values are also important factors affecting implementation of the curriculum. Because, teachers are a bridge between the theoretical and practical part of the curriculum and it would be beneficial to find out value profiles of the teachers and consider these profiles during the curriculum development process.

REASON FOR NON-ATTENDANCE TO PHYSICAL EDUCATION CLASSES IN PRIVATE ELEMENTARY SCHOOLS

Yildirim, A., Cicek, S.

Middle East Technical University, Turkey

The purpose of this study was to investigate reasons of non-attendance to physical education classes in private schools in Turkey.
Three private elementary schools were participated in the study in Ankara, Turkey. 12 classes from 8th grade, 10 classes from 7th and 10 classes from 6th grade were observed (total 32). Data were collected classroom observation and interview with non-attending students. Information related with attendance, gender, physical appearance, reason for non-attendance, and behaviors of non-attending students were noted. Data collection was performed during regular physical education classes.
Descriptive statistics were used for statistical analysis.
Results showed that, there were 129 non-attending students over the observed 32 classes. Non-attendance rate was 16.8%. Non-attendance rate were 6.3%, 23.5% and 21.7% for grades 6-7-8 respectively.
In all classes female students had slightly higher non-attending rate than male students (54.3% vs 45.7%). Physical appearance of non-attending students considering body fat was quite normal.
Behavior of the non-attending student was passive sitting on a bench in gymnasium (79.1%).
Forgetting sports equipment (50.4%), illness-injury (36%), having health report (11.6%), parents permission (9%) were seem to major reasons for non-attendance to physical education classes.

WHY DO ATHLETES PERCEIVE LOWER LEVELS OF CHRONIC STRESS? THE RELATIONSHIP BETWEEN RESOURCES AND THE PERCEPTION OF CHRONIC STRESS AMONG CHILDREN IN COMPETITIVE SPORTS

Hoffmann, K.

University of Leipzig, Germany

Much research has been conducted in recent years regarding the benefits of physical activity on mental health. However, this research mainly focuses on adults and adolescents, and is predominantly based on physical activity and exercise in general. Consequently, research investigating children in competitive sports is limited. Recent work indicates that children active as athletes experience significantly lower levels of chronic stress than their non-active peers (Richartz, Hoffmann & Bernardt 2005).

Based on this result the present study aims to answer the question why the levels of chronic stress are lower among athletes than among non-athletes. By using a combined model of the Cognitive-Motivational-Relational Theory (Lazarus 1991) and the Conservation of Resources Theory (Hobfoll 1998) the role of competitive sports in the process of chronic stress will be analyzed. For this purpose the relationship between children's perception of chronic stress and different kind of protective resources shall be explored.
The empirical research comprises a longitudinal survey with two points of measurement in two groups of children (athletes n=598; non-athletes n=499) aged 7-12. The data was collected using the questionnaire 'Strains and Resources among children' (BR-K, Belastungen und Ressourcen im Kindesalter) which was designed specifically for the project. Findings derived from the first point of measurement verify the significantly lower stress-scores for active athletes in comparison to their non-active peers.

THE EFFECT OF COOPERATIVE SCHOOL GAMES ON PUBESCENT GIRLS' DECISION AND STUDY ASPECT OF SOCIOMETRIC STATUS

Katalin, K.

Semmelweis University Faculty of Physical Education and Sport Sciences, Hungary

According to Kotschy (1998) one of the traits of practical cognitive aspect in applied pedagogy is that the solution for most educational problems is the development of an aptitude for thinking. The cognitive aspect is not concerned with either the emotional development of the student or the quality of interaction between students, in spite of the fact that the quality of social interactions has a major impact on

performance. Therefore, one of the major issues in educational social-psychology is the modification of inter-student contacts and relationships to improve personal develop and group structure.

To develop personality, physical skills and/or social qualities and abilities must be used as an educational tool. Indeed, in a good group the students require the support of each other and benefit from the cooperative attitude as well as high performance (N. Kollár, 1997). Thus school games and cooperative games in particular, are an excellent tool to develop personality traits.

Our research of several years hypothesized that cooperative games have a positive impact on group structure and reduce the degree by which students on the group periphery were marginalized by their peers. Success in cooperative games depends on working together, so the answers to the decision question will mirror social abilities which could also be apparent in the answers to the study question.

Sociometric status for the aspects of decision and study were measured by asking each student two questions ("How willingly would you make a decision in an important question with each of your class mates?" "How willingly would you study with each of your class mates?") and plotting the results using an expanded matrix version of the Shellenberger's Group-Evaluative Method (1980).

The participants were freshman girls (experimental group N=74, control group N=71), from three different secondary schools (downtown, suburban, and catholic) in Budapest, Hungary. The test groups practiced cooperative school-games during every P.E. class for 10 to 15 minutes twice weekly during the first examination period. In the second examination period the physical education teacher decided on a case by case basis how often to utilize the cooperative games program.

In the answers for the decision aspect, it was found, primarily in the small groups, that the overall position the girls in the experimental group (both liked and disliked) shifted in a positive direction, indicating that for important decisions the classmates would listen to each other more then before the program. However, because the entire group shifted in a positive direction, the socio-distance between the group and the disliked students did not increase, but it did not decrease either. In the control group the position of the students either deteriorated or did not change.

In this presentation we analyze the answers for the study aspect to determine if the same or different results are observed.

TEACHING SOCCER IN PHYSICAL EDUCATION – LONG-TERM EFFECTS OF USING A FUTSAL BALL INSTEAD OF A NORMAL OR AN INDOOR (FELT) FOOTBALL

Heim, C., Frick, U.

Johann Wolfgang Goethe-University Frankfurt, Germany

Introduction

Football (soccer) is – at least in Europe – one of the most popular sports for pupils. At the same time, soccer is often regarded as a difficult sport to teach (see Heim & Frick 2006a in this volume for a detailed description of some possible difficulties). A possible solution for some of these difficulties may lie in the use of a Futsal ball (FUT) instead of a normal (FOT) or a felt (FEL) football. The aim of this study was therefore to evaluate whether beginners learning success may be enhanced by the use of a FUT in comparison to a FOT or FEL.

Methods

Over a period of two years, a longitudinal study was conducted with 64 fifth-grade pupils (age-range 10-12 years) in three different classes. Identical six-week teaching units were performed in each of the classes; each class was instructed with a different ball (FUT, FOT or FEL). Participants' technical football skills were tested in isolated trials (e.g. controlling a bouncing ball that drops from a certain height with a reproducible velocity) and during play using a quantitative video analysis (every action – e.g. passing, shots on goal etc. was counted for each player and coded as "positive" or "negative") before and after the teaching unit. All classes performed the isolated trials with all three balls; the tournaments before and after the teaching were played with ball each class used during the teaching unit. Additionally, to attain reference values, each class played a second tournament with a FOT before and after the teaching unit.

Results

Evaluation of the tournaments played with the ball used for training in each class before and after the teaching unit showed significant increases in the number of ball contacts each player had during play (FUT +10.9%, T=1,634; df=21; p=0,059; FOT +4.0%, T=0,649; df=20; p=0,649; FEL +10.9%, T=1,868; df=23; p=0,038). A comparison of the actions coded as "positive" however showed significant differences in favour of the class that trained with the FUT (FUT +16.2%, T=1,826; df=21; p=0,038; FOT +3.3%, T=0,458; df=20; p=0,326; FEL +2.1%, T=0,363; df=23; p=0,360). Similar results were achieved for the isolated tests of football skills. An analysis of transfer effects when playing with a FOT after training with either a FEL or a FUT showed significant increases for the class training with the FUT only (+8,5%, T=0,907; df=21; p=0,188; FEL -12,9%). Again, similar results were achieved in the isolated tests of footballs skills (class instructed with a FUT +13.1%, T=2,329; df=21; p=0,015; class instructed with a FEL +6.0, T=1,736; df=21; p=0,049).

Discussion

Results indicate that the beginners can greatly benefit and achieve better results if a FUT instead of a normal or a felt football is used in PE soccer tuition. It is therefore concluded that football tuition in schools should be performed with a FUT instead of a FOT or FEL when soccer is played indoors.

WAYS OF MARKETING WATER SPORT IN A.R.E

Mekky, A.

Physical Education, Egypt

Ways of marketing water

Sport in A.R.E

The research aimed at the aknowledg of the best scientific ways marketing water sports which involved of water saeling , water skiting , catching fish and diving in A.R.E , and the difference between the academics and the practicas in their ways of some marketing water sports . the research designed an application form for academic coachers . the staff at the faculty of physical education and the faculty of commerce and practical cooches who had trianed turns and working in water sport club . the researcher applied the application form on (60) members of the staff specified in water at the faculty of commerce specified in business arrangement and 75 coaches from water sport club .

The researcher attained some results the most important once are :

* the best marking ways which used in measurement by a scientific ways .

* the best way which depend on investment and the development of materials for water sports club .
* put are bublic staratigy for developing and marketing the water sport in all Egypt areas , espiecally in the cities which look at the sea such as the Red sea middel what sea the cancel of
* establishing a specific parts for sport tourism in the ministry of tourism , these parts making a plans and programmes in order to activited sport tourism of water sport , and this is for have shows and competion and working to increasing the coaches in the field of water sport tourism among the faculties of phisycals and the faculity of tourism and hotel .
* put in consideration the scintific principle in planning for water sports club in A.R.E .

RESULTS OF OLYMPIC EDUCATION IN POLISH SCHOOLS

Nowocien, J.

The Jozef Pilsudski Academy of Physical Education in Warsaw, Poland, Poland

"Olympic education" refers to all the processes aimed at transforming a person-student mainly through sport and Olympism according to relevant social ideals and educational pur-poses. Its essence consists in the application of sport and olympic values of P. de Coubertin in the education process: Olympism being the main education content, while sport the major educational method.
Since 1990's, Polish schools implement alternative curricula for Olympic education. 15 years of education resulted in significant pedagogic results.
1. Positive change in students' attitude towards sport and other forms of physical education.
2. Positive students' social attitudes have been marked by implementing the fair play principle as major educational content.
3. Education through sport and olympism has successfully raised students' moral be-haviours in the area of sports and others.
4. Educational results depend on teachers' knowledge, their motivation, readiness to embrace innovative teaching methods, ability to co-operate with students, other teachers and parents.

CHILDREN'S OPPORTUNITIES TO BE PHYSICALLY ACTIVE IN PRESCHOOL

Cools, W., De Martelaer, K., Adries, C., Samaey, C.

Vrije Universiteit Brussel, Belgium

Introduction Early childhood is known as a sensitive period for the development of fundamental movement skills (Gallahue & Ozmun, 1995). The development of fundamental movement skills is crucial for a child for several reasons:
- being capable to perform daily routines like getting out of bed, brushing tooth, walk to school, etc. …,
- becoming able to be engaged in physical play activities (Bredekamp, 1992); through play preschoolers explore and experience their surroundings,
- participating in physical activities at a very early stage in life is positively related to a child's health (Ketelhut et al., 2005; Zimmer, 2002).
Both school and family environment of the child have been recognized as actors when it comes to proximal influences on the child's behavior (Bronfenbrenner, 2000). In this contribution we will focus on the school environment as stimulus for physical activity among preschoolers, preliminary results of school environmental opportunities to be physically active will be presented.
Methods All schools in the province of Antwerp (537) were informed about the study. 100 school directors signed up and agreed to take part in this study. All participating schools completed the survey concerning the opportunities for preschoolers to be physically active during school time.
Results The results provide preliminary information on children's opportunities to be physically active during: PE lessons, other moments (free play moments, morning, noon and afternoon breaks) and classroom time.
Conclusion In several schools there is a positive attitude towards the importance of a physically active lifestyle. Nevertheless there are some spearheads to be taken into account:
Schools should engage parents, teachers and children to take the effort:
– to decorate the walls with attractive paintings serving as target to throw and kick at.
– paint squares and lines (traffic zones) onto the hard surfaced playground floor,
Because of the overall decrease in green zones there is a challenge for school to offer children the experience of playing in natural mazes and on grass fields.
Every school should create a covered play area, providing enough space for the children to play when it rains.
Schools must be stimulated to look and act more 'movement inclusive' in education in general and in early childhood in particular.

A COMPLEMENTARY PROGRAM FOR SIX TO EIGHT-YEAR CHILDREN WITH WEAK KINETIC PERFORMANCE

Hammoudy, A.S.

Faculty of Physical Education, Assiut Univ. Assiut, EGYPT, Egypt

Background and Problem
Physical education has specific goals and different types whereas kinetic education helps children enjoy their spare time and encourages them to be active. It tends to enable children understand their bodies and kinetic communication.
It is believed that the best age for kinetic education is ranging from 6 to 12. In this stage, children are ready to learn the rules and skills of specific games. Due to the importance of this stage, the researcher believes that low-kinetic primary stage children need a supplemen-

tary program for developing their physical fitness and kinetic activities. As known, the need of kinetic decreases as a result of elimination of kinetic.
Objectives
- Eliminating children's fear of athletic kinetic activities through the preparatory physical fitness and kinetic activity stage.
- Developing low-kinetic children's athletic kinetic performance.
Approach
Due to the nature of this research, the experimental approach is used.
Sample
This research involves 225 first, second and third graders from 15 government and private primary schools in Assiut Governorate.
Instruments
- Questionnaire prepared by the researcher.
- Burdo's scale of kinetic recognition abilities.
Pilot Studies
In the period from 20-30 September 2005, the first pilot study was carried out to check the validity and reliability of Burdo's scale of kinetic recognition abilities. This study repeated on 15 October 2005.
In the period from 20 - 22 October 2005, the second pilot study was carried out using some activities of the program to check their suitability.
Success Conditions
Affording training experiences and tools.
Affording training chances related to the program objectives.
Playing with and on the athletic equipment.
Controlling study groups.
Training Principles
Basic elements Activity Time
Warming-up
Actual Playing
Development
Closing Free play to create self- confidence.
Developing the concept of playing.
Focusing on certain style of play.
Positive relaxation 10 ms, 20 ms, 10 ms, 5 ms
Pre-Test: The study groups were pre-tested on 23-27 October 2005.
Program Application: The program was administered in the period from 1/11/2005 to 2/1/2006.
Post-Test: The study groups were post-tested on 3 -9 January 2006.
Main Findings
As a result of the preparatory stage of kinetic education, children got ride of fear of kinetic activities. They could walk forward and backward on a wooden bar 15cm high, 2.40cm long and 10cm width using their left leg, right leg and both.
The program developed children's kinetic recognition and physical fitness. The children could, in stand position, move their arms and legs. They could pass the obstacles of Burdo Scale.

SCREENING OF GROSS MOTOR SKILLS AMONG SWEDISH CHILDREN AND ADOLESCENTS

Tidén, A., Nyberg, M.
Stockholm University College of Physical Education and Sport, Sweden

Physical Education teachers in Sweden have noticed that pupils are getting worse in their ability to manage gross motor skills. The gross motor skills and coordinative skills are the solid ground for sports and other health activities. If not developing their gross motor skill children tends to avoid taking part in games and sports. The benefits of sports and outdoor activities such as social and health benefits can therefore be missed. In the spring 2001, The aim of this study, the motor skills test, was to make a survey of what Swedish pupils can manage in gross motor skills today. Based upon these results we can in the future tell whether the pupils are maintaining today's level of gross motor skills or not. The Swedish curriculum for "sports and health" states that pupils should manage gross motor skills in the 5th year of school. The study started with the construction of the gross motor and coordinative skill tests. The movements selected for the test were based on gross motor skills, coordinative skills and combinations of these skills. The test included 16 movements measured on a scale from 1 to 4. The levels of the scale have a written description to support the ocular observations. Examples of skills tested were; skipping, jumping, crawling, rolling, being upside down, bouncing and throwing balls. The results are analyzed both on an aggregated level here referred to as gross motor skills profile, as well as on a single movement level. The results indicate that 29% of the pupils in the 6th school year are not able to manage the gross motor skill tests without remarks. The pupils with the lowest scores can be found among young female children with low strength and overweight. The test also shows that in the 9th school year boys are stronger than girls. Boys and girls in the lower ages (school year 3 and 6) are more similar in the gross motor skills profile but not on the single movement level. It can also be noted that girls are better in skipping and some of the movements of more gymnastic character whereas boys are better in throwing. Boys and girls have nearly identical results in the test of balance, walking on a balance beam where gender or age does not seem to have any affect. From the main findings of the tests we can observe that the younger pupils have not yet developed the gross motor skills. It is also noticeable that many of the pupils in the 6th school year are achieving poor results in the tests even though the Swedish curriculum for "sports and health" states that the pupils should have achieved these skills already in the 5th school year. Many of the girls in the 9th school year are very poor in the movements that included some strength ability. If children do not have the gross motor skill and some strength it is more likely that they will choose other activities or have other interest then physical activities and sports on their leisure time. This may in the future give them health problems because we know from fact that physical inactivity is one of the main causes to bad health.

CHALLENGES AND OBSTACLES IN MOTOR LEARNING: CONTEXTUAL FACTORS IN GYMNASTICS AND CALISTHENICS

Fügedi, B., Bognár, J., Honfi, L., Salvara, I. M.

Eszterházy Károly College, Hungary

Introduction

Although growth and maturation influence the acqusition of motor skills in physical education, learning plays a more significant role in the process. During the process of motor learning, significant changes occur in knowledge, error detection and correction, cordination, and visual attention.

Gymanstics and calisthenics are included in most physical education programs in Hungary. It is well known that physical education takes place in a specific context. This context refers to all factors that can certainly influence what and how content is learned. These influences could either facilitate or inhibit the implementation of instruction.

PE teacher are challenged to teach gymnastics and calisthenics to children of varying physical maturity, interest, and physical abilities. Also, the different levels of contextual factors can have major influences on the quality of the teaching-learning process.

Hence, the purpose of this study was to find out how future physical education teachers perceive the challenges and issues concerning gymnastics and calisthenincs at the primary school level. More specifically, the center of our attention was to examine instructional resources and teachers' knowledge levels in these two activities.

Methods

Participants of this study were purposefully sampled and were all undergraduate students in the Eszterházy Károly Teacher Training College in the Physical Education program, Eger (N=194). All students filled out questionnaire with closed- and open ended questions. Questions were formed in a five-item Likert scale (5 being exceptional and 1 being poor). The questionnare was preceeded by initital semi-structured interviews with 12 students (3 from each year). The purpose of the initial interviews was to identify common themes and ideas in instructional resources and teachers' knowledge.

Results

From the intitial interviews, two contextual factors seemed important to explore: PE faculty and instructional resources. Schol location, student demographics, and administration, according to future PE teachers' beliefs, do not play a significant role in progressing in gymnastics and calisthenics.

The level of instructional resources in gymnastics was rated very low (M=1.9433), and in calisthenics medium (M=3.1443) level. PE teachers' knowledge base both in gymnastics and calisthenics rated in medium level (M=3.03 and M=3.47). 44.8% of students found 'poor' instructional resources in gymnastics. For each question chi-squared showed a significant difference. Interestingly, there were no significant differences between genders, among year in college, and best sport result.

Summary

Teacher knowledge level is paralel to the instructional resources, which mean they teach according to their possibilities. Both should be improved for better learning experiences. Better facilities, equipment, resources would possibly increase the level of practices and success levels, so teachers' knowledge base would also be perceived higher.

COMPARISON ANALYSIS OF DIFFERENT SPORT GROUPS CONCERNING TO BALANCE

Huszar, A., Leibinger, E., Muranyi, N., Hamar, P.

Semmelweis University, Hungary

Hungarian public education is typically multicolored if the education politics and control are taken into consideration. The applying of different school structures and curriculum refers to this. Besides traditional sports many other movement ingredients such as extreme sports can be found among the syllabus. Therefore these new sports are getting more popular between the students. It can be stated that these kinds of movements can help the students conditional and coordination abilities positively.

Analyzing the coordination abilities it is known that gymnastics helps and develops the children' balance activities. The best period to develop static balance is 7 to 9 age and dynamic balance is 10-12 ages.

In our research primary school students balance activities were measured. The research took place in Hungary in 2006. The following groups were observed:

1.Students who take part only in physical education class

2.Students who take part in not only physical education class but also extracurricular gymnastics activity (also doing gymnastics in physical education class)

3.Students who take part in not only physical education class but also extracurricular skating/roller-skating activity (also doing skating/roller-skating in physical education class)

The question is if there are differences between the groups. We also would have liked to know which group was the best in these abilities. Therefore not only curriculum writers can use our results but also can help physical education teachers' decision while choosing activities.

COMPARING THE CURRENT SITUATION OF PHYSICAL ACTIVITY FOR ELDERLY PERSONS IN EUROPEAN COUNTRIES

Djobova, S., Van Coppenolle, H., Huijsmans, K., Niemiro, A.

Katholieke Universiteit Leuven, Belgium

Ageing is undoubtedly an issue that more than ever stands in interest. In the past 50 years, one of the most important changes within Europe has been the rapid increase in the number of people living into their 70s and beyond. Most of those ageing people will have some physical or mental disability, regardless the fact if they acquired this disability at birth, later in life or through the normal process of ageing.

Recently, the traditional disability model has changed to agree with the suggestion that disability is not only the consequence of a disease or an accident but also of lifestyle choices. Ageing is a process which brings gains as well as losses: gains, because it brings maturity, wisdom and respect; and losses, because it often affects and restricts the physical and psychological level and devalues the social perceptions of people who are growing older. Numerous research projects have successfully demonstrated that the benefits of physical

activities for health are indisputable. As seniors are the fastest growing age group, attention needs to be given to them as a special population with specific needs in the area of exercise and sport.
Qualified professionals in the area of physical activity for the elderly have to be prepared now, so they can meet the new demands of the future. A Thematic Network is needed to bring together data throughout whole Europe, concerning physical activity for seniors, to create a basic profile and to implement the subject of adapted physical activity for the elderly in the European higher education curricula, in order to compensate for the current lack of information in that specific domain.
The aim of this study is to analyse and compare the data gathered by the Thematic Network, THENAPA II.

TEACHING SOCCER IN PHYSICAL EDUCATION – IMMEDIATE EFFECTS OF USING A FUTSAL BALL INSTEAD OF A NORMAL OR AN INDOOR (FELT) FOOTBALL

Heim, C., Frick, U.

Johann Wolfgang Goethe-Universität Frankfurt, Germany

Introduction
Football (soccer) is – in Europe – one of the most popular school sports. Yet, soccer is often regarded as a difficult sport to teach. Many schools do not have their own pitch, and so football in Physical Education (PE) is normally taught indoors in gymnasiums with the result that the ball bounces a lot more on the hard floor than it would on a grass field. This makes it difficult to control the ball, particularly for beginners. Also, as there is less space in a gymnasium than on a pitch, opponents are in close proximity to each other, further increasing the pressure on the time players have to control the ball. However, ball control is essential for any further skills such as passing, dribbling or shooting. Literature (e.g. Schmidt 2004) suggests using semi-pressurised or soft balls to make it easier for beginners to control the ball. However, this reduces the ball's form stability, making it more difficult to dribble and enhancing the risk of twisting an ankle by stepping onto the ball. A possible solution for this problem may lie in the use of a Futsal ball (FUT) instead of a normal (FOT) or an indoor (felt) football (FEL). FUTs are constructed in such a way that they bounce a lot less than either FOT or FEL, making them easier to control while at the same time being form stable. The aim of this study was therefore to compare the immediate effects of using a FUT in PE instead of a FOT or FEL.
Methods
A cross-sectional study was designed with 410 fifth-grade pupils (ages 10-12 years). Participants' technical football skills were assessed in isolated trials and during play using quantitative video analysis (see Heim & Frick 2006b in this volume). Both the trials and the videotaped tournaments were performed with a FUT as well as a FOT and a FEL. Additionally, after the tournaments pupils were asked to complete a questionnaire of 19 football-related items comprising statements relating to four categories (fear of the ball, enjoyment, involvement in the game, quality of play). Pupils were to indicate their agreement with the statements on a likert-type scale.
Results
The results of the trials indicate that isolated technical elements can be performed significantly faster with a FUT than with either a FOT or a FEL. Video analysis of the matches with the different balls showed that the number of ball contacts and the number of "positive" actions significantly increased for each player when playing with the FUT compared to playing with the other balls. Results of the questionnaire data indicate that pupils are significantly less afraid of hurting themselves when playing with the FUT (T=4,208; df=126; p=0,000).
Discussion
Results indicate that the quality of play can be greatly enhanced with beginners when using a FUT instead of a FOT or a FEL in indoor-soccer. It is therefore concluded that football tuition in schools should preferably be performed with a FUT.

PARENT, TEACHER AND PEER AUTONOMY SUPPORT AND LEISURE-TIME PHYSICAL ACTIVITY: A CROSS-GENDER EVALUATION OF THE TRANS-CONTEXTUAL MODEL

Pihu, M., Hein, V., Koka, A.

University of Tartu, Estonia

Introduction
Teacher, peer and parent autonomy support to the leisure-time physical activity (PA) have been tested with the trans-contextual model (Hagger, 2005). The trans-contextual model proposes a motivational sequence in which perceived autonomy support predicts autonomous motives, intentions, and behavior in a leisure-time PA context. Although, the differences between cultural contexts have been investigated (Hagger 2003; 2005), the gender differences are still unclear. Therefore, this study tested equality of models across gender in which the influence of the perceived autonomy support by peer, teacher and parents on physical education and leisure-time motives, attitudes, intention and PA behavior were observed.
Methods
The participants, at age of 14 –17 years (girls = 149; boys = 115) completed measures of the model constructs using three-wave prospective design. To measure perceived autonomy support from teachers, peers and friends, perceived locus of causality in a physical education and leisure-time context, intentions and attitudes, leisure-time PA behavior, different questionnaires were used (Hagger, 2005). Equality regression model was specified so that perceived autonomy support from different sources predicts PA behavior directly and indirectly via autonomous motives, attitudes and intentions in both groups – boys and girls.
Results
The multiple-group regression model with no cross-group equality constraints (the basic model), showed acceptable fit (chi-square/df =42.55/32, GFI= .96, NFI=. 95, RMSEA=.050), indicating that the general structure is tenable. The results of the equal regression analysis indicated that error variances of the dependent variables of the two groups were not different, as the change in chi-square statistics was not significant. The change in chi-square statistics between freely estimated model and the model with the equality constraints on the intercepts was also non-significant. These results indicated that the model have equivalent measurement properties and are invariant across gender. All together, the observed components of the model accounted for 43 % of the variance in physical activity behavior.
Discussion/Conclusion

The results showed that pattern of relationships between the perceived autonomy support by peer, teacher and parents, physical education and leisure-time motives, attitudes, intention and PA behavior were similar across groups of boys and girls. However, the impact of the teacher autonomy support on intentional physical activity behavior among girls was higher in comparison with boys.

THE EFFECT OF SELF-DEFENCE TRAINING ON MORPHOLOGICAL AND MOTOR DIMENSIONS

Zorec B.

Faculty of Criminal Justice and Security, Ljubljana, Slovenia

Self-defence belongs to the group of polystructural acyclic sports where there dominate acyclic movements carried out in a limited and direct fight with the opponent. Self-defence training has an important place in the training processes forming part of the education in the police, military forces and recently among pupils and students also due to the fact that by training or recreational training of self-defence significant influence on the dimensions of the psychosomatic status can be achieved. The study has been carried out on a sample of 48 students attending the University of Ljubljana aged from 19 to 24 years. The experiment (of self-defence training) lasted 7 months and took place two times a week. The morphological status has been defined by 15 morphological measures and the motor status comprises 7 motor variables. First, all basic statistic parameters were calculated for all variables: arithmetic mean, variance, maximal and minimal result. The significance of the differences between the results of initial and final measurements was assessed by the application of the t-test for small dependent samples. The significant differences in the morphological space of the trainees between the initial and final state of the measurements show above all in the dimensions of subcutaneous fat tissue. Some significantly smaller transformations occurred in the dimensions defining the voluminosity. From this it can be concluded that in the morphological space the effects of self-defence training show above all in the reduction of subcutaneous fat tissue: it decreased by 19 %. Similar results were obtained by Agrež, 1992. At an insignificant change of the body weight this means that there occurred, to the same extent, the increase in the muscular mass and significant differences in the circular measures of the forearm and thigh that is in the segments of the lower and upper extremities which are the most active ones during training. The largest progress was achieved in the field of strength. The repetitive strength of the trunk increased by 14 % and the static strength of the arms and shoulder girdle by 12 %. The training of self-defence techniques caused significant positive changes in the segment of flexibility as well. The flexibility of the trainees improved by 8%. Despite expectations there were no significant differences in the test of basic endurance (600-m-run), where the results depend on the capacity of the cardiovascular, respiratory system, rationality of running and motivation. The results of the research represent a strong argument in favour of the fact that by self-defence training it is possible to improve the quality of some dimensions of the psychosomatic status, which in turn can also indirectly have a positive effect on the improvement of the health status.

Agrež, F. (1992). Vpliv usmerjenih motoricnih programov na morfološke in motoricne dimenzije odraslih oseb. Kinesiologia Slovenica, 2(1): 9-12.

EFFECT OF EDUCATION METHODS USED BY PHYSICAL EDUCATION TEACHERS FOR STUDENT AFFECTIVITY IN HUNGARY

Murányi, E., Huszar, A., Leibinger, E., Hamar, P.

Faculty of Physical Education and Sport Sciences, Semmelweis University, Budapest, Hungary

Introduction: Different education methods are used in the interest of the solution of certain didactic problems. Choosing of the method is a foundation-stone of PE –theory or one of the measures of effectiveness of the attainment process. This question is supported by the pedagogy specialist e. g. Endre Ballér, Zoltán Báthory, Edit Biró-Nagy, Sándor Nagy.

A research from other aspect could be also important besides the methodology namely: what is the affectivity of the students towards the education domain of PE and Sport. This question is also supplied by pedagogy specialise e. g. Endre Burka, Edit Biró-Nagy, Pál Hamar or Ariah Lewy at international level. On the basis of all these the aim of the research is to map the attitude of the students of different ages during the PE lessons. Beside it answer was searched how does the methods chosen by the teacher influences the affectivity of the students. This is important for several reasons: 1.: By choosing the right methods effectiveness of the attainment process and positive attitude of the students towards PE can be reached. The other reason is that the teacher shouldn't leave out of consideration that during his/her work some changes in the students' behaviour, attitude towards PE can happen, as a result of the process of teaching-learning cautiously.Methods: The aim of the research justified the use of a double method. On one hand the affectivity of Hungarian primary and secondary school students towards PE was surveyed within cross-sectional research. The answer for the question was searched for with the help of a questionnaire. The so called „target" model was applied instead of the traditional one. The survey was carried out in academic year 2003/2004. The number of the tested persons was (n=) 300. The other method was the observation. The frequency distribution of the methods was surveyed during the observation. An observation diary was kept. The survey was carried out in the first semester of academic year 2002/2003. The research was carried out between 6 to 12 year-old students of Hungarian primary and secondary schools. 30 schools from Budapest and from the countryside took part in it with altogether 300 pupils. During data processing the basic statistical calculations, correlation matrix calculation and calculation of percentage were done.

Results: As a summary, it can be said that the 12 to 18 year-old primary and secondary- school students feel well during the PE lessons. So the affectivity towards the subject seems to be given. But it is a striking surprise that oral communication has an excess rate during the lessons. The students do not feel that they can learn such things which can be useful later as well. It is not a favourable viewpoint either that students do not often meet the feeling of tiredness after these lessons. The students do not feel the importance of learning the teaching material of PE, and that the evaluation of the students' work is pushed to the back with the secondary school teachers.

WHAT DO CHILDREN INVOLVED IN SPORT THINK ABOUT MORAL DILEMMATIC SITUATIONS?

Graça, A., Fraile Aranda, A.

University of Porto, Portugal; University of Valadollid, Spain, Portugal

Introduction

Children involvement in sport is a rich domain for querying and reflecting about moral dilemmas. As Stuart (2003) refers sport offers opportunities for children to identify and resolve moral issues, however the child's perspective has been relatively ignored by researchers. Psychological research conveyed that comparing boys to girls and team sport participants to individual sport participants or non-

participants, boys and team sport participants are less mature in moral reasoning (Beller & Stoll, 1995; Bredemeier & Shields, 1986). Nevertheless, the soundness of that research is not unquestionable (Jones & McNamee, 2000).

This study has a double purpose, firstly it intends to examine the choices children sport participants make on sport specific moral dilemmas, taking in account gender and type of sport, and then to probe how children justify the reasons for their choices.

Method

Participants were 273 Portuguese children (from 11 to 13 years old) of both sexes (120 girls and 153 boys), involved in sport (176 team sport and 97 individual sport). Children were faced with 8 typical sport situations embodying moral dilemmas related to fairness, companionship, discrimination and racism, equality of opportunity and peace/violence in sport. In each situation participants have to choice one of two alternatives. Descriptive statistics were used to analyze children responses.

Complementarily, four participants, two girls (gymnastic and team handball), and two boys (swimming and basketball) participate in a small group discussion for collecting arguments children use to justify their choices. Basic descriptive, interpretative procedures were used to make sense and draw conclusions from qualitative data.

Results and conclusion

Excepting for one dilemmatic situation (faking a penalty), for which opinions divided, a wide majority of sport participants made reasonable choices. Albeit, both gender and type of sport have an impact on children stance towards moral dilemmas associated to sport situations. In comparison to other groups, boys and team sport participants reveal higher percentages of objectionable choices.

Arguments for children choice rely on weighting principled reasoning and team or self interests, along with the particularities of the situation.

LONG TERM MULTIDISCIPLINARY THERAPY DECREASE PREVALENCE OF METABOLIC SYNDROME IN BRAZILIAN OBESE ADOLESCENTS

Caranti, D.A., Cristofalo, D.J., Siqueira, K.O., Prado, W.L., Stella, S.G., Piano, A., Tock, L., Tufik, S., Mello, M.T., Dâmaso, A.R.

Federal University of São Paulo Paulista Medicine School - UNIFESP-EPM-Brazil., Brazil

Adolescence has been emphasized as a critical period for the development and expression of obesity-related co morbidities in both sex, especially metabolic syndrome. The aim of this study was to determine the prevalence of metabolic syndrome and verify effects of a multidisciplinary long-term therapy (1 year) in predictors of metabolic syndrome among Brazilian obese adolescents. Were recruited 51 post-puberty obese adolescents, 24 boys (36,19+2,64 wt/ht2) and 27 girls (34,34+2,89 wt/ht2). Visceral fat was analyzed by ultrasound and metabolic syndrome was determined under WHO criteria. All patients were submitted to a weight loss multidisciplinary program (nutrition, exercise, psychology and clinical). We observed that 31,37% of the obese adolescents presented metabolic syndrome and only 2% after intervention. Indeed, in boys BMI (36.19+2.64 to 30.82+5.92), visceral fat (4.14+1.01 to 2.91+1.01) and HOMA (3.77+2.07 to 0.75+1,51) and in girls glucose (92.09+5.85 to 86.00+5.92) showed statistical reduction. The multidisciplinary long term therapy was effective to promote beneficial changes in some parameters and decrease the prevalence of metabolic syndrome.

NUTRITIONAL INTAKE IN JUDOKAS 3 DAYS BEFORE AND DURING THE COMPETITION DAY

Ramon, K., Verbeke, K., Zinzen, E., Deriemaeker, P., Vanmalderen, K., Clarys, P.

Vlaamse Judo Federatie; Vrije Universiteit Brussel; Hogeschool Antwerpen, Belgium

Introduction

Judo is a contact sport with heavy demands for the athletes. As competition is performed in weight classes a number of athletes are involved in weight reduction practices competing up to 5 to 10 % below normal weight. Most common methods for weight reduction are energy restriction and dehydration the last week or even the last days before competition. It was the aim of our study to estimate nutritional intake and energy expenditure 3 days before the day of the competition and to estimate the nutrient and fluid intake during the day of the competition.

Methods

32 Belgian judoka's (21 female and 11 male) volunteered. They completed a questionnaire concerning normal weight, competition weight and weight loosing strategy. A 3-day nutritional intake and training diary (before competition) was completed. During the day of the competition the athletes were asked to record fluid and food intake and this before and after the weigh in procedure but equally between the different fights.

Results

72% of the volunteers had to reduce weight before the competition. Hence, the judokas were divided into 3 groups: female judokas who needed to lose weight (FLW), male judokas who needed to lose weight (MLW) and female judokas that were on competition weight (FCW). Only 17% of the judokas involved in weight reduction practices did this in a gradual way using a 3 weeks period. The remaining judokas performed their weight reduction in less than 2 weeks before the competition. The used methods were: heavy sweating by training with occlusive clothing (52.1%); strong reduction of the fluid intake (39.9%) and taking a sauna (30.4%). Total weight reduction averaged 2.31 ± 0.91 kg which is 3.51 ± 1.3% of their body weight.

The 3 days diet and training dairy indicated that weight losing judokas had a deficient energy intake compared to their expenditure with intakes of respectively 3919 ± 2550 kJ for the FWL and 5828 ± 1272kJ for the MWL while their expenditure reached respectively 10288 ± 1989 kJ and 11848 ± 2119 kJ. In the FCW group the energy intake met the energy expenditure. Quantitative analysis of the nutrient intake indicated that for judokas under weight reduction carbohydrate intake was too low (2.31 ± 1.27 g/kg body weight for the FLW and 2.59 ± 0.69 g/kg body weight for MLW – recommended intake = 3.5 g/kg body weight). Fluid intake was equally too low with 30.31± 15.69 ml/kg body weight for the FWL and 23.77 ± 11.20 ml/kg body weight for the MWL – recommended intake 40-60 ml/kg body weight). The time between the weigh in procedure and the first fight averaged 2 hours.

Discussion

Judokas performing weight reduction show a significant energy deficit in regard to their average energy expenditure the last 3 days before the competition. Especially the carbohydrate and fluid shortage may compromise the performance capacity during the competition since the judokas under weight reduction have to compete with low glycogen levels and in a status of dehydration.

THE EFFECT OF RED BULL ADMINISTRATION ON 2000M ROWING ERGOMETER PERFORMANCE IN ELITE OARSMEN

Donovan, T., Nichol, C., MacLaren, D.P.

Manchester Metropolitan University, United Kingdom

Introduction. Caffeine has been shown to improve both short term (Jackman et al., 1996), prolonged (Graham et al., 1998) endurance exercise and 2000-m rowing ergometer performance (Bruce et al., 2000) at doses of both 5 mg.kg-1 and 9 mg.kg-1 body mass. One of the current methods for athletes to ingest caffeine is through Red Bull which has a relatively low caffeine concentration (30 mg.100ml-1) but also contains taurine (0.04%) and glucose (4.4 g.100ml). Purpose: To investigate the effect of administration 2 cans of Red Bull (500ml) on 2000-m rowing ergometer performance in elite rowers. Methods: In this randomised, double blind crossover study 14 elite male rowers (peak oxygen uptake [VO2 peak] 5.3 ± 0.32 l.min-1, mean ±SD) performed a familiarisation trial of 2000-m rowing on an air barked ergometer, followed by 2 experimental trials 7 days apart, each 45 min after ingesting 2 cans of Red Bull or placebo. Venus blood samples were taken 5 minutes prior to the warm up and 5 minutes following the 2000-m trial. Heart rates and breath by breath VO2 and VCO2 were measured throughout the trials. The trials were preceded by a standardised warm up of 5 mins at 70% VO2 peak. Results: Administration of 500ml of Red Bull resulted in a significant (p = 0.0013) improvement in performance of 2.9-s ± 2.7. There were no differences in heart rate, VO2 or plasma lactate between the trials. The athletes could not distinguish between the treatments both before and after the trials. Conclusion: Ingestion of 500 ml of Red Bull 45 minutes prior to exercise produces an improvement in 2000-m rowing ergometer time of 2.9 (± 2.7) seconds in elite rowers.

THE EFFECTS OF PROBIOTIC YOGURT ON GASTRO-INTESTINAL PROBLEMS DURING ONE WEEK OF ALTITUDE ADVANTURE ACTIVITY IN YOUNG ADULTS

Dinç, S.C.,C., Basoglu, S., Turnagöl, H., Karaman, M., Yenipmar, G.

Hacettepe University, Turkey

Probiotics have been reported to enhance the digestion and absorption of protein, fat, calcium and phosphorus. They produce their own lactase and may help overcame lactose intolorance. It refers to use of microorganism in a positive way to benifit health. An example is the way some people ingest bacteria in live yoghurt to enhance their intestinal flora and so aid digestion. Thus, the purpose of this study is to prevent the digestive problems frequently encountered by the university students during outdoor adventure activity at altitude approximately 2500 meters on Taurus Mountains for a one week, by intake of probiotic yoghurt. 59 students (n:39 male, and n:20 female) voluntarily have participated as subjects. One week prior to the activity the subjects were devided in to control (n: 29) and experiment (n:30) groups, where feces samples were taken and while control group was given a normal yoghurt, the experiment group was given probiotic yougurt, totaling up to 500 ml in two porsions daily. All subjects had similar diet during the activity according to their needs. All digestive problems were recorded daily according to toilet frequency and feces consistency. At the end of the activity feces samples were collected for the analysis of Lactobacillus Aciddophilus and Clostridium Perfringens values for comparison. As a result there was no statistical difference between the normal and probiotic yoghurt groups ($p>0.05$). However, there was less complaint among the probiotic group in diarrhoea and digestive problems compare to normal yogurt group ($p<0.05$). In conclusion, probiotic yoghurt can be suggested to those who stay at certain altitudes for outdoor activities, to lessen the frequency of diarrhoea complaints due to normal yoghurt intake.

THE EFFECT OF SHORT-TERM HIGH CARBOHYDRATE DIET WITH HIGH AND LOW GLYCAEMIC INDEX ON ENERGY SUBSTRATE UTILISATION DURING RUNNING EXERCISE

Malkova, D., Aberham, T., Taylor, P., MacAlphine, K., Kessaris, D., Hillier, F., Higgins, S.

University of Glasgow, United Kingdom

Pre-exercise ingestion of carbohydrate rich foods of varying glycaemic index (GI) has been reported to cause alterations in glycaemic, insulinaemic and lipolytic responses during subsequent exercise (Febrraio et al, 1996, DeMarco et al, 1999). Specifically, high GI foods, consumed prior exercise, may significantly increase blood glucose and insulin levels and by attenuating fat oxidation compromise exercise performance (Thomas et al, 1991 Kirwan et al, 2001). It remains unclear if consideration of GI of CHO foods is important when prior an athletic event a high-CHO diet is consumed for the duration of several days. Thus, the aim of the present study was to investigate the effect of high carbohydrate diet with high and low GI consumed for the duration of 3 days on metabolic responses and energy substrate utilization during running exercise conducted in the fasting state.

Thirteen healthy, recreationally active men (age, 26 ± 5 years; BMI, 23.4 ± 2 .4kg∙m-2; body fat, 14.9± 3.5%) in counterbalanced order performed three 90 minute treadmill running trials. Trials were separated by at least 14 days and were conducted in the fasted state at a speed corresponding 90% of lactate threshold. In the last minute of every 15-minute exercise stage samples of expired gas and blood were obtained and measurements on heart rate were conducted. One trial was performed after subjects had been consuming their habitual diet (control trial), another after three days on a high CHO low GI diet (LGI trial), and third after three days on high CHO diet

with high GI (HGI trial). Diets were isoenergetic and provided 9.5 ± 1.6, 10.9 ± 0.9 and 10.8 ±1.0 MJ in control, LGI and HGI trials, respectively. In the habitual diet % of energy obtained from CHO was 47 ± 5% while in LGI and HGI diets CHO provided approximately 70% of total energy. The GI values were 54 ± 6, 36 ± 1, and 76 ± 3 for control, LGI and HGI diet, respectively.

There were no significant differences between trials with respect to plasma insulin and non-esterified fatty acids (NEFA) response. Concentration of plasma glucose was lower (two-factor ANOVA, P = 0.05) in the control trial than in LGI and HGI trials but was not different between LGI and HGI trials. Rates of CHO and fat oxidation and the proportion of energy derived from fat (Control, 46.1 ± 3.4 %; LGI, 41.0 ± 4.7 %; HGI, 45.5 ± 3.6 %) and carbohydrate (Control, 53.9 ± 3.4 %; LGI, 59.0 ± 4.6 %; HGI, 54.5 ± 3.6 %) were not significantly different between the three trials.

In conclusion, changing from habitual diet to high CHO diet with either low or high GI for the duration of 3 days facilitates plasma glucose maintenance and at the same time has no detrimental impact on fat oxidation during submaximal exercise conducted in the fasted state.

EFFECT OF CREATINE SUPPLEMENTATION ON THE CONCENTRATION OF BLOOD LACTATE IN PROTOCOL OF WEIGHT EXERCISES UP TO EXHAUSTION IN TRAINED WOMEN

Trindade, M., Dodero, S.R., Cyrino, E.S., Tirapegui, J.

Group of Study and Research in Metabolism, Nutrition and Exercise (GEPEMENE); Faculty of Pharmaceutical Science/University of São Paulo., Brazil

The objective of this study was to evaluate the behavior of blood lactate in a protocol of weight exercises up to exhaustion, after five days of creatine supplementation. Thirty healthy young women ((22.1 ± 4,4 years; 60,8 ± 8,8 kg; 165,1 ± 5,0 cm), after being trained in a in a systemized program of exercises with weights throughout 16 weeks, were submitted to a protocol of effort up to exhaustion. The protocol was executed after these women were supplemented with creatine (n=17) or placebo (n=13) (maltodextrine) during 5 days (4 doses of 5 g = 20g/day), in a double blind delineation. 48 hours after the accomplishment of the tests of one maximum repetition (1-MR), the volunteers performed four series of bench press exercises in horizontal bench, squat and arm curl of biceps, at 80% of 1-MR until exhaustion. The interval of recovery between the series was of two minutes and the interval between the different exercises from was of three to five minutes. A sample of arterial blood was collected in basal situation (pre-effort) and one minute after the accomplishment of the last series of each exercise during the exhaustion protocol, for the dosage of blood lactate, using an electrochemical analyzer (YSL 1500 Sport). For statistical treatment the analysis of variance (ANOVA two-way) for repeated measures was used followed by the post hoc test of Scheffé when $P < 0.05$. Although the concentrations of blood lactate increased during the protocol up to exhaustion, no modification that could be attributable to creatine supplementation was verified in the comparisons among the groups ($P< 0.05$). The highest concentrations of lactate after the protocol up to exhaustion were identified after the squat exercise (7.2 ± 2.2 versus 5.4 ± 2.5 mmol, for the creatine and placebo groups, respectively). The results suggest that the supplementation of creatine doesn't seem to modify metabolic acidosis provoked by efforts of high intensity and short duration, executed up to exhaustion, in women trained in exercises with weights.

MUSCLE DAMAGE IN RATS SUBMITTED TO MODERATE PHYSICAL TRAINING AND DIETARY DEFICIENCY IN MAGNESIUM

Amorim, A., Pires, I., Tirapegui, J.

University of São Paulo Faculty of Pharmaceutical Sciences , Brazil

INTRODUCTION: Physical exercise can lead to tissue damage, especially in the muscle. Several studies have suggested that a dietary deficiency in magnesium causes an increase in the susceptibility to muscle damage resulting from physical exercise. Nonetheless, this has been poorly investigated by experimentation in animals. This study aims to verify if the ingestion of a diet poor in magnesium may increase the muscle damage in rats submitted to moderate physical activity.

MATERIALS AND METHODS: Male Wistar rats (n=18, with initial body mass of 280g) were divided into 4 groups: sedentary control (SED, n=4); exercised control (EX, n=4); sedentary and deficient in Mg (DEF, n=5); and exercised and deficient in Mg (DEFEX, n=5). The control diet was formulated according to the AIN93M recommendations (500 mg of Mg/ Kg diet) whereas the Mg deficient diets had only 200 mg of Mg/Kg diet. The animals were fed during 6 weeks ad libitum and submitted to swimming exercises sessions, 1 hour/day, 5 times weekly. Blood was collected 24 hours after the last exercise session. The activity of enzymes creatine kinase (CK) and lactate dehydrogenase (LDH) in the blood serum was evaluated.

RESULTS: The activity of CK of each group was (in increasing order): SED (348 U/L), EX (449 U/L), DEF (458 U/L) and DEFEX (492 U/L), without significant differences. The activity of LDH in the animals belonging to the DEFEX group was greater than those presented by the other groups and a significant difference ($p<0,05$) was found with respect to the DEF and EX groups.

CONCLUSIONS: The dietary deficiency in magnesium increased the susceptibility of the muscle tissue to lesions in exercised animals. Consequently, the time taken for muscle recovery in animals submitted to Mg deficiency is greater compared to that of animals with a diet adequate in Mg.

RAPID WEIGHT LOSS IN GERMAN TAEKWONDO ATHLETES IN PREPARATION FOR COMPETITIONS - A REPRESENTATIVE SURVEY

Furian, T., Bluemel, M., Euen, K., Striegel, H., Brueckner, H., Niess, A.

Medical Clinic, Department of Sports Medicine, University of Tuebingen AND Institute of Nutritional Sciences, University of Giessen, Germany

Rapid weight loss (RWL) in preparation for competitions is a common method in certain sports to achieve a desired weight which enables the athlete to compete in a lower weight category. To reach the requested competition weight, athletes achieve RWL by dehydration

through such methods as vigorous exercise, fluid restriction, wearing vapor-impermeable suits, and using hot environments such as saunas. Illegal practices include the consumption of diuretics, emetics, or laxatives. Less often, a negative energy balance is created by restricting food intake, increasing endurance exercise, and self-induced vomiting. More often, combinations of these techniques are employed during the days preceding the competition.

These methods adversely affect cardiovascular function, electrical activity, thermal regulation, renal function, electrolyte balance, body composition, and muscular endurance and strength. Sporadic deaths associated with intentional RWL have also been reported. The incidence of these undesired effects is dependent on the period, the amount of weight loss, and the practices used.

Most of the studies and reports to date have been carried out with North American wrestlers. Data from other sports and regions have not been published extensively.

The objective of the study was to gain representative data about RWL in German Taekwondo (TW) athletes.

Athletes from the national and state TW teams, as well as athletes from local TW clubs were surveyed using a standardized questionnaire. 582 questionnaires (response rate 32.1%) were analyzed.

More than half of the athletes stated having used RWL to prepare for a competition at least once, and 52.2% stated they often had to lose weight before competitions. On average, athletes reported losing 2.1+/-2.1 kg, which is equivalent to 3.3 +/- 2.0% of their body weight (BW) 8.4 +/- 7.8 days before a competition. The highest weight loss reported was in the two lowest weight classes, with 4.0 +/- 2.8% and 4.1 +/- 2.4% BW, as well as in members of the national team with 3.6+/- 2.6%.

Aside from restricted food intake (79.4%), the athletes also reported tampering with their fluid balance (sweat suits 51.4%, sauna 25.9%, reduced fluid intake 13.3%). During RWL, it is relatively common for athletes to experiences subjective health problems, for example fits of dizziness (11.4%), headache (10.8%), or cardiac arrhythmia (5.6%). Furthermore, 15.1% of the athletes experience deterioration of their general performance and 17.1% in their sport specific performance, particularly strength (26.9%) and endurance (19.1%). Nevertheless, 42.5% of the athletes are convinced that RWL is necessary to increase their chances of success in a competition.

We can conclude that RWL is a common practice in German TW athletes although to a lesser extend as reported in studies examining North American wrestlers. In contrast to the latter group only a few athletes exceed the critical limit of losing 5% of their body weight within a few days; however health problems still occur relatively often.

LARGE EFFECT OF CARBOHYDRATE ELECTROLYTE DRINKS CONTAINING GLUCOSE AND FRUCTOSE ON ENDURANCE PERFORMANCE

Hulston, C., Stevens, C., Hetherington, R., Jeukendrup, A.E.

The University of Birmingham, United Kingdom

Introduction: Carbohydrate (CHO) feeding has the potential to improve endurance performance typically by 1-3%. Recently we have demonstrated that ingesting drinks containing glucose and fructose during exercise increased exogenous CHO oxidation rates, spared endogenous energy stores and increased fluid delivery compared with glucose-only drinks. The effects of a glucose+fructose drink on performance, however, have not been investigated. Also, few studies have investigated the magnitude of a placebo effect in these conditions. Therefore the aims of this study were (1) to investigate the effect of a carbohydrate-electrolyte solution (CES) (glucose+fructose) on performance and (2) to determine the size of a placebo effect during prolonged cycling exercise.

Methods: In a double blind, cross-over design eight endurance-trained male cyclists (VO2max: 63 ± 3 mL/kg/min) performed three exercise trials separated by at least 7 days. Each trial consisted of 120 min cycling at approximately 60% VO2max followed by a performance test (time trial) designed to last approximately 1 h. During the time trial subjects were required to complete a set amount of work as fast as possible. In random order subjects ingested either plain water (WAT), artificially coloured and flavoured water (Placebo) or a 6% CES containing glucose and fructose in a 2:1 ratio. Subjects ingested a 600 mL bolus at the onset of exercise followed by a further 150 mL every 15 min thereafter and after completion of 25, 50 and 75% of the time trial. Placebo and CE solutions were produced with identical colour and taste. To investigate the possibility of a placebo effect subjects were told that both flavoured drinks would contain CHO.

Results: Mean power output sustained during the time trial was significantly higher with CES (245 ± 18W) compare to WAT (219 ± 12W; $P < 0.05$) and Placebo (219 ± 12W; $P < 0.01$). This resulted in a significant reduction in time to complete the set amount of work and thus exercise performance was improved with CES ingestion (11.7% compared to WAT $P < 0.05$ and 11.3% compared to Placebo; $P < 0.01$). Time to complete the set amount of work was 59.69 ± 1.24 min, 66.67 ± 2.42 min and 66.44 ± 1.49 min for CES, WAT and Placebo, respectively.

Conclusions: The main finding of the present study was that a carbohydrate-electrolyte drink containing glucose and fructose substantially improved time trial performance by approximately 11.5%. Additionally, we conclude that during a prolonged (~3 h) test of cycling performance the placebo effect is negligible.

IMPACT OF A SINGLE EXERCISE SESSION ON PREPRANDIAL AND POSTPRANDIAL RESPONSES OF PLASMA GHRELIN

Malkova, D., McLaughlin, R., Manthou, E., Nimmo, M.

University of Glasgow and University of Strathclyde, United Kingdom

Ghrelin, one of the most potent orexigenic substances produced by the human body (Broglio et al, 2003) seems to be resistant to exercise (Schmidt et al, 2004). However, information in relation to exercise and ghrelin is very limited and there are no studies that report on the impact of exercise on ghrelin concentrations in the postprandial state. Therefore, the aim of the study was to investigate the role of a single exercise session on preprandial and postprandial responses of plasma ghrelin and evaluate how these responses are mediated by insulin and IL-6. Eleven healthy, recreationally active male individuals were recruited (age, 23.8 ± 5.8 years; BMI, 23.3 ± 2.9 kg∙m-2; body fat, 13.7 ± 3.4%; VO2 max, 41.8 ± 7.2 ml•kg-1 •min-1). Subjects took part in two trials, one exercise (E) and one control (C), separated by 3 days. Both trials started after a 12-hour fast. In the E trial subjects exercised on a cycle ergometer at 90% lactate threshold for the duration to expend 2092 KJ and in the C trial subjects rested quietly for the same duration of time. Two hours after the intervention a meal, isocaloric to the subject's habitual lunch was provided. Mean values of the plasma concentration of ghrelin, insulin and IL-6 over preprandial and postprandial periods were calculated using the total area under the concentration versus time curve divided by time. For the preprandial calculations values at base line, immediately after and 2 hours after intervention and for the postprandial calculations values at 2 hours after intervention (pre-meal) and at 30, 120, and 180 minutes after meal consumption were considered. Mean preprandial values of plasma ghrelin (C, 724 ± 65 pg∙ml-1; E, 697 ± 55 pg∙ml-1) and insulin (C, 6.6 ±

2.0 µU∙ml-1; E, 5.1 ± 1.1 µU∙ml-1) were not significantly different between trials while mean preprandial values of IL-6 were significantly higher in the E trial (C, 1.53 ± 0.26 pg∙ml-1; E, 2.76 ± 0.55 pg∙ml-1; P< 0.05, t-test). Mean postprandial values of insulin were not significantly different between trials (C, 34.9 ± 9.0 µU∙ml-1; E, 36.1 ± 8.4 µU∙ml-1) but mean postprandial values of ghrelin were significantly lower (C, 670 ± 47 pg∙ml-1; E, 585 ± 41 pg∙ml-1; P< 0.05, t-test) and values of IL-6 were significantly higher (C, 1.62 ± 0.26 pg∙ml-1; E, 2.31 ±0.33 pg∙ml-1; P< 0.05, t-test) in the E trial. Plasma ghrelin was not only negatively correlated with insulin in both trials but also with IL-6 immediately after exercise (r = -0.8, P<0.05) and 3 hours after meal consumption (r = -0.7, P<0.05) in exercise trial. In conclusion, these findings suggest that preprandial and postprandial ghrelin does not increase in a compensatory manner to changes in energy homeostasis induced by exercise and allows the hypothesis that the response of ghrelin to a negative energy balance induced by a single exercise session is blunted because of exercise induced increase in IL-6 concentration.

POST-EXERCISE REHYDRATION WITH APFELSCHORLE, A SPORTS DRINK AND MINERAL WATER

Shirreffs, S.M., Keil, M., Phillips, S., Love, T.

Loughborough University, United Kingdom

Many athletes will become dehydrated during exercise because of the amount of sweat they lose. Effective replacement of these losses after exercise may be an important part of the recovery process if further exercise is to be undertaken later the same day. This study aimed to determine the effectiveness of four commercially available drinks in restoring fluid and electrolyte balance after exercise-induced dehydration.

After University Ethical Committee approval and written informed consent of the volunteers, eight healthy males undertook, on four occasions, intermittent exercise in the heat until they had lost 1.94±0.17% of their body mass. This was estimated to be a sweat loss of 1.33±0.23 l in which an estimated 88±27mmol of sodium (Na) and 6.4±1.3mmol of potassium (K) was lost as determined from sweat patch collection from the upper back during exercise. Thirty minutes after the end of the exercise subjects started a 1h rehydration period during which they ingested, either a sports drink (Gatorade: 353±4mosmol/kg, 26±0mmol/l Na, 6±1mmol/l K), carbonated water/apple juice mixture (Apfelschorle: 404±14mosmol/kg, 8±1mmol/l Na, 30±1mmol/l K), or two different brands of mineral water (Evian: 16±4mosmol/kg, 0±1mmol/l Na, 0±0mmol/l K and San Benedetto: 15±4mosmol/kg, 1±0mmol/l Na, 0±0mmol/l K) in a volume equal to 150% body mass loss. The effectiveness of the drinks was monitored for 4h after the end of the rehydration period. All volunteers were subject to all treatments, with the order determined by an incomplete latin square randomisation. Trials were separated by seven days. Immediately before and 30min after exercise and at 1h intervals thereafter blood and urine samples were collected to monitor water and electrolyte balance recovery. Statistical differences (P<0.05) were determined by repeated measures ANOVA and appropriate post-hoc tests.

Four hours after the end of the rehydration period, subjects were in net negative fluid balance on trials Apfelschorle (-365±319ml; P=0.030), Evian (-529±319ml; P=0.000) and San Benedetto, (-401±353ml; P=0.016) but on trial Gatorade subjects were essentially euhydrated compared to their pre-exercise state (-201±388ml; P=0.549). Subjects were in negative sodium balance on all trials for the rehydration and recovery period and only on trial Apfelschorle did subjects remain in positive potassium balance after rehydration. However, when net cation balance was estimated from net sodium and potassium balance, the deficit was significantly less on trial Gatorade (-88±15mmol) compared to trials Evian (-156±49mmol; P=0.010) and San Benedetto (-163±36mmol; P=0.004), but similar to trial Apfelschorle (-103±38mmol; P=0.872).

These results suggest that in this scenario, recovery of fluid balance can be achieved when significant quantites of sodium are ingested after exercise but replacing this with potassium does not result in as effective a recovery.

This study was supported by the Gatorade Sport Science Institute.

HYPOHYDRATION IN YOUNG FEMALE GYMNASTS

McNeal, J.R., Sands, W., Colvin, K., Jemni, M., Walker, J.

Eastern Washington University, Cheney, WA , United States

Euhydration is the term used for normal daily body water content, while hypohydration is defined as a decrease from the euhydrated state. It takes a remarkably small reduction in body water to lead to performance decrements. Most studies on children and youth regarding hydration have utilized athletes working in warm and humid environments. Gymnasts represent a population of young athletes who typically work in comfortable environmental temperatures, but who often participate in long training sessions and multiple training sessions per day, which may induce a hypohydrated state independent of environmental characteristics. The purpose of this study was to describe the hydration status of young gymnasts prior to and following a gymnastics training session using measures of urine specific gravity (SG). Twenty-eight gymnasts (age 14.7 ± 1.7 yrs, mass 43.1 ± 9.7 kg, height 151.5 ± 9.8 cm) completed this study. Participants ranged in competitive level from USA Gymnastics Level 7 to pre-elite, and were currently training 21.4 ± 4.6 hours per week. Gymnasts provided a mid-stream urine sample at their gymnastics training facility immediately prior to their training session and within 15 minutes following the conclusion of the same training session. Gymnasts trained 4-5 hours between samples. Urine specific gravity was measured using a refractometer to the nearest 0.001 g/mL. All gymnasts exhibited a pre-training SG of ≥ 1.020 g/mL, with 13 gymnasts (46.4%) achieving a value of 1.025 g/mL or higher, and 4 gymnasts (14.3%) above 1.030 g/mL. Regulations by the National Collegiate Athletic Association and data provided from previous research suggest that a euhydrated state exists when SG is less than 1.020 g/mL, while increasing values represent increasing hypohydration. A one-sample t-test showed no significant change in SG from pre to post training (p = 0.093). However, a Wilcoxon signed ranks test showed that there were significantly more gymnasts who became further hypohyrated following the training session than those that either improved or showed no change in their hydration (p =.04). At the conclusion of the training session, 2 gymnasts had SG values below 1.020 g/mL, while 19 (67.9%) were above 1.025 g/mL, and 7 (25%) were at or above 1.030 g/mL. No significant correlations were found between age, ht, wt, competitive level, or training hours and the change in SG. The results of this study show that competitive female gymnasts are not properly hydrated when they begin training, and they tend to become further hypohydrated throughout the training session. These results point to the importance of promoting fluid intake by young gymnasts before and during training sessions, as well as following training when consecutive sessions will occur within a matter of

hours. Further study needs to be conducted to investigate whether or not decrements in gymnastics performance occur subsequent to hypohydration.

Poster presentation (PP)

PP1-09 Motor Learning 1/1 - "Exhibition Hall"

DESCRIPTION OF MOTOR LEARNING PROCESS OF ELDERLY SUBJECTS IN ECCENTRIC ERGOMETER TRAINING

Purtsi, J., Vihko, V., Havas, E.

LIKES-Research Center and University of Jyväskylä, Finland

Eccentric exercise has recently been proposed as a feasible and effective method for strength training especially for the elderly (LaStayo et al. 2003). However, as a relatively uncommon and seldom used training modality eccentric exercise may be a challenging motor task and difficult to learn for the elderly. The purpose of this study was to evaluate and describe the learning process during the course of eccentric training intervention.

17 females and 16 males (64, sd 6 yrs) volunteered for the study. The subjects completed a 10-week individually administered progressive training program on motor driven eccentric bicycle ergometer (2-3 training sessions per week). The subject´s task in eccentric bicycle ergometer exercise was to resist the movement of pedals by producing a constant and steady force against the pedals. The target force level was indicated to the subjects by a visual feedback system, but the actual force the subjects generated was also continuously recorded from the current intake of ergometer´s motor. The uniformity of force production during a 30 second period was used to describe the motor performance, named here as proficiency index (PI). PI was calculated by dividing the standard deviation of peak force values by the average of peak force values times 100. PI was analyzed from the second, sixth, 12th and 18th training sessions.

Every subject was capable of operating and function with the eccentric ergometer safely by the 12th training session. The initial PI for the subjects in the 2nd training session was 24.9 (sd 9.1) %. PI improved ($p<0.01$) continuously during the course of training, being 19.3 (sd 8.8) % in the 6th, 12.1 (sd 5.2) % in the 12th, and 9.2 (2.4) % in the 18th training session, respectively. Interestingly, a significant difference in PI between the superior leg and the inferior leg was found in every training session ($p<0.001$). Unfortunately, neither the dominant leg nor specific leg being superior in every training session could not been indicated in these experiments.

By using an objective measure of motor performance we were able to characterize the progress of acquiring a new motor task in a group of elderly subjects. The results indicated that the subjects reached a fairly constant level of motor performance during a 10-week training program. The results suggest that most of the motor learning occurred before the 12th training session, and after that some subjects showed sings of the autonomic phase of motor learning such as being able to talk without it influencing the performance. However, the results also suggest that there may be differences in the motor control and coordination between lower extremities of elderly subjects.

EFFECTS OF HIGH-INTENSITY RUNNING ON SENSORIMOTOR ADAPTATION UNDER CONSIDERATION OF THE EEG SPECTRAL POWER

Mierau, A., Schneider, S., Abel, T., Strüder, H.K.

German Sport University, Germany

Introduction: In most sports physical fitness and technical skills are key factors for high performance. In the practical field, athletes often work on both aspects during one training session. Therefore the correct temporal order of training contents is very important for coaches and athletes. So far only little research has been conducted investigating the interaction between exercise and motor learning with inconsistent results. The aim of this study was to investigate the effects of running at high intensity (anaerobic energy consumption) on brain cortical activity and sensorimotor adaptation. Methods: The testgroup (TG) consisted of 10 right handed subjects (age: 26 ± 1.6 years, height: 178.8 ± 6.2 cm, weight: 74.7 ± 9.1 kg). The experiment started with a pre-exercise resting EEG recording of 2 min duration. After completing EEG recording, subjects started running on a treadmill at 2.0 m•s-1. Velocity was increased in 5 min stages by 0.5 m•s-1. Subjects stopped running when subjective exhausiation was reached. Heart rate (HR), blood lactate concentration, and Borg rate of perceived exortion (RPE) were recorded after each stage. Immidiately after running a 2 min post-exercise resting EEG was recorded. Thereafter subjects were asked to perform 30 episodes (6 Blocks x 5 Episodes) of tracking with reversed visual feedback in the horizontal plane. Manual performance of each tracking episode was quantified as root mean square error (RMSE). The experiment finfished with a post-tracking EEG of 2 min and in resting postion. The controlgroup (CG) (age: 23.9 ± 3.2 years, height: 183.4 ± 5.8 cm, weight: 79.4 ± 7.0 kg) learned the same tracking task without exercising. 2 min resting EEG recording were done before and after tracking. Results: After running abortion subjects reached a mean blood lactate concentration of 10.5 ± 2.19 mmol/l, a mean maximal heart rate (HRmax) of 201 ± 5.3 beats • min-1 and a RPE of 20. Analysis of variance (ANOVA) with the factors Group x Block x Episode showed a significant Group x Block interaction (p ≤ 0.01) in the tracking task. This interaction was further analysed with the LSD-Post hoc Test showing significant smaller RMSE for Block 1 and 2 (first 10 episodes) in the TG. EEG alpha and beta2 power were increased after running in the testgroup as well as alpha, beta1 and beta2 after tracking in the controlgroup (ANOVA: p ≤ 0.01). Conclusion: We concluded that there is an overal increase in cortical activation after running at high intensity. This activation could have positive effects, such as higher level of attention, on the initial sensorimotor adaptation process. Further research is needed to investigate whether peripheral changes, such as muscular fatigue, are more likely to be the reason for reduced sensorimotor adaptation after intensive exercise.

STUDY OF ATTENTIONAL FLUCTUATIONS DURING A BALL FLIGHT, IN NEUTRAL OR OFFENSIVE CONDITIONS IN TENNIS PLAY

Journeault, N., Chabaud, P.

Université Claude Bernard - Lyon 1, France

The aim of this study was to highlight the attentional processes engaged by the tennis player during incoming trajectories. Two hypotheses are tested: firstly, attentional level of the player should vary during the ball flight; secondly, the player should be able to pay different

attention (at the same time of the ball flight) between two conditions: in neutral situation (backhand to backhand), and when the opponent is going to play a volley. So, we built an experimental protocol to probe attentional demands for the player involved in the game, and respecting real conditions of the game: ball speed, uncertainty and variability.

This study is based on the dual-task methodology. The explanatory model is Kahneman's (1973). Twelve male tennis players voluntary participated in this experiment. Subjects (aged 17 to 34 years) are intermediate level (30 to 15/1, french ranking). They were equipped with a High-Frequency (HF) helmet and a HF microphone. First, they were asked to perform a Choice Reaction Time task, with sound stimuli (lateralised left/right) and vocal answer ("Left" or "Right"). This is the Reaction Time (RT) reference condition. Then, on the court, Subjects (S) were asked to perform a dual-task. They have simultaneously to answer to the same stimuli (named secondary task) and to play against a Partner (P) player (named primary task). Each point is divided into two phases. In a first time, S and P are playing together (the exchange phase, or neutral condition), cross the line, on the backhand side of the subject. Then, at any time, P can break the exchange phase (attack, or offensive condition). Among these breaking actions, P must go to play a number of hitch volley. The subject tries to win the point as soon as he detects an offensive action from P.

During these two experimental conditions, some critical instants of the time course of the trajectory from P to S are studied. The neutral condition presents 4 temporal zones studied : zone 1- close to P hitting the ball; zone 2 - when the ball cross the net; zone 3 - just before the ball bounds; zone 4- between the bound and S hitting. The offensive condition explores only the two last zones.

Median RT for the reference condition is 432 ms. In neutral condition, zones 1 and 3 present the most important RTs (770 and 759 ms respectively) versus zones 2 and 4, lower RT (712 and 713 ms respectively). Zone 1 differs significantly from zones 2 and 4, zone 3 differs only from zone 4 ($p<0.05$). Different attentional levels engaged by the player in neutral condition are shown during trajectory of the ball. Then, offensive condition presents median RTs significantly higher in zone 4 from zone 3 (853 vs 736 ms, $p<0.05$). Zone 4 median RTs are significantly different between neutral and offensive conditions ($p<0.05$). This shows that attentional fluctuations are also dependent on the condition of play (neutral vs offensive).

"BRAINS IN SPACE I" - EFFECTS OF STRESS ONTO SENSORIMOTOR ADAPTATION

Brümmer, V., Schneider, S., Mierau, A.

German Sport University Cologne, Germany

Background

Changed forces of gravity lead to a variation of sensorimotor coordination. Until now it has not been differentiated between primary influences of weightlessness and secondary influences due to psycho-physiological factors (e.g. stress). Therefore it seems necessary to correlate sensorimotor deficits during weightlessness with stressors that arise from the situation. This would show whether changes in the level of gravity themselves lead to changes in sensorimotor performance or whether these changes are merely secondary stress-related. Moreover it seems helpful to substantiate previous assumptions of „non-specific effects of multiple stressors" (Fowler, Bock, and Comfort, 2000; Manzey, 2000) as well as to clarify what consequences potential changes in central nervous activities and increasing concentration of hormones do have on sensorimotor qualities. The result should reveal basic information on the processing of the human sensorimotor system and therewith allow a better preparation for long-term inhabitations of space and to enhance the scheduling of minute motor activities in space

Method

During the recuring one-G (normal gravity) phase of a first parabolic flight campaign seven subjects were asked to perform a sensorimotor learning task. Task performance was quantified as RMS-Error over 23 episodes, each lasting 18 seconds. To visualise changes in cortical activity a EEG at rest was taken at the beginning, at the end and at two times during the flight. EEG was subdivided by FFT into alpha and beta frequency ranges. Blood was taken from the subjects before the first parabola, after the 5th, the 15th and the 25th parabola. Cortisol and prolactin were determined out of this blood samples. A second group of subjects performed the same procedure including tracking task, rest EEG and blood collection under 'stresslless' conditions in our laboratory.

Results

Comparing the learning performance we found a distinct decrease in performance during the one-G phase compared to the control group. This decrease came along with an increase of beta1 and beta2 frequency ranges which traditionally is regarded as an increase of arousal and stress. No changes in cortical activity were found for the control group. Moreover cortisol and prolactin values increased significantly for the flight group whereas no changes were detected for the control group.

Discussion

Results seems to approve the assumption that a decrease of sensorimotor performance during phases of weightlessness is not only dependent on gravity levels. Psycho-physiolocigal effects have to be considered as a relevant factor for sensorimotor processes as a decrease in sensorimotor performance can be found even when tasks are performed under one-G-conditions in parabolic flights.

A following parabolic flight campaign in May in which subjects will perform the same task under zero-G conditions should reveal to what extend task performance is dependent on gravity level.

CAN PROCEDURAL AND DECLARATIVE MEMORY BE INFLUENCED BY BLOCKED PRACTICE ORGANIZATION IN ADOLESCENTS?

Berchicci, M., Robazza, C., Bertollo, M.

Faculty of Human Movement Science, Italy

The interference that results from practicing various tasks was called contextual interference (Battig J.W., 1979). Moreover Anderson J.R. (1982) proposed that, during motor skill acquisition, declarative process come before to procedural memory process. However procedural knowledge can be acquired in absence of declarative knowledge (Maxwell J.P., Masters R.S.W. & Eves F.F., 2003).

Our primary purpose, in the present study, was to determine the influence of the practice organization (blocked, random and control) on motor learning. The second aim was to establish the different level of learning acquisition between blocked or random organization on motor memory and memory for movement, which are related to procedural and declarative knowledge.

Sixty-nine students (age M=16.06, SD=1.17) were required to perform a complex skill, constituted by a sequence of steps, electronically originated through the "all music dance" instrument. The participants had to follow a luminous arrows sequence prospected on the screen. No participants had prior experience with the task. The software assigned a score in function of spatial and temporal precision. Scoring was available on video during practice.

The protocol phases were:

1. Testing phase: in the first day four assessment were implemented (1 baseline and 3 tests) comprising different footstep sequences.

2. Practice phase: practice involved 25 participants in a blocked organization and 22 participants in a random organization. The control group (22 participants) took part in regular physical education lessons on coordinative tasks. Each group performed tasks in six lessons (30 min per lesson), twice a week.

3. Retention and recognition phase: in this step all participants reproduced the 3 footstep sequences on a mat controller. Afterwards 3 recognition test (McPherson & Thomas, 1989) were administered to evaluate memory for movement that refers to their knowledge on relevant facts for each footstep sequences.

RM-ANOVA 3 (practice condition: blocked, random and control) X 2 (mean test and mean re-test) showed significant effects of practice organization on performance, F2,69=7.409, p=.001, eta2=.183. Sheffè post hoc test (p=.001) indicated that the blocked group obtained higher score than the control group.

MANOVA 3 (practice organization) X 4 (test: baseline, mean test, mean retest and mean recognition) showed significant difference between performance in the test main factor, Wilks' λ=.733, F2,69=2.651, p=.001, eta2=.144. Univariate ANOVA showed significant difference only for practice organization group at retest, F2,69=9.524, p=.000, eta2=.224. Scheffè post hoc yielded significant differences at retest. Both blocked and random groups reported higher learning score compare to the control group.

In conclusion finding support the argument that motor memory and memory for movement contribute differently to performance (Maxwell J.P., Masters R.S.W. & Eves F.F., 2003).

ELECTROMYOGRAPHICAL CHANGES OF REPETITIVE BALLISTIC CONTRACTION TASK IN SHORT TERM

Yamanaka, K., Sasada, S., Yoneda, T.

Juntendo University, Japan

The neural mechanism for the rapid voluntary movements such as kicking or jumping has been postulated to be derived from the stereotyped neural program of the cerebral cortex. This means that the results of ballistic force exertion must depend on the precision of the program made by the cerebral cortex. It has also been reported that ballistic force exertion is not only a stereotyped simple phenomenon but is a changeable. If the training effect is observed in ballistic contraction training, how long a term and/or how much strength should be required? This is an especially important factor for muscle activity in sports which need powerful work. Classen et al. (1998) reported that rapid plasticity of "cortical movement representation" occurred in continuous training during only 30 min. We tested whether the repetitive practice of ballistic force exertion in short term induced training effects or not, by means of EMG.

Twenty-three subjects (7 women and 16 men) conducted 3 sessions (1st, 2nd and 3rd session in a day) of a "Force matching task" (3 targets, 10, 30 and 50%MVC) under ballistic isometric voluntary contraction by knee extension with the electrodes affixed continually (60 trials = 1 session). Subjects were instructed to perform the task as fast as possible and with accuracy. From surface EMGs (from m. rectus femoris, m. medial vastus and m. lateral vastus), we analyzed EMG dwell time (EDT) and integrated EMG only for the period when it contributed to the force generation.

First, we confirmed that time to peak force of force performance was improved by training. Secondly, we observed that EDT of 3rd session was shortened significantly in all agonist muscles across subjects compared with those of 1st session ($p<0.001$). Furthermore, amount of discharge was decreased significantly at only m. rectus femoris between 1st and 3rd ($p<0.001$). However that of m. lateral vastus was increased significantly ($p<0.001$). That is, muscle discharge tendencies which showed increase or decrease were not unitary among muscles.

From these results, it could be said that the on-off neural program of ballistic force exertion could change in the short terms through repetitive training. In terms of amount of discharge, the inconstant results described above showed inconstant contribution among agonist muscles after repetitive training. It seems likely that the neural strategy using single joint muscle and double joint muscle should be flexible.

Classen J., Liepert J., Wise S., Hallett M. and Cohen L. (1998) Rapid plasticity of human cortical movement representation induced by practice. J Neurophysiol 79, 1117-1123.

HEART RATE VARIABILITY AND BREATHING RTHYTHM DURING LIANGONG OF CHINESE HEALTHY GYMNASTICS

Nagata, A., Yokoyama, Y., Tajima, T.

Toyama International Research Center for Traditional Medicine, Japan

Purpose: This study has been planned to get what effects would appear on the neurology field of the autonomic nervous activity (ANA) during Liangong gymnastics (LG). Also, we designed this experiment having the object of demonstrating some relationship between the breathing exercises and ANA. And as the traditional Chinese exercise, LG should be proposed as "Breathing relax" gymnastics, psychophysiologically. Methods: Five patterns of LG were selected such as MAHO, SUIKEN, SHOUKI, KAIKYU, and HAKU-IKI as the typical motion, and these LG patterns were practiced three routines of each motion for five minutes. As other exercise, the slow walking (WK, 75m/min) was practiced on the treadmill for five minutes to compare with LG on the viewpoint of the neurology. Six healthy volunteers of three LG career and three beginners were measured the expired gas, the heart rate variability (HRV), and the breathing rhythm (BR) during those exercises. HRV and BR were processed by the time series analysis to get Power Spectra (PS) for 30sec with the sampling rate of 500Hz. The frequency program of MemCalc was applied for those data of HRV and BR at elapsed time during those exercises. Then, PS of HRV was divided to twice bands of High Frequency (HF, 0.15-0.4Hz) and Low Frequency (LF, 0.05-0.15Hz). PS of BR were classified in four bands related to densities of PS and following bands were divided to Low Frequency (LF, 0.03-0.15Hz), Middle Frequency (MF, 0.15-0.4Hz), High Frequency (HF, 0.4-1.0Hz), and Very High Frequency (VHF, 1.0-10.0Hz). Those densities of PS bands have been estimated with the activity balance of ANA of the parasympathetic nervous system (PSN) & the sympathetic one (SN), individually. Results: The heart rate of LG showed average 90±5 bpm, and WK one was mean 105±7 bpm. Cardio-circulatory variables of the oxygen uptake and the carbon dioxide output were observed on little changes during those exercises, and LGs metabolic intensity was kept the average 2.5 ± 0.7 METs. While, METs of WK was the mean 3.2 ± 0.8. HF and VHF bands of HRV and BR in the case of the career during his LG increased more remarkable than ones in the case of the beginner during his WK, significantly. In reverse, LF and MF bands of HRV and BR during LG decreased more substantially than ones during WK. Discussion & Conclusion: PSN activity during LG of the career might increase more significant than that during his WK. While, SN one should be attenuated during this LG. Then, WK is thought to be the typical aerobic exercise with SN, and LG may be such a relax type with PSN as a breathing movement. Furthermore, such Chinese classical gymnastics as LG or Wuginxi should be dignified as the typical psychological exercise promoting action of PSN, utilizing to the mental healthy treat-

ment and the spiritual healing in our living. Reference: Mikko p. Tulppo, et al, Effects of aerobic training on heart rate dynamics in sedentary subjects. J Appl Physiol 95: 364-372, 2003.

EFFECT OF CADENCE ON LEG MUSCLE RECRUITMENT DURING CYCLING IN NOVICE AND HIGHLY TRAINED CYCLISTS

Chapman, A.R., Vicenzino, B., Blanch, P., Hodges, P.W.

The University of Queensland, Australia

The relationship between muscle recruitment, cadence and cycling training history has not been fully investigated. This study investigated the relationship between leg muscle recruitment and cadence in novice and highly trained cyclists. Participants were nine highly trained and ten age-matched novice (i.e. recreational level) cyclists, who had been cycling for 10.2 ± 1.4 and 1.4 ± 0.4 years, respectively. Each of the highly trained cyclists had Australian national or international level competition experience or had qualified for World Championship representation in the year of testing. Four experimental conditions of cycling at individual preferred cadence (IPC), 55-60, 75-80 and 90-95 rpm were investigated. Cycling intensity was controlled using ratings of perceived exertion (RPE). Participants were provided with feedback to modify exercise intensity until an RPE of 15 was obtained. Electromyographic (EMG) activity of tibialis anterior, tibialis posterior, peroneus longus, gastrocnemius lateralis and soleus muscles was recorded using intramuscular electrodes. The effect of cadence on muscle recruitment was analysed by comparing times of EMG onset, offset and peak amplitude, mean and peak amplitudes, individual variance (variability of muscle recruitment between pedal strokes), and muscle coactivation between cadences, using analysis of variance (ANOVA), and modulation of muscle activity (i.e. relative amplitude and duration of primary (main burst) and secondary (between main bursts) muscle activity) between cadences using general linear models. The relationship between EMG variables and IPC was investigated using regression estimates and ANOVA. IPC was not different between novice (77.1 ± 4.4 rpm) and highly trained cyclists (79.7 ± 3.4). Peak EMG amplitude increased linearly with cadence in both groups. However, EMG amplitude in periods between primary EMG bursts (secondary muscle activity), as well as the duration of primary EMG bursts (and therefore muscle coactivation), increased with increasing cadence in novice cyclists but were not influenced by cadence in highly trained cyclists. Cadence did not influence times of peak EMG activity or individual variance in either group. EMG variables were not different at IPC to predicted values in either novice or highly trained cyclists. Therefore, IPC does not appear related to leg muscle recruitment. However, increases in the duration of primary muscle activity, relative amplitude of secondary muscle activity and muscle coactivation with increases in cadence are likely to reflect less skilled control of the movement and increased energy cost at higher cadences in novice cyclists.

MEASUREMENT OF CAPACITIES OF DECISION IN THE BASKETBALL

Refoyo, I., Sampedro, J., Calderon, J., Lorenzo, A., Calleja, J.

Faculty of Sciences of the Physical Activity and Sports. U.P.M., Spain

The object of this study is the one to value the improvement of the capacities of decision in an equipment sport as it is the basketball. The selected methodologic design is based on a qualitative method descriptive compound, adapting it to the characteristics that come together in this investigation. We made a longitudinal temporary design, in which to the group it is compared to him with same himself. In our case, 11 players of between 17 and 18 years old of high level. In order to measure this reliability between the registries 300 (approximately a 10% of the total) registries of each observer and each observation were chosen (second and third). Was a coefficient of correlation of 0,90. The triangulation method determining to 3 observers was used. Between the 300 registries a value of 0,92 was determined the coefficient of correlation between these three observers obtaining. In the conceptual measurement of the knowledge of the correction of the tactical decision a questionnaire of 12 questions was used type test the questionnaire was validated by 22 experts. For the analysis of the tactical decision in game actions of numerical equality were used and in those of offensive numerical superiority. The final election of these exercises was validated with the contributions of 17 experts: 1 against 1; 2 against 2; 2 against 1 and 3 against 2. The valuation of the tactical decision was always made on the player in possession of the ball. For the valuation of the decisionales aspects the technique of observation of the exercises previous, being elaborated a registry table contemplating the following sections and valued was used like INCORRECT vs CORECTO. These tests were repeated with a difference of 3 months. In the statistical valuation of the percentage differences a chi-square test was used (2, SPSS 9,0).

Results: the subjects that have better conceptual knowledge, are those that less incorrect decisions make. (11,2%), on the contrary the subjects whose value is located below the value of the medium one in the score of the questionnaire, present/display a greater percentage of mistakes (16,9%). The results reflect an improvement in the tactical decision obtained in the second test with respect to those of first. The percentage correct decision of the 1 against 1 in the first test is of a 78.5% being of a 87.2% in the second test. In the situation of 2 against 2, in the first test a percentage of correct decision of a 77.2% being in the second test of a 92,9% takes shelter. In the situation of game of 2 against 1, in the first test we found that the percentage of correct decisions is of 87.4%, being of a 93.1% in the second. Finally, in the situation of game of 3 against 2 we appreciated a percentage of correct decisions of the first test of a 90.1%, and a 92.7% the percentage of the second test.

VISUAL SEARCH PATTERNS AFTER VISUAL TRAINING PROGRAMMES IN NOVICE TENIS PLAYERS

Moreno, F., Luis, V., Menayo, R., Reina, R.

Universitiy of Extremadura , Spain

Introducing visual training programmes to a tennis player's regime has proved to be very effective in reducing the time between visual perception and reaction response (Abernethy & Wollstein, 1989). Researchers have suggested that knowledge of the most pertinent or informative areas of the display is crucial to successful performance (Williams et al. 1999).

The aim of this study is to examine the role of visual search strategies in sport learning and how can it be modified. We have analysed the influence of two visual training programmes and practice on visual search strategies of novice tennis players in a task of approaching the net. Many programmes have used video as a means of improving reaction response time but few studies have been performed in real-life, on court situations. In this work, analysis has been made both in a video-based condition and on court. A tennis approach shot situation is simulated by a video-projection, whereby the player has to react quickly and precisely in an attempt to win the point with a volley. The programmes applied, based on anticipation techniques, seek to improve performance responses to the specific task.

Forty novice tennis players participated in the experiment. After an initial evaluation of their performance, the participants were divided into the following four experimental groups of equal size and similar performance level. Using a 5x3m retro-projection screen in the laboratory, the players had to simulate an approach to the net in an attempt to win the point with a volley. They observed film of a skilled

tennis player hitting a passing shot and then had to react as quickly as possible in the correct direction to the on-coming passing shot. Two of the groups carried out two training methods, precueing and occlusion. One group only practice in laboratory situation and one group was used as control.

The dependent variables were the fixation location, fixation time and, specially, visual search pattern. The variables have been analized regarding to visual training programmes, in relation with the type and direction of pashing shot, and in video-based or on-court conditions. The results show differences in visual fixations in duration and location after the training. The visual search pattern shows singular modification regarding both the most pertinent areas located by the players and the sequence of fixations. This poster presentation will focus on to represent qualitative changes in visual patterns after the training.

SHORT TERM TRAINING EFFECTS OF VOLUNTARY RAPID CONTRACTION

Sasada, S., Yamanaka, K., Yoneda, T.

Juntendo University , Japan

Estimation ability of ballistic force exertion is important for understanding rapid work capacity. It has been reported that some training effects were shown in long term training of repetitive ballistic contractions (Yoneda & Kimura 1984). Furthermore, it has been reported that voluntary movements were exposed to plasticity of CNS even in thirty minutes (Classen et al. 1998). An interesting new problem arises as to whether rapid force estimation can be improved in the short term or not. The purpose of this study was to clarify the training effects of repetitive voluntary rapid contraction in the short term.

Twenty three subjects (7 women and 16 men) performed a "ballistic force matching task" (3 targets force, 10%, 30% and 50%MVC, repectively) by knee extension under isometric condition in a day. Subjects were asked to hit the target line as fast as possible, and accurately, in the task. One session of each target force consisted of sixty trials (15trial ×4set), and then subjects performed three sessions (1st -2nd -3rd). The interval between each session was 4 hours. Forces performed by subjects were analyzed according to the performance of accuracy (absolute error: AE and constant error: CE) and time (time to peak force: TPF and force ratio: df/dt). We compared the recorded data in intra- and inter-session.

TPFs of all target forces in the 2nd session were significantly shortened in comparison to these of 1st session ($p<0.05$) in all subjects. TPFs of 30%MVC and 50%MVC target forces in 3rd session were also significantly shortened in comparison to that of 1st session ($p<0.05$) in all subjects. AE of 30%MVC and 50%MVC target forces did not significantly change in all subjects. In 10%MVC target force, the performances were not uniform in all subjects. However, training effects were not uniform in the short term for each subject.

In this study, TPF improved in spite of the fact that AE remained in ballistic force matching task. Taking account of "Speed-Accuracy Trade-Off' (Fitts, PM, 1954), these results suggested that performance was improved. Our results supported these of previous studies (40 days training: Yoneda and Kimura.1984, a weeks training: Moritani & Mimasa, 1990). Furthermore, this study clarified the training effect of voluntary ballistic force exertion in a day. The improvement of the performance implies at short term training causes some changes of CNS.

PROGRESSIVE RESISTANCE TRAINING FOR RESTITUTION OF MUSCLE MASS AND STRENGTH IN HUMAN CANCER CACHEXIA

Renk, H., Krakowski-Roosen, H., Weber, M.A., Kinscherf, R., Künkele, A., Schmitt, T.L., Kauczor, H.U., Hildebrandt, W.

German Cancer Research Center, Germany

Cancer cachexia is associated with progressive muscle wasting leading to reduced exercise capacity of relevant locomotor muscles. At present there is no effective clinical intervention to preserve muscle mass and function. It is unclear whether workloads that are anabolic stimuli at health may aggravate muscle wasting in cancer cachexia, because circulating cytokines that to contribute to cancer cachexia (IL6 and TNFα) are expressed and released by skeletal muscle itself upon exercise. This study for the first time evaluated the effect of strength training on muscle mass, function, and morphology in cancer-cachectic patients compared to healthy controls.

The anabolic effect of progressive resistance training (isokinetic system ISOMED 2000) was studied in 10 cachectic patients with mainly gastrointestinal cancer as compared to 26 healthy controls of similar age. The training program was performed in 16 sessions (8-10 weeks) of isokinetic knee extension-flexion-cycles at 75% peak torque (PT) and isometric contractions at 100% PT. Measurements before as well as after training included body weight, body cell mass (BCM) by bioimpedance, knee extensor maximal cross-sectional area (CSA) by magnetic resonance tomography, and aerobic capacity (VO2max). Knee extensor isokinetic and isometric PT were assessed at each training session. Moreover, biopsies from the vastus lateralis muscle were obtained for morphological analysis from all patients and 10 age- and gender-matched controls at baseline and after training (5 patients).

The training increased muscle mass and strength in cachectic patients which revealed incremental slopes of knee extensor isometric and isokinetic PT (20.1+-6.1% and 13.7+-4.4% per 8 w, respectively; mean+-SEM) that were virtually identical to that of controls (22.2+-5.8% and 10.2+-4.1%). Corresponding increases in knee extensor CSA were observed in both groups together with slight increases in BCM and body weight. Muscle biopsies at baseline showed a significantly reduced mean fiber size and an increased count of type IIa fibres at the cost of type I and IIx fibers in cachectic patients compared to controls. Upon training intervention type IIx fiber size and fractional area increased in controls ($p<0.05$) and patients ($p<0.10$). Isokinetic PT per muscle CSA correlated with type IIx fiber size and fractional area

and increased as well. Training significantly enhanced VO2max in patients but decreased it in controls, thereby corresponding to the morphological response of type I fibers.
Controlled progressive resistance training is a save, tolerable and effective countermeasure against muscle wasting and weakness in cancer cachexia. It increases muscle strength, CSA, and BCM within a rather short time and may reverse the morphological changes with cachexia. Thus it has the potential to become an important component of rehabilitation programs.

RESISTANCE TRAINING IMPROVES NATURAL KILLER CELL ACTIVITY IN CACHECTIC CANCER PATIENTS

Künkele, A., Renk, H., Schmitt, T.L., Hildebrandt, W., Krakowski-Roosen, H.

German Cancer Research Center, Germany

Training has already been described as a modulator of human immune defence leading to increased activity and count of NK-cells, which are reduced upon over-training. In healthy humans moderate e.g. endurance training succeeded in stimulation of NK cell activity but data in cancer patients are scarce. The aim of this study was to evaluate the influence of a strength training program on the immune system of healthy humans and cachectic cancer patients.
Method: Blood samples from 16 cancer patients that suffered from cachexia and from 30 healthy controls were taken before the resistance training period: 16 times in 8-10 weeks with isokinetic (60-90°/s) and isometric bouts of knee flexion and extension with a workload of up to 100% MVC. 5-10 days after the last training set blood was taken again in 4 cancer patients and 24 controls. NK cell activity was obtained by a Chrom51-release immunoassay. VO2-max was obtained by a spiroergometry with stepwise load increments of 25 W every 2 minutes. All data are given as mean ± S.E.M.
Results: Before training the NK cell activity of the cancer patients was significant lower than in the healthy controls (25.2 ± 4 and 41.1 ± 4 respectively). Training increased NK cell activity of all cancer patients from 24.6 ± 6.4 to 35.5 ± 9.4, but data were only obtained from 4 patients who were able to sustain the training period. In contrast, the NK cell activity of the healthy controls (n=24) decreased significantly from 43.7 ± 4.7 to 31.4 ± 3.1. At baseline a significant correlation between NK-cell activity and VO2-max per body weight was found. Moreover, training related changes in NK-cell activity correlated with changes in VO2-max within the small group been analyzed.
Conclusion: These preliminary data from 4 cachectic cancer patients suggest, that controlled progressive resistance training seems to be a save, tolerable and effective method to stimulate the immune system of cancer patients by improving the activity of the NK cells. Furthermore this strength training program could improve endurance capacity in the patients, but failed to do so in the healthy controls. At the moment it remains unsolved whether the link between VO2-max and NK-cell activity may be a direct pathway or is simply coincidental or by cocorrelation. The results warrant further investigations.

THRESHOLDS OF PHYSICAL ACTIVITIES FOR NEEDED TO LIVING A SELF SUPPORTED LIFE FOR ELDERLY WOMEN

Hayato, N., Takahiro, Y., Tatsuya, M., Taketaka, H., Katsuo, N., Lixin, W., Takashi, S., Shigeo, F.

Graduate School of Medicine, Osaka City University, Japan

Purpose: To decide the thresholds of physical activities necessary for a self-supporting life using a discriminate analysis between community-dwelling elderly people and daycare service received elderly people in Japan.
Method: Total twenty-six elderly women, twelve elderly living a self-supported life (self-supporting elderly) and fourteen elderly using a daycare service (daycare elderly) were recruited in this study. The parameters of physical performance examined were grip strength, sit and reach, 10m obstacle walking, 6minutes walking distance (6MD), one leg balance with eye opened and functional balance. Isometric knee extension and flexion muscle forces measured by a handheld dynamometer and muscle mass measured by bioelectrical impedance analysis. And activities of daily living (ADL) score was evaluated by using the number of steps daily and ADL index concerning 12 items for daily living. Data analysis was used unpaired student-t-test and discriminate analysis for examined between self-supporting elderly and daycare elderly.
Results: Muscle masses, grip strength, knee extension/flexion muscle force, 6MD, 10m obstacle walking, one leg balance with eye opened and functional balance in elderly living a self supporting life were higher than those in using a daycare service elderly. In this study, we examined that thresholds of physical abilities for living a self-supporting life using the methods of discriminate analysis between self-supporting elderly and daycare elderly. The most clearly discriminated item of physical abilities parameters was 6MD, which the classifies point and classifies accurately were 313.01m, 100%. Furthermore, the second clearly discriminated item was 10m obstacle walking, which the classifies point and classifies accurately were 18.25 sec., 96.0%. These results indicate that gait abilities were important index for needed to living a self-supporting life by elderly people over 75 years old. And another items of classifies point better than 75% classifies accurately were knee extension force (257.10 N), total body muscle mass (14.27 kg), thigh muscle mass (4.58 kg), ADL index (23.21) and daily steps (2342 steps).
Conclusion: The present study indicates that thresholds of physical activities including gait abilities, muscle force and muscle mass were very important index to maintain a self-supporting life for elderly people. Especially, it was shown that gait abilities were necessary to recover a self-supporting life for daycare service received elderly people as well as recover the lower-extremities muscle force and muscle mass.

SPECIAL CHARACTERIZATION OF LINEAR CHANGE OF PLACE

Koltai, E., Szilagyi, T.

Semmelweis University, Hungary

Special characterization of linear change of place
E. Koltai–T. Szilagyi
Semmelweis University, Faculty of Physical Education and Sport Sciences
Dept. Biomechanics
Keywords: injuries of lower extremity, gait, out body aid equipment, animal movement, stability, rehabilitation
Human gait is connected to vertical body position. In case of physiological walking the advancement is resulted from coordinated movement of lower extremities. This type of movement may have two supports because it resulted from two mechanical apparatus. In reality, the sole provides three point support itself.

After an injury the joint/muscle coordination structure is damaged. The affected person has to use medical support equipment. Our previous analyses has been performed in four manner: without medical support equipment, with supporting stick, elbow crutch and walking frame. Results of using medical aids in these types of movement could be described with multi point support. As for conclusion the elbow crutch is the best supporting equipment.

Our previous studies investigated gait of different persons in cases of using different medical aids with fixed and free lower extremities. This study deals with linear movement phases of different living systems: healthy human movement, human movement with medical aid equipment, horse movement and insect movement. Our investigations tried to compare the similarities and differences between these movement types.

The main indication of application of a medical aid is that the most stable support is assured by three points. Using equipments external to the body can modify the dynamical stability and can provide the three point support. After injury the main purpose of the rehabilitation program is the stabilization of the gait mechanism to obtain the maximal safety and best similarity to physiological gait.

Our goal was analysing the effect of different medical aim equipments on the structure of gait and to compose some basic principles for helping the rehabilitation. It is important, because of sometimes the injuried persons are not informed properly on using the medical equipment but their effectiveness under medical processes is very important. The perfect explanation, interpretetion and control of practice increases the possibility of success.

For computerised analysis we used the APAS video system. The sampling frequency was 60 Hz. We used three cameras (2 JVC GR-DVL 9800 NTSC and 1 PANASONIC M10 PAL). Shutter speed was 1/100 sec.

The result of this investigation is that the use of medical aids effects the physiological gait from many points of view. The movement structure with medical aid differs from the structure of free movement. The results demonstrated that generally the three point support assures appropriate stability. In some cases more point support required. As for conclusion, it is possible to define the best medical aid equipment for the rehabilitation process and therapeutist can teach the patient to optimal movement with these equipment.

EXERCISE ACTIVITY DURING HAEMODIALYSIS - THE TOOL FOR BETTER QUALITY OF THE LIFE IN PATIENTS WITH CHRONIC RENAL FAILURE

Mahrová, A., Bunc, V.

Faculty of physical Education and Sports, Czech Republic

Introduction:Patients with chronic renal failure (CRF),treated with dialysis,are often polymorbid.They are characterised by sever functional limitations that leads to reduced physical activity and sedentary lifestyle preferences.Owing to hypokinesis,they lose physical fitness,which in turn,results in loss of self-sufficiency and self-reliance.Their quality of the life (QL) is getting worse together with the disease´s progression.

Aim:To evaluate the effect of regular application of the exercise activity during haemodialysis sessions on functional condition and on QL in patients with CRF.

Study population and methods:We observed the group of 23 patients. According to active focus for participating in the project,we separated the whole group on experimental (EG) and control group (CG).EG included 13 patients (mean age: 59,3±14,6 y.) that were interested in exercise program participation.CG included 10 patients (mean age:62,9±16,1 y.).For evaluation of the functional condition we used the„Senior Fitness Test Manual"(RIKLI – JONES, 2001).For evaluation of the QL we used standardized questionnaire tool SF-36.In consequence was the QL evaluated after an exercise intervention,separately in an EG and CG.Changes of variables in SFT tests within the groups at the start and the end of the study were evaluated using the Wilcoxon signed rank test.The Mann-Whitney U test was used to compare the results between groups.

Results:After 12-weeks exercise program we noted in EG statistically significant improvement above all in tests,which requiring for its implementation muscular strength of lower extremities and physical efficiency.According to exercise program contents,which was mostly specialized on lower extremities strength,we claimed,that expectant positive effect of regular physical activity on functional condition was proved.In CG we noted between measurements mostly inconclusive and statistically non-significant impairment of the performance.

We noted a positive effect on the QL in patients of EG.The QL in CG was getting worse,especially in physical function domains.

Conclusion:Results from our project confirmed the positive influence of regular exercise activity on the QL in HD patients.The improvement in physical functioning in CRF patients after exercise training is found to be accompanied by distinct psychosocial benefits, morbidity and mortality decrease,the quality of the life with dialysis is improving.An acceptable choice of regular exercise activity for patients with CRF together with another treatment methods is the best way of non-pharmacological character, that offers to the patient an opportunity to achieve an optimal functioning and psychosocial level for each one almost equal to premorbid state.

A COMPARISON OF RANGE OF MOTION GAINS BETWEEN PNF PROTOCOLS

Wheeler, N., Fiolkowski, P., Paine, T.J., Sheard, P.W.

University of Luton, United Kingdom

Introduction: Proprioceptive neuromuscular facilitation (PNF) is a frequently used therapeutic intervention which has been demonstrated to increase range of motion (ROM) at the treated joint. While the positive outcomes of PNF in increasing range of motion (ROM) have been substantiated repeatedly, there is still no clear guideline as to the optimal protocol for this treatment. Many patients will receive a variety of PNF protocols, with one variable being the strength of the muscular contraction. While some protocols call for 100% maximal voluntary contraction (MVC) there are a variety of protocols that indicate differing intensities. The purpose of this project was to compare the ROM gains following PNF treatment using 2 different intensities of MVC.

Methods: Twelve healthy male adults with no history of injury to the lower extremity served as participants in this study. Participants' mean age was 23.17 +/- 2.92 years. All participants signed an informed consent prior to the start of data collection. Data collection consisted of 2 sessions in which participants performed a 5 minute warm-up on a stationary bicycle followed by the PNF protocol at 30% MVC or PNF at 100% MVC. The protocol consisted of repeated 10second isometric contractions after the limb had been moved to its end ROM. ROM at the hip with the knee fully extended was measured with a clinical goniometer (MIE Medical Research) following the warm-up massage and then again after each PNF treatment. All test sessions were completed 1 week apart. Treatment sessions were randomized using a Latin Square design and data were analyzed with a repeated measures ANOVA.

Results: The mean ROM gain following PNF at 30% MVC was 15.5 +/- 5.1 degrees. Mean ROM gain following PNF treatment at 100% MVC intensity was 14.4 +/- 5.0 degrees. The results indicate no difference in ROM gains when comparing the contraction intensity (p = 0.24).

Conclusion: There is a plethora of research to identify treatments for improving ROM, or restoring ROM following injury or immobilization. PNF has been studied for years, and the outcomes for both strengthening and flexibility are not in dispute. While 100% MVC is a common technique, this intensity of contraction may not be applicable in all situations, such as in rehabilitation from an acute injury or when it may be advisable to avoid systolic pressure rises. Anecdotal reports from the participants indicate that maximal intensity contractions can be quite uncomfortable, and 3 subjects reported cramping. The results of this study indicate that improvements in ROM are comparable whether the clinician is using a 30% or a 100% MVC. From a clinical standpoint, this may provide further guidelines for the planning of a safe and effective rehabilitation program.

PHYSICAL FUNCTION IMPROVED IN ELDERLY WOMEN ADMITTTED TO A REHABILITATION PROGRAMME

Juhl, C.

Gentofte Hospital / University of Copenhagen, Denmark

BACKGROUND AND PURPOSE:

The number of elderly patients in geriatric hospital departments is increasing, especially patients above the age of 90.The elderly patient's level of physical function at the end of the rehabilitation process is an important outcome to assess, since it often determines whether a patient can return to his or her own home. The aim of this study was to investigate the effect of a multidisciplinary rehabilitation programme on physical function in elderly women admitted to at Geriatric department.

MATERIAL: All women admitted to a geriatric department in 2005 were included: 228 women, mean age 85,8 years (CI 95% 73,8 – 97,9 years).

METHODS: Outcome measures were: Timed "up and go" (TUG), Guralnik's test of balance and a 30-sec. chair-stand test (sit-to-stand). Patients were tested within three days after admission and at discharge.

The multidisciplinary rehabilitation programme was individualised according to patient needs and consisted of medical care and treatment, physical therapy and occupational therapy.

ANALYSIS:

The data were analysed in three age groups 70 – 79, 80 – 89 and above the age of 90.

Pre and post in the three age groups was compared with Student's one sample t-test groups, and the Length of stay (LOS) between groups was compared with a two sample t-test.

RESULTS:

In the 3 age groups baseline for TUG was respectively 28,1 sec., 31,2 sec. and 48,1 sec. The TUG score improved to 17,8 sec., 24,4 sec. and 31,4 sec. at discharge. The improvement was significant in all three age groups (p= 0,002, 0,000 and 0,000). The Guralnik balance test improved in the three age groups from respectively 19,5sec, 17,1sec and 14,1sec to 22,7sec, 20,2sec and 17,2sec (p=0,088, 0,000 and 0,005). 30-sec. chair-stand test (sit-to-stand) improved significantly from 5,6; 5,2 and 4,2 times to 7,0; 6,5 and 5,4 times (p=0,027; 0,000 and 0,000).

Length of stay (LOS) was 17,1 days (18,2 days, 16,8 days and 17,0 days). No differences in LOS was found between the three age groups (p> 0,5 in all LOS comparisons).

DISSCUSSION:

Physical function can be greatly improved in elderly women participating in a multidiciplinary rehabilitation programme. Even in the very old (>90), an improvement in physical function, similar to that of women in their seventies and eighties, can be achieved during the same length of stay in hospital. Pre and post test were obtained in TUG, Guralnik and 30-sec. chair-stand test in approximately 85% of the included patients equal distributed to the age groups.

CONCLUSION: Multidiciplinary rehabilitation programmes help the elderly female patient maintain her level of physical function and independence and old age (>90) does not seem to limit the possibility of improvement of physical function.

HUMERAL AND HUMEROSCAPULAR ROTATIONAL MOTION CHANGES IN 14 TO 16 YEARS OLD VOLLEYBALLPLAYERS

Baeyens, J.-P., Cabri, J., Taeymans, J., Cattrysse, E., Meeusen, R.

Vrije Universiteit Brussel, Brussels Belgium - Hogeschool Antwerpen, Antwerp Belgium, Belgium

Introduction

Arthrokinematic range of motion characteristics were obtained from the dominant and non dominant shoulder in 32 male elite volleyballplayers from the Topsortschool Vilvoorde (Belgium) aged between 14 to 16 years (15.14 yrs SD 0.89) without history of shoulder problems. Their data were compared with an age-matched control group of non throwing (soccer playing) children (15.45 yrs SD 0.81).

Informed content was obtained.

Methods

Minitiarized (0.5 mm wide) electromagnetic tracking sensors (MiniBird -Ascension Technologies) were placed on humerus, scapula and sternum. A fourth sensor was used as a pointer to relate the sensors to anatomical frames following the ISB standards.

The motions investigated were exo and endorotation in 90° abduction, glenohumeral horizontal adduction (i.e. until the scaoula starts to move) and 90° horizontal adduction with endorotation.

Results

In the volleyballgroup, significant larger amplitudes of motion ($p<0.05$) were found in the dominant shoulder for humerosternal exorotation, humerosternal 90° horizontal adduction with endorotation and glenohumeral horizontal adduction for the humerus related to the sternum as well as the scapula.

In the controlgroup a significant ($p<0.05$) larger humeroscapular exorotation and humeroscapular horizontal adduction was observed in the non dominant arm.

Comparison between the volleyball and the controlgroup revealed significant ($p<0.05$) larger values in the dominant shoulder of the volleyballplayers for humerosternal 90° horizontal adduction with endorotation and humerosternal horizontal adduction.

Discussion

Literature accentuates an enlarged glenohumeral exorotation and diminished endorotation in throwing athletes (Meister et al.). In volleyballplayers, Wang et al. (2000 2001) found significant (p<0.01) lower endorotation in the dominant arm but n o significant difference in exorotation. Already at the young age of 14 to 16 years our data demonstrate range of motion limitations in the volleyballshoulder accentuating posterior capsule stiffness, without enlarged exorotation. This may mimick the specific loading of the shoulder complex related to volleyball.

MEASURING FREE LIVING DAILY ENERGY EXPENDITURE IN CHF WITH DOUBLY LABELLED WATER AND QUESTIONNAIRE: A PILOT STUDY

Garet, M. 1, Barthélémy, J.C. 1, Degache, F. 1, Normand, S. 2, Laville, M. 2, Roche, F. 1

1 Laboratory of Clinical and Exercise Physiology, PPEH, 2 CRNHL, France

Aim : The Daily Activity Questionnaire In Heart Failure (DAQIHF) allows quantitative and qualitative assessment of physical activity and daily energy expenditure (DEE) in patients with CHF along with an estimation of peak V'O2. This questionnaire has been validated against indirect measurements of physical fitness (peak V'O2, anthropometry, litterature...) bas has never been validated against a gold standard measurement of free-living energy expenditure. Therefore, this study aims to assess the validity of DAQIHF questionnaire against the doubly-labelled water technique.

Methods: Six patients with CHF (NYHA I to III, age: 58±15 ys, LVEF=38.4±4.3%) taking their habitual medication (diuretics, vasodilators, beta-blockade) performed an incremental symptom-limited V'O2(peak) test. Free-living DEE was estimated with the DAQIHF (DEEquest) and measured over 2 weeks using doubly labelled water (DEEdlw). Resting energy expenditure was measured by indirect calorimetry (REEcalo) after a 12-h overnight fast and body composition was assessed both from total body water (deuterium dilution) and 50-Hz bioelectrical impedance analysis (REEbia).

Results: At group level, there was no difference in DEEdlw and DEEquest (152.8±26.1 vs. 146.2±31.5 kJ.24h-1.kg-1 respectively; R=0.99, P=0.0002) nor in REEcalo, REEbia and REEquest (P=NS). Individual estimates of DEEquest ranged from –8.2% to +7.4% in comparison to DEEdlw. Peak V'O2 estimated from the questionnaire was similar to measured peak V'O2 (16.7±4.1 vs. 16.0±4.2 ml.min-1.kg-1; R=0.91, P=0.001) and both DEEdlw and DEEquest were correlated to measured peak V'O2 (R=0.82 and 0.96 respectively, P<0.05 both).

Conclusion: The questionnaire is valid for free-living DEE calculation both at the group and individual level in patients with CHF and confirms its previous concurrent validation. Peak V'O2 appears related to DEE and can be accurately estimated from the questionnaire in patients with CHF.

RISK FACTORS FOR CONTACT-NONCONTACT ANKLE SPRAINS IN AMATEUR SOCCER PLAYERS

Kofotolis, N., Kellis, E.

Aristotle University of Thessaloniki, Greece

Introduction

A large number of studies have investigated injury risk factors in professional soccer (Hawkins et al 2000, Ostenberg & Ross 2000, Woods et al 2003) whereas few studies have focused on amateurs' players (Junge et al 2002, Emery et al 2005). Although ankle sprains are very common in soccer, the role of various risk factors for this type of injury (Giza et al 2003) in amateur soccer players is rather unclear. The purpose of this study was to examine ankle sprain injuries, associated factors and mechanisms.

Methods

Nineteen amateur soccer (male) teams were observed during a two-year period. Ankle sprains injury incidents, participation time loss, injury mechanisms and ankle region injured were recorded in games and practice sessions using questionnaires.

Results

A total of 336 athletes who sustained 208 ankle injuries were recorded. Of these, 139 (66.8%) were ankle sprain injuries with over 62.5 % of sprains involving anterior talofibular. Ankle injuries led to a total of 975 training sessions lost, with an average time loss per injury equal to 7.0 sessions. There were 42.692 exposures, of which 29.485 (69.1%) were in practice and 13.207 (30.9%) in games. Most injuries occurred through contact than non-contact (p< 0.05). Player contact accounted for 78.4% of contact injuries and 49.6% of all injuries (p<0.05). For those injuries resulting in fewer than seven sessions lost, the rate of contact injuries was 21.0 times that of a non-contact injury. For those injuries resulting in seven or more sessions lost, the rate of non-contact injuries was 25.5 times that of a contact injury. Player to player contact was responsible for 63.3% of injuries whereas 36.7% were non-contact injuries. Further, 58.8% of non-contact ankle sprains occurred during landing, twisting and turning, and running.

Discussion

These results can be used to plan prevention strategies to reduce injuries. Once the risk factors for ankle ligament sprain are determined, future intervention studies can be performed to reduce the incidence and severity of ankle ligament trauma.

EFFECTS OF TWO PHYSICAL THERAPY PROGRAMS ON MUSCULAR AND FUNCTIONAL PERFORMANCE IN WOMEN WITH CHRONIC LOW BACK PAIN

Kofotolis, N., Kellis, E.

Aristotle University of Thessaloniki, Greece

Introduction

Exercise is one of the most frequently used modalities in the rehabilitation of patients with chronic low back pain (Kofotolis & Sambanis, 2005). Proprioceptive Neuromuscular Facilitation (PNF) techniques have been often used to improve the range of motion of the joint, and endurance as well as performance in vertical jump (Kofotolis et al., 2002; 2005). The purpose of this study was to examine the effects of two proprioceptive neuromuscular facilitation (P.N.F.) exercise programs on muscular and functional performance in patients with low back pain.

Methods

One hundred and eight women with chronic low back pain were randomly assigned into three groups: rhythmic stabilization training (RST), combination of isotonics training (COT), and control group (C). The program duration was 4 weeks and the main aim was to improve trunk muscle strength and stability of the trunk. Static and dynamic trunk muscle endurance and lumbar mobility were measured, prior to training, immediately after, and four and eight weeks following the end of the program. The Oswestry and back pain intensity indexes were also determined.

Results

Two-way analysis of variance designs indicated that both training groups demonstrated significant improvements in lumbar mobility, static and dynamic muscle endurance ($p<0.05$) and the Oswestry Index measurements while the highest improvements were observed following RST training.

Discussion

A treatment routine consisting of an isotonic program combined with alternating concentric, eccentric, and static contraction of agonists without relaxation for the trunk muscles seems to be an appropriate method for trunk muscular endurance development in chronic low back pain patients.

BILATERAL STRESS FRACTURE OF THE MALLEOLUS MEDIALIS OF A TEAM HANDBALL PLAYER – AN EXTRAORDINARY CASE REPORT

Weisskopf, L., Rist, H.J., Segesser, B., Martin, U.

Praxisklinik Rennbahn, Switzerland

Stress fractures in sports are very common. They sports specifically happen at typical anatomical locations. The involvement of the malleolus medialis is rare. Using instructive illustrations and pictures the interesting case of a bilateral stress fracture of the malleolus medialis of a 30 year old elite team handball player is described. The clinical history was documented by x-ray and computer tomography in such a way that the development of the fracture can be comprehended well. Furthermore, the surgery, the functional after treatment and possible aetiologies are discussed.

ATHLETE COMPLIANCE TO THERAPIST REQUESTED CONTRACTION INTENSITY

Sheard, P.W., Paine, T.J.

University of Luton, United Kingdom

Introduction Disputes over the efficacy of muscle energy techniques (MET) and proprioceptive neuromuscular facilitation (PNF) post-isomeric relaxation (PIR) techniques are premature in that they pre-suppose that the athletes can in fact produce the therapist requested intensity of contraction. Whilst there are many minor variations in application of PIR techniques, a survey of the literature shows that MET-PIR and PNF-contract/relax (CR) techniques vary primarily in intensity of contraction. This project aims to define the athletes' ability to comply with the requested contraction intensity.

Methodology A convenience sample of thirty-seven university athletes (male n=25, 20.7  0.8 years, 182.7  7.8cm, 83.5  14.2kg; female n=12, 20.5  0.8 years, 168.1  5.7cm, 65.4  9.3kg) was recruited from the student population at the University of Luton. After completing ethical consent and medical screening, maximal voluntary contraction (MVC) was established at one of three muscle groups: hip adductors, hip flexors or pectoral. The highest of two contractions, measured by a strain gauge dynamometer (ErgoMeter, Globus, Codogne, Italy), was taken to be representative of MVC.

Target PIR contractions were set at 20, 50 and 100% MVC, assigned via a Latin Square design, and monitored throughout the contraction with the dynamometer. The following PIR stretch protocol was used: active motion to first bind point; build to target contraction over 5 seconds; hold target contraction for 10 seconds; relax for 15 seconds; active re-set to new bind point; repeat sequence for 3 contractions. A 3x2, 2-way, repeated measures ANOVA with Bonferonni post-hoc analysis provided insight into the athletes ability to comply with the target contraction.

Results Post-hoc analysis indicated that athletes were not able to match the target contraction values at 20 and 100% MVC: $p = 0.001$; mean diff = 8.02%, 95% CI = 3.74 to 12.30%; and, $p < 0.001$; mean diff = -12.64%, 95% CI = -6.48 to -18.80%, respectively. At the 50% MVC athletes demonstrated an ability to match the target contraction ($p = 0.219$; mean diff = -3.15%, 95% CI = -8.26 to 1.96%). However, the above results are based on the mean contraction score of the three contractions within each of the three PIR stretch protocols. When examined for consistency across the three contractions the athletes demonstrated widely variable scores (CV = 19.12 to 25.92%, 95% CL = 14.50 to 55.28% at 20% MVC; CV = 22.90 to 35.90%, 95% CL = 17.61 to 83.94% at 50% MVC; and, CV = 8.53 to 10.30%, 95% CL = 6.23 to 19.12% at 100% MVC).

Discussion Without a method of quantifying and feeding back contraction effort to the athlete, athletes can not be expected to match and maintain a requested contraction effort. Until such a method is regularly used, the efficacy of any requested contraction level will remain unknown, as the athletes' level of contraction has been shown to be both inaccurate and inconsistent.

SCHOOLBAG WEIGHT AND SPINAL MOBILITY MEASURES IN SCHOOLBOYS: ARE THEY RELATED?

Kellis, E., Emmanoulidou, E., Kouvelioti, V., Kofotolis, N.

Aristotle University of Thessaloniki, Greece

Department of Physical Education and Sports Sciences at Serres, Aristotle University of Thessaloniki, Greece

It is often claimed that schoolbag carriage is related to excessive musculoskeletal loading and therefore leads to development of back-pain in children. This may also be linked to altered curvature of the spine across the range of motion. Spinal mobility is affected both by muscular and skeletal properties of the spinal column. Prolonged carriage of high loads (schoolbags) may be associated with alterations in spinal mobility in children. The purpose of this study was to examine the relationship between spinal mobility measures and schoolbag weight in primary and secondary education children.

Methods

Three hundred and eighty five (210 boys, 175 girls) students between the ages of 6 and 14 years (9.7 yrs) volunteered to participate in this study. Body weight and schoolbag weight were measured to an accuracy of 0.5 kg. Measures of spinal mobility were made using the Spinal Mouse system. The device was guided along the midline of the spine (or slightly paravertebrally in particularly thin individuals with prominent spinous processes) starting at the spinous process of C7 and finishing at the top of the anal crease (approximately S3); Two rolling wheels follow the contour of the spine, and distance and angle measures are recorded every 1.3 mm as the mouse is rolled along the spine. This information was then used to calculate the relative positions of the sacrum and vertebral bodies of the underlying bony spinal column using a recursive algorithm. Pearson correlation coefficients were used to examine the relationship between schoolbag weight, thoracic and lumbar mobility.

Results

The results indicated that the correlation coefficients between schoolbag weight and thoracic and lumbar mobility in flexion and extension ranged from 0.03 to 0.453. Most correlation coefficients were not significant.

Discussion/Conclusion

The present results demonstrated that schoolbag weight is not associated with reduced spinal mobility. It is suggested that the any schoolbag effects on musculoskeletal system may be due to other factors and do not necessary cause alterations in mobility of the spine. Further research is required to examine the above suggestion in a wider population.

This study is supported by an EC and Greek Ministry of Education (EPEAEK II) grant under the "Pythagoras II" program.

INFLUENCE OF STAGE OF READINESS TO ADOPT EXERCISE ON DAILY ACTIVITIES AND PHYSICAL PERFORMANCE IN PATIENTS WITH HEART FAILURE

Parish, T. 1, Kosma, M. 2, Moore, C. 3, Welsch, M.A. 2

1 Mississippi College, 2 Louisiana State University, 3 Univ. Medical Center, United States

The benefits of regular physical activity for patients with heart failure, are overwhelming. However, research indicates few heart failure patients engage in regular physical activity. As a result daily energy expenditures and physical performance scores are often low, increasing the patient's risk of complications. The problems may in part be because little attention has gone into assessing the motivation and readiness of patients to make necessary behavioral changes. PURPOSE: To examine the stages of readiness to adopt exercise as it relates to daily activities and physical performance. METHODS: One-hundred eleven heart failure patients (81 men and 30 women; Age: 53±14yrs) participated in this study. All patients were classified as Class II or III according to the New York Heart Association (NYHA), with an average left ventricular ejection fraction (LVEF) of 28.66±14.41%. Each participant's stage of change (SOC) for exercise adoption was assessed, using a previously published algorithm (Reed et al. 1997). Daily activities were determined from a modified and English translation of a published self-reported questionnaire thought to reflect habitual activities in heart failure patients (Garet et al. 2004). Physical performance was measured using a 6-min walk test in a hallway with maximum walking distance (MWD) as the dependent variable. RESULTS: The SOC algorithm revealed 12 patients in Precontemplation (PC), 29 in Contemplation (C), 30 in Preparation (PR), 20 in Action (A), and 20 in Maintenance (M). No differences in age, LVEF, nor NYHA class were noted among the SOC. Average MWD was 349±118m. A MANOVA revealed significant differences between the SOC ($p<0.05$) for daily activities over 3 METS (METs 3-5: PC,C,PR <A<M; METs > 5: PC,C<PR,A<M). An ANOVA indicated significant differences for MWD ($p < 0.01$) (PC,C<PR<A<M). Thirty-six percent of all the patients scored below 300m. More specifically, 34 of 71 patients in Pre-action scored below 300m versus only 3 of 40 from the A/M groups. Significant associations were noted for MWD and daily activities between 3-5 METs ($r = 0.52$, $p = 0.0009$), over 5 METs ($r = 0.56$, $p = 0.0001$), and total minutes of daily activity ($r = 0.32$, $p = 0.005$). CONCLUSION: Patients in pre-action stages of readiness to exercise report significant lower daily activities then those in A/M. Moreover, those in pre-action have significant lower physical performance scores. In fact, approx. 50% of patients in pre-action may be at even greater risk for complications and early mortality secondary to scoring <300m on the 6-min walk test (Cahalin et al. 1996). These data suggest the need to develop and deliver stage-matched exercise motivational programs to advance individuals from the early stages of readiness to exercise toward the A/M SOC.

ASSESSMENT OF LOWER EXTREMITIES FUNCTION IN ELDERLY PEOPLE WITH DYSFUNCTION

Kai, Y., Murata, S.

Technical School of Medical and Welfare Ryokuseikan, Japan

PURPOSE: To quantify the function of the lower limbs, the muscular strength and movement of the center of gravity in the standing position are generally measured using a cybex or a hand-held dynamometer. However, since apparatuses used for the measurement are generally expensive, clinical measurement is performed in limited institutions. In this study, we quantitatively examined the function of the lower limbs in elderly subjects with disorders using a commercially available scale, and evaluated the reproducibility and validity of measurements. RELEVANCE: Simple evaluation of function of the lower limbs in the elderly is important to support their health. SUBJECTS: The subjects were 43 elderly patients, consisting of 5 males and 38 females, with a mean age of 84.8 years. The patients had physical disorders, and those with mental disorders were excluded. Walking was possible in 25 patients and impossible in 18 pa-

tients. METHODS: The maximal force of pressing a scale by a lower limb was defined as the loading strength of the lower limb, and we examined the relationships between the measurements and the daily activity index (BI) or walking rate (5-m fastest walking on the flat ground). The roducibility of the loading strength of the lower limb was examined using the intraclass correlation coefficient (ICC) determined by the test-retest method, and its validity was examined using Pearson's correlation coefficient determined by evaluating the relationships between the measurements and the BI, or walking rate. RESULTS: The ICC was 0.823, indicating good reproducibility of the loading strength of the lower limb. There were significant positive correlations between the loading strength of the lower limb and the BI or walking rate, suggesting the validity of the loading strength. Discriminant analysis demonstrated that the discriminant ratio of the lower limb-supporting strength to the body weight between the walking and non-walking groups was 42.9%, and its accuracy was 86.0%. CONCLUSION: The lower limb-supporting strength measured in this study was useful for simple evaluation of function of the lower limbs in the elderly, suggesting that this parameter can be used for the evaluation of walking ability.

PHYSICAL AND COGNITIVE FACTORS ASSOCIATED WITH FALLS AMONG ELDERLY DISABLED AT HOME

Murata, S., Tsuda, A., Kumagai, S., Kai, Y.

Daiichi Welfare University, Japan

PURPOSE：There are several reports that falls in the elderly markedly reduces the quality of daily life and can be a cause of bed-confinement. It is very important for the clarification of risk actors to prevent the falls. There have been various studies on risk factors for the falls. These factors include the ability to stand on one leg, lower limb muscle power, and ankle mobility. Some studies have reported significant association between falls and cognitive function, especially attention. However, a little attention have paid for psychological problems at the time of the falls and the causes of the falls such as "stumbled" or "caught oneself", and few of them have been based on objective measures. Therefore, we evaluated the association between falls and attentiveness evaluated by using Trail making test - Part A（TMT-A）in the elderly with disabilities at home. RELEVANCE：This study can shows not only effect of physical fitness but also additive effect of cognitive function to the fall.

SUBJECTS：Among elderly people with disabilities living in home who visited in 4 different rehabilitation institutions, 110 persons without a diagnosis of dementia were selected as the subjects. Their ages were in a range from 69 to 94 years (the mean : 83.1±5.2 years old). Number of subjects in the falls and non-falls groups was 28 and 82, respectively. No significant difference was observed between 2 groups in age. METHODS：The presence or absence of the falls during the past 1-year period, Mini - Mental state examination（MMS）, and TMT-A were evaluated. As measurements of physical fitness, we evaluated the grip, foot-gripping forces, ankle dorsiflexion angle and flexibility of the body. In addition, the time to keep one-leg standing and walking speed were determined. The differences between two groups, the fallen group and the non-fallen group consisting of subjects with and without the experience of fall, respectively were analyzed by unpaired t-test and Mann-Whitney's U test ($p<0.05$) using SPSS for Windows. RESULTS： The result of the experiment was that we found differences between the group with and without falls. The TMT-A score was significantly higher in the non-falls group($p<0.001$), suggesting their higher attentiveness. The foot-gripping force($p<0.001$), ankle dorsiflexion angle($p<0.05$), time to keep one-leg standing($p<0.01$) and walking speed($p<0.05$) as parameters of physical strength were significantly higher in the group without falls. No significant difference was observed in age, MMS and grip. Logistic regression analysis indicated that falls group had less ankle dorsiflexion angle and foot-gripping force than Non-falls group, also lower TMT-A scores, these items were identified as factor associated with falls. CONCLUSION：This result suggested that impaired cognitive function in addition to reduction of physical fitness were candidate for the risk factor of the falls in the elderly persons.

ADIPOSE TISSUE TRIACYLGLYCEROL LIPASE ACTIVITY IN LEAN AND OBESE MEN DURING RESISTANCE EXERCISE

Chatzinikolaou, A., Fatouros, I., Petridou, A., Papassotiriou, I., Mastorakos, G., Mitrakou, A., Jamurtas, A.Z., Lazaropoulou, C., Taxildaris, K., Mougios, V.

Democritus University of Thrace, Greece

Introduction

Excessive body fat is associated with increased rates of systemic lipolysis and release of free fatty acids into the circulation contributing to insulin resistance, diabetes, and dyslipedemia (1). Triacylglycerol lipase, also known as hormone-sensitive lipase is an important enzyme in the control of adipose tissue lipolysis (2). Although resistance exercise (RE) can be used to reduce fatness, its effects on adipose tissue lipolysis have not been investigated so far. The purpose of the present investigation was to study triacylglycerol lipase activity (TGLA) in gluteal adipose tissue during an acute bout of resistance exercise in lean and obese men.

Methods

Seventeen healthy young men were assigned one of two groups (matched for age and cardiovascular conditioning): a) Lean (L, N=8, BMI<23 kg/m2, body fat <16%) and, b) Obese (O, n=9, BMI>30 kg/m2, body fat > 28%). After an overnight fast, subjects performed a 30-min resistance exercise protocol (3 sets, 10 exercises, 10-12 repetitions, 4-6 s/rep, 30-s pause between exercises, 2 min rest between sets 70-75% 1RM in a circuit training fashion). Gluteal adipose tissue biopsies and blood sampling were performed at baseline, at the 5th min of exercise and at the end of the first, second, and third set. VO2 and respiratory exchange ratio (RER) were monitored continuously throughout exercise via a portable gas exchange analyzer. Blood was analyzed for NEFA, glycerol, glucose, catecholamines, insulin, glycagon, cortisol, IL-6, and TNF-α. TGLA was measured in fat tissue (3). Differences were examined through MANOVA with re-peated measures on time ($P<0.05$).

Results

TGLA increased 6-fold by the 5th min of exercise in L and at the end of the 1st set in O and declined thereafter in both groups without reaching baseline until the end of exercise. Serum NEFA and glycerol increased by the 5th min in L and after the 1st set in O, maintaining a plateau thereafter. However, L and O reached similar peak levels in all of these variables. RE induced a relative hyperglycemia until the end of the 2nd set; serum glucose normalized thereafter. Catecholamines demonstrated a progressive increase throughout the exercise protocol in both groups. Insulin demonstrated a progressive decline which was delayed in O. Glucagon and cortisol increased similarly

by the end of the 3rd set in both groups. IL-6 and TNF-α did not demonstrate any significant changes during exercise. RER increased progressively increased until the end of 2nd set and declined slightly in the 3rd set.

Discussion

Our data indicate that RE does increase adipose tissue lipolysis. This increase seems to be related to changes in hormonal responses during exercise. However, lipolytic activity in obese non-diabetic men demonstrates a delay which may be related to the insulin response.

OXIDATIVE STRESS RESPONSES TO RESISTANCE EXERCISE OVERTRAINING

Margonis, K., Fatouros, I., Jamurtas, A.Z., Kouretas, D., Mastorakos, G., Mitrakou, A., Douroudos, I., Taxildaris, K., Papassotiriou, I.

Democritus University of Thrace, Greece

Introduction

Overtraining may lead to performance deterioration and significant physiological perturbations (1). Overtraining is associated with an acute inflammatory response (2) that includes muscle infiltration by neutrophils and macrophages (Evans, 1991) and free radical generation that promote postexercise inflammation, removal of damage tissue, and repair (Fielding, 1993). Although there have been many attempts, currently there is no single simple marker for diagnosis of overtraining. In this study we aimed to investigate the responses of selective oxidative stress and antioxidant status indices to a chronic resistance exercise protocol of progressively increased training volume.

Methods

Seventeen young men (21.3±2.3 yrs) participated in 12-wk resistance training consisting of five separate training periods (each lasting 3 wk) of progressively increased training volume. During T1 subjects trained 2 d/wk (2 sets/exercise, 10-12 reps/set, 70% 1RM). During T2 subjects trained 4 d/wk (4 sets/exercise, 6-10 reps/set, 75-85% 1RM). During T3 subjects trained 6 d/wk (6 sets/exercise, 1-6 reps/set, 85-100% 1RM). During T4 subjects trained 2 d/wk (2 sets/exercise, 10-12 reps/set, 70% 1RM). Subjects performed 8 resistance multi-joint exercises. Blood samples were collected at baseline (T0) and 96 hours following the last training session of each period. Samples were analyzed for total antioxidant capacity (TAC), catalase, reduced (GSH) and oxidized glutathione (GSSG), the ratio GSH/GSSG, TBARS, and protein carbonyls. Data were analysed by ANOVA repeated measures ($p < 0.05$).

Results

Performance increased after T2 and declined thereafter. Catalase (μmol/mL/min) increased ($P<0.05$) after T2 (29.4±0.8) and T3 (42.2±0.5) compared to baseline (22.7±0.6). GSH (mM) declined ($P<0.05$) following T3 (0.27±0.05 vs. 0.38±0.06 at baseline). GSSG (mM) increased ($P<0.05$) following T2 (0.096±0.01) and T3 (0.11±0.009) compared to baseline (0.088±0.02). GSH/GSSG declined ($P<0.05$) following T2 (3.9±0.6) and T3 (2.4±0.4) compared to baseline (5.08±1.09). TAC (mM DPPH scavenged) declined ($P<0.05$) following T3 (0.53±0.1 vs. 0.69±0.06 at baseline). TBARS (μΜ) and protein carbonyls (nmol/mg protein) increased only after T3 compared to baseline (11.8±3.4 vs. 7.9±1.7 and 0.54±0.13 vs. 0.39±0.09 respectively).

Discussion

Neutrophils and macrophages peak within 2 or as late as 7 days postexercise (5). Our results indicate that selective indices of oxidative stress and antioxidant status, measure as late as 4 days postexercise, are responsive to a significant increase in resistance training volume suggesting that oxidative stress markers may be useful in diagnosis of overtraining.

PHARMACOLOGICAL AND TOXICOLOGICAL CHARACTERISATION OF "DESIGNER STEROIDS" AND "PROHORMONES" MISUSED IN DOPING

Friedel, A., Geyer, H., Kamber, M., Laudenbach-Leschowsky, U., Schänzer, W., Thevis, M., Vollmer, G., Zierau, O., Diel, P.

Center for Preventive Doping Research, Germany

Since the ban of anabolic steroids, athletes and their entourage have always tried to find new products and applications to evade the doping controls. Rumours of new steroids, produced and used specifically to escape doping tests in sport have been spread for more than 15 years. Over the last years several never-marketed steroids like tetrahydrogestrinone the first true "designer steroid", designed, synthesized and distributed solely as an undetectable doping agent were detected. This indicates the existence of alarmingly sophisticated and illicit manufacturing facilities and of an underground network to distribute these substances. There is an unknown number of abusers in sport, even though the substances' anabolic-androgenic potency and hormonal properties are not yet resolved. For doping prevention and control it is essential to know the effects and side effects of these "designer steroids" to plan informational and educational campaigns for athletes.

Therefore, the aim of our study was to further characterise the pharmacological profile of the "designer steroids" and prohormones androstenedione (AND), norandrostendione (NOR), norbolethone (NB), propyltrenbolone (Propyl), desoxymethyltestosterone (Madol, DMT), and 1-testosterone (1-Testo). Binding affinity of the substances to the androgen- (AR), glucocorticoid- (GR), progesterone- (PR) and mineralcorticoid receptor (MR) was tested. To determine the biological activity of the steroids a yeast AR-transactivation assay was performed.

In a classical hershberger assay the anabolic and androgenic action of the substances was determined in vivo. To characterise molecular and toxicological mechanisms the gene expression of the androgen receptor and myostatin (MSTN) in the gastrocnemius muscle and tyrosin aminotransferase (TAT) expression in the liver was analysed by real time PCR.

AND, NOR, NB and 1-Testo bind with high affinity and specificity to the AR. In contrast, Propyl turned out to bind with comparable affinity to the AR, GR and PR.
In vivo analysis indicated that 1-Testo has a similar anabolic and androgenic potency like Testosterone. Propyl in vivo displays a low androgenic and anabolic potency. Very surprisingly, DMT and NOR had only low androgenic but significant anabolic potency.
For DMT a slight induction of the TAT expression in the liver was detectable. Like testosteronepropionate (TP), administration of DMT resulted in a stimulation of IGF-1 and MSTN mRNA expression in the gastrocnemius muscle.
In summary, our data characterise 1-Testo as a typical androgenic and potent anabolic steroid, whereas Propyl in vivo has no significant anabolic and androgenic potency. In contrast, NOR and DMT show highly anabolic potency without effecting the seminal vesicle and the prostate weight. These Substances can be characterised as powerful anabolic steroids with SARM like properties and possible liver toxic side effects. Therefore, there is need for a strict control of possible misuse.

EXERCISE-INDUCED OXIDATIVE STRESS IN G6PD-DEFICIENT INDIVIDUALS

Nikolaidis, M.G., Jamurtas, A.Z., Paschalis, V., Kostaropoulos, I.A., Kladi-Skandali, A., Balamitsi, V., Koutedakis, Y., Kouretas, D.

University of Thessaly, Greece

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a common genetic disorder that can result in increased sensitivity of erythrocytes to oxidative stress which may lead to hemolytic anemia. Despite the existence of a theoretically sound background for diminished resistance of G6PD individuals to oxidative challenge, no controlled study has examined the antioxidant and oxidative stress responses to exercise in G6PD-deficient individuals. We examined the effects of acute high-intensity exercise to exhaustion on blood oxidative stress markers in G6PD-deficient individuals and matched controls. We also investigated whether the duration of exercise is an important determinant of the magnitude of the exercise-induced oxidative stress. Nine males with established G6PD deficiency and nine males with normal G6PD activity performed two exhaustive treadmill exercise protocols of different duration (the shorter one lasting ≈12 min and the longer one ≈50 min). Several hematological parameters, reduced glutathione (GSH), oxidized glutathione (GSSG), thiobarbituric acid reactive substances (TBARS), protein carbonyls, catalase and total antioxidant capacity (TAC) were measured in the blood before and immediately after each exercise bout. Both GSH and GSSG were significantly higher in the control group compared to G6PD-deficient group at baseline and, as a result, their ratio was not significantly different between the two groups. All other oxidative stress indices were not different between groups at rest. Exercise of short duration affected significantly the levels of all oxidative stress indices (except for GSSG and GSH/GSSG) either in G6PD-deficient group or in control group. Exercise of long duration affected significantly the levels of all oxidative stress indices in both groups. Heinz body formation was not seen in both groups either pre- or post-exercise in both protocols and both groups. To our knowledge, this is the first investigation of the effect of exhaustive exercise on the redox status of individuals with G6PD deficiency. G6PD-deficient individuals are able to perform short and long duration acute exercise without experiencing greater oxidative stress than non G6PD-deficient individuals (as indicated by the oxidative stress biomarkers used in the present study). The present findings illustrate that despite the theoretically lower capacity of G6PD-deficient individuals to resist perturbations in their redox status, they are not more susceptible to oxidative stress, probably because they have developed alternative protective mechanisms. On the other hand, the effect of exercise on glutathione status was dependent on duration, whereas exercise increased the levels of TBARS, protein carbonyls, catalase activity and TAC, independently of duration. Future studies should aim to delineate the mechanisms that enable G6PD-deficient individuals to adequately respond to an oxidant challenge, such as that imposed by an exhaustive exercise.

THE ASSOCIATION BETWEEN CIRCULATING LEPTIN, IL-6, TNF-α AND BODY COMPOSITION IN TRAINED AND SEDENTARY FEMALES

Zolnowska, M., Lutoslawska, G., Malara, M., Zuziak, S.

Academy of Physical Education, Poland

It is well known that circulating leptin, TNF-α and IL-6 correlate with measures of adiposity. Furthermore, many studies have examined the effects of exercise on their plasma levels and have revealed a decrease in circulating cytokines mostly due to exercise-induced reduced body fat [1]. In addition, there are data indicating that physical activity per se affects circulating leptin even in the lack of changes in body adiposity [2]. This study was undertaken to evaluate the relationships between selected cytokine plasma levels and body composition in sedentary and highly active young women. A total of 59 females volunteered to participate in the study - 29 students engaged in high-performance sports (18.4 h/week) and 30 sedentary students enrolled in 1.5 h/week of physical activity. All the subjects were regularly menstruating and none of them took oral contraceptives. The participants gave their written consent prior to the participation and experimental protocol was approved by the local Ethics Commission. Triceps, subscapular and abdominal skinfolds were measured to assess body fat [3]. Blood was collected from the antecubital vein after overnight fast between days 5-8 of the menstrual cycle into heparynized tubes. Plasma was separated by centrifugation (15 min/4000 rpm, 40 C) and stored at -700 until analyzed. Leptin, TNF-α and IL-6 were assayed by radioimmunoassay techniques using commercial kits containing monoclonal antibodies. The trained subjects were slightly younger and taller and were characterized by significantly lower fat mass, percent of body fat and higher lean body mass than their sedentary counterparts. Plasma leptin levels in sedentary females were significantly higher than in their trained counterparts. On the contrary neither IL-6 nor TNF-α plasma levels differed in trained and sedentary participants. Both in trained and sedentary subjects plasma leptin levels were significantly and positively correlated with fat mass and the percentage of body fat ($r=0.576$, $p<0.002$; $r=0.458$, $p<0.02$ and $r=0.521$, $p<0.004$ and $r=0.628$, $p<0.003$ in trained and sedentary women, respectively). In trained subjects a significant correlation was also noted between leptin plasma levels and lean body mass ($r=0.443$, $p<0.03$). Our results indicated important differences in the association between body composition and circulating leptin in trained and sedentary females. In both groups plasma leptin levels were significantly correlated with body fat. However, exclusively in trained women did lean body mass affect circulating leptin levels. It could be tentatively speculated that leptin secretion and its plasma levels were adjusted to training-induced elevated lean body mass.

DICLOFENAC STRATUM CORNEUM RESERVOIR FORMATION AFTER IONTOPHORETIC DELIVERY

Clarys, P., Lambrecht, R., Clijsen, R., Barel, A.O.

Vrije Universiteit Brussel, Faculty of Physical Education and Physiotherapy, Belgium

Introduction: Several clinical studies claim and advanced healing process after iontophoresis of a certain drug while other studies indicate no effect of the applied current. However, the designs often lack solidity to ensure that the improvements were due to the used enhancement technique. In a previous study we reported that application of diclofenac (DF) under iontophoresis did not differ from DF application under occlusion as estimated in the stratum corneum 90 min after DF application. It was the aim of this study to determine the reservoir properties of DF after a single topical application with and without iontophoresis. The presence of DF in the skin can be estimated using the suppression of the response to a topically applied vasodilator (methyl nicotinate - MN).

Methods: Three different groups of 12 healthy volunteers (males and females, aged 18-24) entered the study. Volunteers were asked to omit swimming and extensive showering during the duration of the experiments. A MN test was carried out on skin regions (volar parts of the forearms) treated with DF under the following modalities:(a) cathodic iontophoresis of a 1% DF formulation (12mg/ cm2) at 0.2mA/cm2 during 20 min; (b) passive diffusion of a 1% DF formulation under a semi-occlusive iontophoresis sponge (without current application); (c) passive diffusion of a 1% DF formulation without occlusion. A MN test was carried out on an untreated skin region for the determination of the reference response.

The MN response was evaluated respectively 90 min (group 1), 6 and 24 h (group 2) and 32 and 48 h (group 3) after DF application. The erythema response was quantified measuring skin redness. Measurements were carried out before DF application, before MN application and every 5 up to 40 min post MN application.

Results: The MN response was suppressed at all measurement intervals (respectively at 1.5, 6, 24, 48 h). There was no difference between the MN responses at the DF pre-treated skin sites when comparing the different measurement times (1.5 versus respectively 6, 24 and 48 h) neither for the application under iontophoresis ($p > 0.05$) nor for the application under occlusion ($p > 0.05$) nor for the open application ($p > 0.05$). When comparing the application modalities at the respective measurement times only at 90 min post application a significant difference was detected between the open application and the two other modes of application, ($p < 0.05$).

Discussion: Even 48 h after a single 20 min application DF application we could not discriminate between the different application modalities. This may be an indication for the fact that there is no additional enhancement effect on the DF penetration of iontophoresis compared to occluded and open application.

ACTUAL BLOOD TESTS TO DETECT BLOOD DOPING IN ATHLETES

Robinson, N., Sottas, P.-E., Bader, S., Kamber, M., Mangin, P., Saugy, M.

Laboratoire Suisse d'Analyse du Dopage, Switzerland

In the last 15 years, endurance sports have been taunted by EPO doping. The introduction of synthetic EPO in 1990 to fight patients with kidney damage was also the starting point of the misuse of EPO in endurance sports. To fight this development several international sport federations have introduced blood screening tests before competitions. These analyses are performed on a regularly basis for health purposes to avoid athletes competing with a haematocrit level well above normal and also to select and target athletes manipulating their blood formulae.

STATISTICAL DATA DURING BLOOD COLLECTION FOR DOPING CONTROL AT THE ATHENS 2004 OLYMPIC GAMES

Jamurtas, A.Z., Tsiokanos, A., Tsitsimpikou, C., Karachaliou, E., Schamasch, P., Valasiadis, D.

University of Thessaly, Greece

Doping control has been part of the major athletic events, including the Olympic Games since the 0olympic Games in Munich (1972). Doping Control Services of the Athens 2004 Organizing Committee (ATHOC) organised and implemented the most intensive and efficient Doping Control programme to date in Olympic Games. In a total of 10862 participating athletes there were 671 blood samples that were collected. Although Olympic Games are considered as the major event in sports, there is almost no data available regarding doping control, with the exception of one report describing the medication use by athletes in Sydney Olympic Games. Therefore, the purpose of this study was to derive statistical data that relates to blood sampling for doping control implemented for the first time as part of the official testing program in the Athens 2004 Olympic Games. Permission was granted from the International Olympic Committee to process the Doping Control Official Records (DCOR) that related to blood sampling. Data for blood samples from 37 sports were collected. The prohibited substances detected were human growth hormone (hGH) and hemoglobin based oxygen carries (HBOCs) in serum, along with the prohibited method of blood transfusions in whole blood. Blood collection had to take place within a maximum of 12 hours from completion of competition. The mean time needed for an athlete to report to the Doping Control Station for blood collection was 6.1 hrs. However, 26.6% of the athletes failed to appear within the 12-hrs time limit set. More than half of the serum samples collected were analyzed for hGH (54.8%). The highest percentage of serum samples analyzed for hGH per sport was observed in athletics (24.7%) and swimming (11.6%). Almost half of the athletes (47.7%) submitted to blood collection were tested for HBOCs. The highest percentage of serum samples analyzed for HBOCs was observed in athletics (20.0%) followed by rowing (18.3%). Whole blood was exclusively used for blood transfusions detection implemented for the first time in Olympic Games and in combination with HBOCs and EPO detection in urine consisted of the blood doping screening methods. The endurance sports, as defined by IOC Medical Commission and the respective International Federations, accounted for almost 80% of the whole blood samples collected. For the first time as part of the DCOR the athlete was asked to consent for the use of his/her sample for research purposes. Seventy five percent of the athletes consented, whereas only two athletes presented dissatisfactory comments on the blood sampling procedure. In conclusion, the majority of the blood and serum samples collected and analyzed were in athletics. Furthermore, almost half of the analysis for hGH and HBCOs in the Athens Olympic Games 2004 was accounted by three sports whereas the endurance sports covered almost all of the whole blood analyses performed.

CONTRACTILE ACTIVITY EXACERBATES SUPEROXIDE PRODUCTION FROM THE MUSCLE OF DYSTROPHIC MICE: IMPLICATIONS FOR THE DYSTROPHIC PHENOTYPE

Close, G.L., Baker, A.M., McArdle, A., Jackson, M.J.

University of Liverpool, United Kingdom

Duchenne Muscular Dystrophy (DMD) is an X linked fatal degenerative disease affecting 1 in 3500 male births in the UK. DMD results in rapid skeletal muscle wasting and by the age of 12 boys are often wheelchair dependent and die around the age of 30 [1]. The genetic defect has been identified and located to XP21 of the X chromosome [2]. The protein product of this gene (dystrophin) is absent in DMD patients [3]. In non-dystrophic muscle dystrophin is localised at the muscle membrane as part of a large glycoprotein complex known as the dystrophin-glycoprotein complex (DGC). Neuronal nitric oxide synthase (nNOS) is associated within the DGC, however nNOS is absent from the sarcolemma of muscle fibres in DMD patients. This loss of nNOS may be involved in the pathophysiology of DMD [4]. We hypothesise that the loss of nNOS in dystrophic mice (mdx) results in aberrant production of extracellular reactive oxygen species (ROS) at rest and during contractile activity.

Mice were anaesthetised and microdialysis probes were placed into the gastrocnemius muscle. Probes were perfused with either 50μM cytochrome c in 0.9% saline or 0.9% saline for analysis of extracellular superoxide and nitric oxide (NO) release respectively. Following 1 hour of baseline dialysis collections, hind limb muscles of mice were electrically stimulated to contract as previously described [5]. 1 hour following the contractions mice were killed and muscles removed for the analysis of NOS content. An additional group of mdx and WT mice were treated with the NOS inhibitor L-NAME (50mg/kg body weight) intravenously 30 minutes prior to the start of the experiment.

The expression of nNOS in muscles was reduced in mdx mice compared with WT. A significant increase in extracellular superoxide concentration was seen during the contraction protocol in microdialysates for both WT and mdx mice, although the contraction-induced increase was significantly greater in mdx mice compared with WT mice. Extracellular NO production was reduced at rest and during the contraction protocol in mdx mice compared with WT mice. Treatment of mice with L-NAME resulted in increased superoxide production at rest and during the contraction protocol in WT mice only.

Data indicates that the greater increase in superoxide release from muscles of mdx mice may be related to reduced extracellular NO caused by the loss of nNOS. This hypothesis was substantiated by the observation that inhibition of NOS by L-NAME resulted in increased extracellular superoxide production at rest and during the contraction protocol in WT mice but not in mdx mice. In conclusion, the aberrant production of superoxide in mdx mice may be implicated in the muscle degeneration in DMD.

ASSOCIATION OF ACTN3 GENOTYPE WITH PHYSICAL PERFORMANCE AND RESPONSE TO POWER TRAINING

Druzhevskaya, A., Netreba, A., Popov, D., Lyubaeva, E., Astratenkova, I., Montgomery, H., Rogozkin, V.

St Petersburg Research Institute of Physical Culture, St Petersburg, SSC RF Institute for Biomedical Problems, Moscow, Institute for Human Health and Performance, UCL, London, UK., Russia

Alpha-actinin-3 (ACTN3) plays an important contractile role in the Z-line of the sarcomers, whose expression is limited to fast muscle fibers responsible for generating force at high velocity. C-to-T transition in exon 16 of the ACTN3 gene leads to a stop-codon (polymorphism R577X), which results in no ACTN3 protein detectable in muscle fibres [1]. A single previous study has suggested the X allele to be negatively associated with elite sprinting status [2]. The aim of this study was to extend these observations, examining the association between ACTN3 polymorphism and physical performance, muscle fibre composition and the muscle hypertrophic response.

Russian control subjects (n= 844, CG) were studied, as were athletes (n= 612, 14 kinds of sports) who were divided into four groups according to the nature of their physical activity. R577X ACTN3 genotype was determined by polymerase chain reaction amplification (PCR), restriction analysis, and fragment separation by 8% polyacrylamide gel electrophoresis. In a subgroup of 36 healthy young men, muscle fibre composition was defined in samples of m. vastus lateralis using immunoperoxidase immunohistochemical identification of myosin isoforms. Fiber distribution was described as a ratio of the number of fibers of each type in a section to the total number of fibers. Magnetic resonance imaging (MRI) was used for determination of muscle volume and other muscle characteristics of thighs of 7 athletes before and after 8-week resistance training.

Whilst the frequency for ACTN3 mutant XX genotype was significantly reduced in all four groups of athletes (8%) comparing with CG (13%) (P=0.005), there was no significant difference in allelic frequency between athletes and controls (X allele – 37% vs 38% respectively). The mean percentages of fast fibers in ACTN3 RR homozygotes (54.05±2.53%) were higher than in RX heterozygotes (49.09±2.18%), a difference which did not reach significance. Based on results of MR-images we revealed that the increment of volume of m. quadriceps femoris after 8-week resistance training was greater in RR homozygotes than in RX heterozygotes (P=0.048). Therefore the presence of R allele is associated with increased hypertrophy of muscle fibers which results in higher force muscle characteristics. Thus there is significant association between ACTN3 genotype and athletic performance.

GDF8 IS MODULATED BY TESTOSTERONE AND ANABOLIC STEROIDS DURING MYOGENIC DIFFERENTIATION AND TRAINING INDUCED SKELETAL MUSCLE ADAPTATION

Schluepmann, K., Laudenbach-Leschowsky, U., Diel, P., Friedel, A.

Institute of Cardiovascular Research and Sports Medicine, Dept. Molecular and Cellular Sports Medicine, Germany

The process of muscle adaptation is controlled and modulated by growth factors like Myostatin (MSTN) – known to inhibit skeletal muscle growth –but also by male sex steroids. In our studies we investigated the effects of Testosterone and anabolic steroids like tetrahydrogestrinone (THG) on MSTN expression during myogenic differentiation and training induced skeletal muscle adaptation.

In vitro, C2C12 myoblastoma cells (cultivated in fetal calve serum = FCS) were treated with dihydrotestosterone (DHT) and THG in doses of [10-6 M] and [10-9 M], differentiation serum (DS), and DS + DHT. Expression and localisation of myostatin protein was detected by immunofluorescence using confocal microscopy and western blotting.

In vivo, orchiectomised (ORX) and intact (INT) rats were treated with different doses of testosterone propionate (TP) in doses of 1 mg/kg/BW/d (ORX) and 10 mg/kg/BW/d (INT) and absolved a swim training over 3 days. Treated but untrained animals served as control group.

MSTN mRNA levels were determined in vitro and in vivo using quantitative real time RT-PCR.

In C2C12 cells, application of DS and DS + DHT resulted in a stimulation of mRNA expression of MSTN. Treatment with THG also resulted in a modulation of MSTN mRNA expression. Analysis of CK expression revealed that the increase of MSTN expression correlates with an induction of differentiation. Protein data show that MSTN can be detected in C2C12 after treatment with FKS+DHT, FKS+THG, DS, DS+DHT by immunofluorescence.

In previous studies a downregulation of myostatin mRNA expression could be detected after different endurance training methods (long term wheel running, swim training over five days) .

In our in vivo experiments MSTN expression was downregulated in intact trained animals and in intact trained animals treated with TP. Treatment with TP in the absence of training did not effect MSTN expression. In ORX rats, training resulted in a dramatic up-regulation of MSTN expression, interestingly this effect could be antagonized by TP. Treatment with TP in the absence of training resulted in significant stimulation of MSTN expression.

In summary, our results clearly demonstrate that TP alters the expression of MSTN in vivo and in vitro. Our in vitro results implicate a MSTN function during satellite cell differentiation on mRNA and protein level.

Interestingly, a modulation of MSTN mRNA expression in INT rats could only be observed when treatment was combined with training. These results can be taken as a hint that molecular mechanisms of the anabolic action of testosterone include the modulation of MSTN expression.

The observation that training in the absence of TP results in an enormous increase of MSTN expression, a growth factor known to inhibit muscle growth, may have implications with respect to the phenomenon of age-related loss of muscle mass (sarcopenia) which has to be investigated in future studies.

REACTIVE OXYGEN SPECIES DETERMINE SKELETAL MYOBLAST ADAPTATION TO OXIDATIVE STRESS THROUGH NFKB ACTIVATION AND EXPRESSION OF PROTEIN INVOLVED IN CELL SURVIVAL AND DNA REPAIR

de Perini, A., Dimauro, I., Bonini, S., Parisi, P., Caporossi, D.

University Institute of Movement Sciences (IUSM) , Italy

During physical activity, changes in body demands involve modifications in cellular and subcellular structure and components, which determine the up- or downregulation of specific genes. As a results, body muscles, metabolism, defenses, and also neurological functions, will adapt to the new situation. The aim of our study was to utilize a cellular model represented by L6C5 rat skeletal myoblasts to investigate the molecular mechanisms which determine the positive adaptation of the skeletal muscle to Reactive Oxygen Species (ROS). It is well documented that the response of L6C5 rat myoblasts to ROS largely depends on the intensity of the oxidative stress applied, since enhancement of cell survival and cell proliferation, as well as resistance to ROS-induced apoptosis, have been described following a pretreatment with very low ROS (H2O2 1-10 μM) concentrations (Caporossi et al., 2003).

The first aim of this study was to verify if the peroxide radical had a direct role in the activation of the adaptive response to oxidative stress of L6C5 myoblasts and to determine the time course for the activation of the cellular systems involved in this process. Adding exogenous ascorbic acid (AsAc, 100 μM) during the adaptive treatment, we noted the complete disappearance of the anti-apoptotic response (frequency of nuclear fragmentation) when AsAc was added from the beginning of adaptation, but no effects when it was added only during the final stage of the conditioning (last 8 hr), indicating that the up-regulation of adaptive genes is an early event during adaptation and specifically requires low ROS concentrations. To detect which cellular systems could have a leading role in the L6C5 myoblasts adaptation to ROS, we checked for the expression of several anti-apoptotic and survival genes. We found that ROS preconditioning increases the expression of both the Bcl2 and the αB-crystallin genes: the Western Blot analysis showed that αB-crystallin increased up to 6 hr from the end of adaptive treatment, returning to basal levels after 12 hr. Instead, the product of the Ref-1 gene, an endonuclease which plays a central role in repairing the DNA damage caused by ROS, increased only after 12 hr from preconditioning, in association with the induction of chromosomal breakages. Since L6C5 cells develop apoptosis resistance during differentiation through changes in the levels of antioxidants directly or indirectly regulated by the redox-sensitive transcription factor NFkB (Catani et al., 2004), we analyzed the modification of this factor activity under the adaptive treatment (H2O2 5-10 μM). Our results demonstrate a strong enhancement (8-fold increase over the control) of the NFkB activity after 24 hr of preconditioning with low ROS concentration, suggesting a central role for this transcription factor in the activation of the specific adaptation of skeletal muscle cells to oxidative stress.

AUTOCRINE ROLE OF VASCULAR ENDOTHELIAL GROWTH FACTOR IN PROTECTING SKELETAL MUSCLE CELLS FROM CELL DEATH INDUCED BY OXIDATIVE STRESS AND SIMULATED HYPOXIA

Mercatelli, N., Ciafrè, S.A., Farace, M.G., Caporossi, D.

University of Tor Vergata, Italy

It is presently recognized that survival and regeneration of muscle cells depends on several different endogenous and exogenous molecules. Among these, Vascular Endothelial Growth Factor-A (VEGF-A) is particularly relevant, as it is well known that in conditions of

"physiological stress", such as hypoxia and exercise, skeletal muscle cells express and release VEGF (Ameln et. Al., 2005). Indeed, the expression of VEGF-A, originally described as an endothelial-specific growth factor, was shown in hypoxic muscle fibers, satellite cells, and in regenerating fibers during ischemia. (Germani et al., 2003). Moreover, the expression of the VEGF main receptors Flt-1 (VEGFR-1) and KDR/Flk-1 (VEGFR-2) is not restricted to vascular endothelial cells, but it is widely distributed in a variety of cell types, including osteoblasts, cardiac myocytes and regenerating myotubes (Arsic et al., 2004).

In search for a physiological autocrine protective role of VEGF-A in skeletal muscle cells, we stably transfected C2C12 skeletal myoblasts with a vector expressing the major VEGF165 isoform and we studied the effect of VEGF expression and release on cell survival and apoptosis induced by oxidative stress (exposure to different concentrations of H2O2) and simulated hypoxia (exposure to CoCl2). Both hypoxia and oxidative stress are generated during physical exercise and, if not properly counteracted by cellular defense mechanisms, can contribute to development of muscle fatigue, inflammation and degeneration.

Here we show that C2C12 myoblasts transfected with the VEGF165 cDNA express and secrete large amounts of VEGF into culture medium, in turn yielding a strong increase in cell growth, cell survival and resistance to apoptosis after exposure to cytotoxic concentrations of H2O2 and CoCl2. Indeed, if compared to the control, empty vector-transfected C2C12/pSV2neo myoblasts, C2C12/VEGF165 showed a 20-30% increase in cell survival and a 50-70% lower incidence of cellular apoptosis, with a lower degree of caspase-3 activation. We also demonstrate that these processes are correlated to enhanced VEGFR-2 activation, suggesting that the VEGF released by skeletal muscle cells, beside the well known angiogenic property, can also exert an autocrine effect. Finally, we investigated the molecular mechanisms mediating VEGF protection, and we determined that C2C12/VEGF165 myoblasts showed an enhanced expression of the Hsp27-related small protein αB-Crystallin, known to play a specific anti-apoptotic role during differentiation of skeletal muscle cells.

Our findings suggest that in the future, a therapeutic use of VEGF gene could be proposed to reduce skeletal muscle cells loss in acute and chronic muscular diseases of diverse origins, including traumatic injury or muscular dystrophies.

AN ATTEMPT TO MODEL THE ADAPTATION OF THE OXIDATIVE SYSTEM TO ENDURANCE TRAINING IN MEN – AN EMPIRICAL-BIOLOGICAL APPROACH

Weber, S., Gehlert, S., Bloch, W., Platen, P.

German Sport University Cologne, Germany

Introduction

It is suggested that the performance of a biological system (BS) is in general determined by its functional load (FL). Such BS are e.g. mitochondria whose performance can be estimated in vivo by measuring VO2max or in vitro e.g. by measuring the activity of citratsynthase (CS). According to Taylor et al. (2005) the adaptation of CS to a given training load is thereby related to AMPKK, while the activity of AMPKK is considered to be a function of AMP (Hurst et al. 2005).

Methods

Nine male subjects (25 ±3 yrs., 182 ±7cm, 72.6 ±3.6 kg) performed a cycling training period (TP) of 12 weeks. VO2max, maximum lactate production rate (VLamax) and anaerobic threshold (AT) were measured before, after and once per week during the TP. The power output of each subject was measured during TP using SRM powermeters. The training intensity was set to a constant load of 60% of the AT ensuring a predominant use of ST fibres. The overall training volume varied in a range of 6-22h/week. Muscle biopsies were taken from the M. vast. lat. before and after the training. Based on the recorded power data of each training session, the amount of consumed O2 per week was calculated to estimate the FL of the aerobic metabolism (Barstow et al 1991). The weekly consumed volume of O2 was then related to the corresponding VO2max, expressing FL as a percentage of the chronic use of VO2max (FL%). Finally, VO2max, VLAmax and training data were used to estimate the total amount of produced AMP during the training sessions (Mader 2003).

Results

VO2max, VLamax and AT before TP were: 68.8±6.0 ml/min/kg, 0.63±0.1 mmol/l/s, 307±36 Watt. All subject showed different time courses in the development of their VO2max with a time lag of one week to FL% as well as to AMP. In five subjects two sectors of FL% could be identified which led either to an increase or decrease of VO2max (r=0.88±0.1, respectively r= -0.55±0.35). Individual differences of the adaptation could be found in different slopes of the regression line (0.06–0.27), as well as in different maximum values VO2max (68.9–78.0) within the TP. The amount of built AMP in relation to the percentage of ST fibres (AMP/ST) during the training in the week before the second biopsy appears however to be related to the activity of CS in all nine subjects.Two sectors of AMP/ST values were identified: one related to increase CS activity (r=0.94, n=6) and one for decreasing CS activity (r=-0.98, n=3).

Discussion

The results of this pilot study suggests that the adaptation of the aerobic system to training loads can be described with the FL% and especially with AMP. It seems however necessary to consider other, highly individual parameters such as the fibre type distribution as well. This might allow better predications of the reaction of the aerobic system to a training load.

COMPARATIVE STUDY ABOUT OLYMPIC AND PARALIMPIC GAMES

Kälbli, K., Rigler, E., Gita, S.

Semmelweis University , Hungary

Introduction

Nowadays one of the most prestigious sport events is the Olympic Games. After the Olympic Games, at the same place of a similarly prestigious event passes which gives possibility for people with disability to compete. The name of this event – because of its parallelism with the Olympics - is Paralympic Games.

The goal and the methodology of the research

The goal of our research is to compare the Olympic and Paralympic Games from the aspect of numbers. We tested with the method of Spearman correlation: the correlation between the ranks of the countries in these two events, and the relationship between the rank of the countries at the Olimpics and Paralympics, and the actual economic condition of the countries.

Results

The development and conformation of the number of the competitor, participating countries and sports

The first modern Olympic Games were held in 1896 in Athen. The Paralympics have been formally listed since 1960. The number of athletes, who competed in the Olympics, is forty times more than at the first games (from 245 athletes to 10500), and the number of the athletes parcitipating the Paralympics to ten times more. In Athens 202 nations took part in olympic games (in per cent mostly from African countries), and in Athens at the paralympic games 135 nations took part (Mostly –33%- countries from Europe.)

It is demonstrable that while the number of the sports has increased in the olympic games, the number of the events has widened in the paralimpic games. The reason is simple; the offer of sports can't be expended ad infinitum for people with disability, while the categories established for the sake of the even chance effect the rise of the sport events.

It is remarkable, that the "aesthetic-sports" are fully missing from the programme of the summer paralympic games. In our opinion we can correlate this fact with the people of the 21st century, who aspire to perfection, health and soundness.

About the background of the olimpic and paralimpic results

As a result of our comparative study which we made with the Spearman correlation method we can assume:

• There is significant, linear correlation between the Olympic and in Paralympic rank of the countries. The countries which has better place in the Olimpic rank, has also better place in the paralimpic rank as well.

• Neither the olympics rank nor the paralimpics rank is correlated with the actual economic condition of the countries.

Summary

The quantitative growth can't be the most important purpose in the sport for people with disability. Towards the successful selection of talented disabled athletes the goal is to improve the condition of the sports activity and with its help to offer magnetic alternatives which encourages disabled people to be active.

WATER SAFETY AND BABY-SWIMMING

Magini, V., Di Fiore, V., Dapretto, L., Robert, P., Andreana, G.

University Institute for Movement Sciences, Rome, Italy

INTRODUCTION

Baby-swimming represents an activity which positively influences the child's psycho-physical development, gaining benefits in growth for psychological, emotional and physical aspects; in fact, it allows the newborn to improve his/her self-receptivity.

Practising baby-swimming enhances newborn's ability to perceive the positions of his/her body and all its components in space, strengthens relationship with his/her parents and predisposes the baby to learn swimming in the future.

Baby-swimming occurs in the presence of at least one parent in the swimming pool.

This survey aims to evaluate the possible social value this activity could represent; in particular, if and how baby-swimming could affect parents' level of surveillance and awareness towards their children, near aquatic environments, such as private and public swimming pools, rivers, lakes, seas, etc…

MATERIALS AND METHODS

An anonymous questionnaire was distributed to 30 parents who participated in a baby-swimming course with their children.

The questionnaire proposed the following questions:

- Child's sex and age;
- If the parent involved in the lesson had a past swimming experience, or still has;
- If he did (or still does), for how long;
- If the baby-swimming course has developed in the parent a major sensibility towards safety in water and baby's safeguard and protection.

RESULTS

The questionnaire gave the following results:

- Children were between 6 months and 3 years old, 40% boys and 60% girls;

- Among 30 parents interviewed, 24 (80%) attended a swimming course in the past, of varying duration, while 6(20%) have never attended one;
- All parents replied that, after attending a baby-swimming activity, they acquired greater awareness, attention and sensibility towards safety in water and protection of their children.

DISCUSSION AND CONCLUSION

Children who are less than 3 years old are exposed to death risk due to accidental drowning. The main cause of fatal accidents in water during the first years of life is a lack of surveillance which adults should provide. During this period, differently from other age groups, there is no difference of percentage between boys and girls; however, at a higher age group, there appears to be a difference, with statistics showing 75-80% male and 20-25% female.

Data obtained through this questionnaire show how baby-swimming activities can raise security levels in water for new-borns and children in the 0-3 age group.

A desirable and major diffusion of this activity represents an effective tool in fighting against accidental drowning, with relevant social consequences.

ACKNOWLEDGMENTS

The Authors thank "Euromar" Sporting Center for its kind collaboration.

DISCOURSES OF DIFFERENCE: WOMEN'S EXPERIENCES OF FOOTBALL UNDER FA GOVERNANCE

Welford, J., Kay, T.

Loughborough University, United Kingdom

This paper reports on a qualitative study of women's involvement in football in the UK, in the context of the rapidly developing female game under Football Association governance. Women's football has always been very closely associated with the male structure of football, from being banned by the FA in 1921, through the struggles without male structural backing, through the FA takeover in 1993 to today where most women's teams, especially at the highest level, play under the shadow of male clubs as a way to access facilities and support. This study looks at the current situation and evaluates the role of these male structures in shaping the development of women's football as a whole but also as impacting individual experiences.

The study uses qualitative data gathered from interviews with women involved in football to demonstrate, through the experiences of those involved, how the close association with the male structure of football is influencing their experiences. This involves not just players but also female coaches and administrators. In addition to close ties with the male structure, women's football is also growing both within and outside a traditionally male dominated culture of football in the UK, which is simultaneously enabling and constraining its development, demonstrated through the conflicting discourses that have emerged from the data. The paper utilises a feminist post-structuralist framework in an attempt to gain a greater understanding of these complexities that surround women's involvement in what is a traditionally male preserve of football.

The research was driven by a feminist-influenced methodology which encouraged a reflexive, open and woman-centred approach to data collection and analysis, the significance of which will be acknowledged throughout the paper. Twelve in-depth interviews were undertaken with females involved at the grassroots level of women's football, both as players and coaches. A further methodological consideration to be discussed is that of 'insider' research; the author has been involved in women's football as a player for the last fifteen years; the strengths and weaknesses of this factor will also be examined. The paper concludes by considering how the recent rapid development of women's football in the UK has been experienced at the individual level and makes recommendations for future developments in order to meet the needs of those involved in the game.

PLAYING THE GAME (PLAN): A SOCIOLOGICAL ANALYSIS OF SPORTS DEVELOPMENT OFFICERS

Bloyce, D., Mead, R., Morris, J.

University of Chester, United Kingdom

Introduction

Sports Development (SD) is a growing field within local authorities in England. Despite this, sports development is difficult to define. SD is seen by some as a tool to develop social inclusion and to contribute to a wider feeling of community, for example, while for others it is seen as a tool for promoting participation and international success. Indeed, recently, increasing numbers of stakeholders have taken an interest in sports development, as the UK government promotes its 'joined-up thinking' agenda. It is also a growing area of concern in terms of academic study (Green and Houlihan, 2005; Houlihan and White, 2002; Hylton et al 2001). However, very little has been written about the SD field from a distinctly sociological perspective. In this paper we wanted to examine the 'reality' of the job for SDOfficers (SDOs) on the ground from a figurational perspective.

Methods

The study was based upon semi-structured interviews with sixteen SDOs from ten different local authorities in the west-midlands and north-west of England. The local authorities examined were a mixture of large, medium and small urban areas, and large and small rural areas.

Results/Discussion

Several themes emerged from the interview data. These include: a concern for the lack of resources available in local authority SD work; that there was an increasing bureaucratic aspect to the job; the increased need (and some considered this additional 'bureaucracy') to establish partnerships with a range of organizations; a growing focus on SDOs developing sport in their area for essentially 'extrinsic' factors, such as health promotion, crime reduction, social inclusion and other priorities on the national and local government agenda. In this regard, we argue that the SDOs were all largely constrained by the national agenda set by the government – especially in their policy document Game Plan (2002). Whilst, it could be argued, the SDOs are constrained in this regard, it became clear from the interviews that this also enabled them to develop for themselves a more secure position insofar as they were able to 'offer' something more to their

employers, by utilising sport as a tool for delivering wider social goals. Or, at least, that is the claim that is made. There is very little evidence to suggest that sport can play a part in reducing crime or contributing to social inclusion. As such, SDOs are likely to find themselves in a double-bind, in that their job will increasingly be measured by the wider benefits that are accrued from sport, but that, at least current research suggests, this is likely to be difficult for them to prove.

EATING DISORDERS OF TOP-LEVEL SPORTSWOMEN OF AESTHETIC SPORTS

Zurc, J.

University of Primorska, Science and Research Centre of Koper, Slovenia

The driving force of every sport activity is achievement. Those sports where appearance and body weight are very important (gymnastics, rhythmic gymnastics, figure skating and dance, esp. ballet) are based on values, standards and rules of behaviour representing pressure for unnecessary control of body weight. This is one of the so-called sociological factors which help develop eating disorders.

In the research carried out on a sample of Slovenian sportswomen with diagnosed eating disorders we focused on the problem of eating disorders from the point of view of personal characteristics (perfectionism), attitude to their body, menstrual cycle, attitude to food and connection between characteristics of practising a certain sport or pressure in a sports environment for controlling body weight and development of eating disorders.

It was found that the values, standards and rules of behaviour in these sports represent external views of obsession with appearance. There was constant pressure for weight watching and in consequence the presence of fear of being overweight was always noticed. The sportswomen who took part in the research had a highly developed characteristic of perfectionism. The stated relates to being unhappy with their own body through to harmful behaviour and symptoms of eating disorders.

Behaviour of individuals or their perception of accepted behaviour (part of superego) develops under influence of punishment for behaviour not according to the standards of the social environment. If slimness is important for success in a sport and the trainer, the judges and the other competitors admire and demand it, the sportswoman will internalise such ideal, based on punishment, as her standard behaviour. Slimness will become her value, a part of her personality. If her actions will be rewarded (e.g. praise from her trainer, her partner, medal), these actions will continue. However, the line between diets and eating disorders is very thin and very soon someone can be on the wrong side. Similar studies dealing with this problem in different groups of sportsmen also confirmed the presence of eating disorders in sportswomen in the sports mentioned (Taylor & Ste-Marie, 2001; Williams, 1999).

To answer the question if aesthetic sports could influence the occurrence of eating disorders more accurate and longitudinal studies on the groups at risk should be carried out, based on the experimental method. Two areas should be studied, that is why eating disorders occur in the first place and secondly, what personal profiles the involvement in »aesthetic sports« creates.

OPTIMIZATION OF THE PLANTAR VIEW FOOT GEOMETRY ANALYSES USING A COMPUTERIZED SYSTEM

Sarabon, N., Grcar, M., Starc, G., Labrovic, J.

University of Ljubljana, Slovenia

Introduction

Measuring foot geometry is of a great importance in medicine, footwear industry and sport science. Past analyses were usually done by hand, using a leaf of paper, ink and rulers. This kind of print acquisitions and analyses have several shortcomings such as time-consumeness, subjection to errors, vaguely defined measures. The aim of our work was to develop computerized acquisition and analyses system for countering the mentioned shortcomings. We tested its repeatability and compared it to those of conventional procedures.

Methods and Materials

10 subjects (5♂, 5♀; age 30.8+13.4 yrs; body height 168.7+7.11 cm; body weight 61.2+8.8 kg) volunteered for the study. We first took 10 consecutive foot prints and contours of each subject using pencil, ink and paper. Then, we repeated the same number of measurements using our computerized system. For the purpose of foot print acquisition Vaseline was applied to subject's foot which was then pressed against the mirror; the latter was scanned and thus the footprint digitized. On the other hand, the foot contour was taken by directly scanning the plantar view of the foot. Altogether 20 quantities were computed. For the purpose of statistical analyses these were divided into three groups of measures: angular, transversal, and longitudinal measures. Differences in variability between the two procedures (manual vs. computerized) were tested using paired t-test.

Results

Differences in intra-subject standard deviations between the two tested measurement procedures for all three groups of measures were statistically significant (P<.05). Using the computerized system the longitudinal measures had stdevs 1.23 % of the average mean (the mean values were (in mm): print length 1sttoe-heel (233.4+.9), print length 2ndtoe-heel (231.8+1.2), print length without toeprints (199.8+1.2), print length to the 1st metatarsal joint (170.6+1.8), print length to the 5th metatarsal point (146.9+2.4), contour length (245.8+1.8), contour length to the 1st metatarsal joint (179.6+1.8), contour length to the 5th metatarsal joint (155.9+2.5)), transversal measures 1.15 % of the average mean (the mean values were (in mm): orthogonal print width (80.9+1.7), anatomical print width (91.8+1.0), inner anatomical print width (40.9+0.8), print heel width (49.4+1.0), inner print heel width (23.8+0.6), orthogonal contour width (88.9+0.5),

anatomical contour width (94.6+0.8), inner anatomical contour width (42.4+0.7), contour heel width (58.9+0.4), inner contour heel width (28.9+0.7), contour mid-width (76.3+0.7)) while those of the angular measures were 3.84 % of the mean (Clark's angle (47.3+1.8°)).

Conclusion

The study presents footprint analyses software and furthermore argues its supremacy over the manual procedure. It has been made faster and the human factor has been eliminated up to a certain point. Additionally mathematical and/or algorithmic formalisms were used to define quantities which are computed by the application.

HEALTH ECONOMIC EVALUATION OF CONTROLLED AND MAINTAINED PHYSICAL EXERCISE IN THE PREVENTION OF PROSPERITY DISEASES

Vandenabeele, E., Annemans, L., Lamotte, M., Clarys, P.

De FitnessOrganisatie; Vrije Universiteit Brussel, Belgium

Introduction

Besides a cooperation with the medical sector (prescription of health related physical activity) the Belgian Fitness industry started a policy to negotiate a more beneficial financial climate with lower VAT and tax deductible memberships. To support these efforts a system was developed to improve and control client compliance to regular controlled activities. Additionally a method was developed to estimate the economic impact of maintained physical exercise in different age- and risk categories.

Several studies and reports support the health benefits of frequent physical exercise, on the condition that this exercise is controlled and maintained.

Given the scarce resources that can be spent on health and health care, the objective of this study was to predict the long-term health and economic outcomes of controlled and maintained physical exercise in a fitness setting.

METHODS

A 25-year Markov model with a 12-month cycle-length and states representing diabetes, coronary heart disease, stroke, colon cancer and breast cancer was developed to predict cumulative costs and Quality Adjusted Life Years (QALYs) for 3 defined virtual cohorts, of different risk levels. The risk for evolving to the disease states is dependent on the followed strategy: physical exercise versus no intervention. Reduced risks associated with physical exercise as well as cost of diseases and loss in quality of life if diseases were obtained from published literature. Cost were taken from a societal perspective; Belgium was selected as setting. One way and probabilistic sensitivity analyses were carried out.

RESULTS

For each of the cohorts, physical exercise is predicted to increase the QALYs and to off-set a large part of the initial investment. The cost per QALY varies from 2000 to 15000 per QALY depending on the risk levels, which is better compared to a majority of secondary preventions which are currently publicly financed.

CONCLUSION

Controlled and maintained physical exercise is projected to be very cost-effective, which is likely to be explained by its effect on several diseases and the associated weight loss which affects quality of life positively.

THE ELECTRONIC ATHLETE'S RECORD FOR CONTINUOUS RECORDING AND MONITORING OF ATHLETIC PERFORMANCE

Bang, A., Seifriz, F., Mester, J.

German Sport University Cologne, Germany

Performance in elite sport is a complex phenomenon where the number of influencing factors is high but where at the same time the interindividual longitudinal variability may be very small. For a better understanding of the intraindividual variance of performance modern diagnostics and various scientific approaches with a large amount of information have to be managed. The amount of this data has been growing for the past years and still it is because the number diagnostic methods have increased and the measurement devices offer a huge amount of parameters. For further analysis of the data, they have to be stored and managed as efficiently as possible. Local PC-storage in many cases is not sufficient any longer.

Here special database management systems (DBMS) are the state of the art with appropriate web-based system architectures and database (DB) models.

For the "Electronic Athlete's Record" a client-server architecture with three levels has been chosen: (1) user interfaces, (2) content management system and (3) a database. This architecture ensures fast data transfer, secure data administration and a comparatively quick and easy way to make changes to the system.

The DBMS architecture is designed at three levels. The first level covers three user interfaces, one for the automatic import of data from diagnostic devices, another for the possibility to manually enter data, and the last one is a web-enabled client to view the information. The second level consists of a content management system (CMS). This system makes it possibly to make changes to the DBMS, such as adding new diagnostic devices, without direct user interventions at the DB-level or in the user interfaces. This system also ensures secure authentification and authorization of the users, comparable to banking industry standards (IBM, 2003).

The third level, the data model of the DB (type DB2) is designed to avoid negative, duplicate data. It is possible to use structured query language (SQL) to execute any queries to the DB. Thus, necessary statistics can be produced on demand.

With the current version of the "Electronic Athlete's Record" and through the web interface athletes and authenticated other persons, such as coaches, can directly access data and thus monitor the variability of performance. Moreover data bases of this kind can solve prevalent data management problems within sport organizations. With this system, reliability of data is improved and extraction of statistic parameters is simplified.

To optimize the system, further tests and extended versions are in progress. The trend with ever-growing quantities of data will be even stronger in the future. So DBMS will be a necessity.

IBM (2003). IBM DB2 Content Manager for Multiplatforms, System Administration Guide, Version 8 Release 2. Zugriff am 02.02.2004 unter http:\\www-306.ibm.com\software\data\cm\cmgr\mp\library.htm\c2713354.pdf.

DOPING SCANDALS AND ANTI-DOPING DEVELOPMENT IN THE 20TH CENTURY

Mavrek, S.

Karl-Franz-University Graz, Austria

In today's sporting context, doping refers to the use by athletes of banned substances or methods that may enhance performance. While the term 'doping' first appeared in an English dictionary in 1879, the use of use of drugs is evident throughout the history of sport.

The purpose of this study was to examine and to describe relationships between the biggest doping scandals and development of anti-doping in the 20th century.

The sources of data (public records, books, journals, newspapers, as well as related web contents) were processed by historiography.

The first recorded death due to the use of a drug occurred already in 1886, when English cyclist Linton died from an overdose of trimethyl. In 1928 the International Amateur Athletic Federation (IAAF) became the first International Sport Federation to ban the use of doping (use of stimulating substances). In spite of further escalation of doping abuse and historical argument that doping is incompatible with the ethical nature of sport, the most significant international anti-doping developments occurred just after the biggest doping scandals: 1960 - Council of Europe tabled a resolution against the use of doping after the death of Danish cyclist Knud Enemark Jensen at the Olympics in Rome, 1967 - the Medical Commission of the IOC was established after the death of another English cyclist Tom Simpson in the Tour de France and 1999 - the World Anti-Doping Agency was established as a direct result of the 1998 Tour de France doping scandal. In 1966 UCI (cycling) and FIFA (football) were among the first International Federations to introduce doping tests in their respective World Championships. In the next year, newly established International Olympic Committee (IOC) Medical Commission set up its first list of prohibited substances. The first drug tests were conducted at the Grenoble and Mexico Games in 1968. It is evident that the use of doping increased parallel with advances in technology combined with social, economic and political changes and that the effects of these factors influenced to the development of anti-doping programs during different time-ordered events in the 20th century. Of particular importance in this context was the development of communist regimes in many parts of Eastern Europe and the emergence of the Cold War and of superpower rivalry. Within this context, international sporting competition took on a significance going far beyond the bounds of sport itself, for sport became an extension of the political, military and economic competition which characterized relationships between the superpowers and their associated blocs.

The most important anti-doping event in the last century was the World Conference on Doping in Sport held in Lausanne on 2-4 February 1999, which produced the Lausanne Declaration on Doping in Sport. According to the terms of the Lausanne Declaration, the World Anti-Doping Agency (WADA) was established on 10 November 1999 in Lausanne to promote and coordinate the fight against doping in sport internationally.

EVIDENCE-BASED PRACTICE IN THE SPORT AND EXERCISE SCIENCES: A META-EVALUATION OF METHODS

Weed, M.

Loughborough University, United Kingdom

INTRODUCTION

Evidence-based approaches have played a key role in determining policy and practice in the health and medical sciences. Supporting the use of such approaches are two 'libraries' that act as clearing houses and depositories of best practice. The clinical sciences are supported by the Cochrane Collaboration (www.cochrane.com), and the social sciences by the Campbell Collaboration (www.campbellcollaboration.com). In the sport and exercise sciences, evidence-based approaches have been utilised by researchers in sport and exercise psychology (eg, Feltz & Landers, 1983, on mental practice), physical activity and health (eg, Hagger, et al, 2002, on physical activity behaviour), and sport management and policy (eg Weed, et al, 2005, on voluntary sport administration). The approaches comprise: meta-analysis, systematic review, better-practices frameworks, and narrative review.

METHODS

This paper reviews the range of evidence-based approaches used in the sport and exercise sciences, and conducts a meta-evaluation of methodologies. Meta-evaluations examine the validity and usefulness of methods, and the extent to which, regardless of internal consistency and validity, the methods used result in findings that have any broader utility in the field. Therefore, this meta-evaluation will evaluate the methodologies used and the utility of findings of evidence-based approaches in the sport and exercise sciences.

RESULTS/DISCUSSION

Issues to be discussed in the meta-evaluation include:

1) How various evidence-based approaches judge what counts as 'evidence', and the criteria by which 'evidence' is included or excluded in evidence-based approaches.

2) What weighting is given to various 'categories' of evidence.

3) How qualitative and quantitative studies are reconciled and/or synthesised.

4) The underlying assumptions of the various evidence-based approaches and the outputs produced.

5) The basis on which 'evidence-based' status is ascribed to the conclusions of such approaches

CONCLUSION

As the tradition of evidence-based approaches has emerged from the medical and policy fields, it is largely the psychology, physical activity and policy/management areas of the sport and exercise sciences that have embraced such approaches. However, the issues discussed in this meta-evaluation will show that there is a legitimate concern that an evidence-based model that is derived from clinical practice and policy evaluation may not be suitable for application without modification across the broad spectrum of disciplines in the sport and exercise sciences, and that this has affected the quality of some outputs that claim to be contributing to 'evidence-based practice'.

COMPREHENSIVE STUDY ABOUT ICAS-CAS AND COURT OF SPORTS ARBITRATION OF HUNGARY

Nagyreti, J., Nemes, A.

Semmelwies University Faculty of Sport Sciences, Hungary

At the beginning of the 21 century sport has become from a hobby of citizens or a folksy – childish entertainment an important factor of social culture. To sport science, sport life pertain such traditional foreign sciences as economy and law. And in the case of sport – as by every other social activity conflicts are avoidless.

Only a definite part of the jural conflict cases manifests itself and becomes a legal regulated judicial combat. In the case of manifest and legal regulated jural conflicts there is some regulated procedure in which the solution procedure of conflict has some formal and legal regulated way.

Every Hungarian citizen has the constitutional right to go to law – court. At the same time the most important requirements of jural processes are their simplicity, celerity, cheapness and the special expertise of the proceeding judges. These demands will be provided by the arbitration court.

As one of the most typical tendencies of sport life in the middle of the nineties an evolving of a special jural sport related background has began in Hungary. Though the main part of jurists doesn't acknowledge the existence of sport law as an autonomic science till today, sport law as a specialistic law study has both his extent and quality considerable literature.

The origination of the sport permanent arbitration court is a consequence of in the former section submitted tendency. About the work of the sport permanent arbitration court there is only few to know. Its origination was an important step and it fills deficiency, that's true. I feel the Hungarian sport society is waiting for intervention to solve its problems. It is such an organization which help by conflicts can be solved in professional communities, while procedures of jural and professional expert judiciary.

I have written in the first paragraph the change of importance and thatness of sport is an international change. Establishing the jural background of sport is not only a problem of the hungarian law – makers. For example big international institutions of sport also have to create a sport jural regulation answering to the problems of today. International sport competitors has become sporting millionairs from sporting amateurs, the relaying fees have grown severalfold. With the growing importance of the role of sport conflicts in connection with sport have mulitplied so qunatitatively as qualitatively and have become deeper and complicated.

Discoursing about arbitration court in international fields the one arbitration court is unambigous to analyze.lit is the most important arbitration court, the doubled institution working as one organization the International Council of Arbitration for Sport (ICAS) and the Court of Arbitration for Sport (CAS) In my presentation I compare the process regularization, methods and working of the SÂV , ICAS-CAS And the presentation have a specially intresting: the city of conference is the seat of ICAS-CAS too.

SPORT AND CIVIC IDENTITY IN THE UNITED STATES

Gems, G.

North Central College, United States

In his landmark book, From Ritual to Record, Allen Guttmann identified several characteristics of modern sports: rationalization, secularization, bureaucratization, quantification, and specialization. This study argues that commercialization has evolved as the most important factor in the modernization process, having become the engine that drives urban sport.

It endeavors to show, through a hegemonic theoretical framework and an historical explication, how capitalists usurped play and transformed it into a commercial and civic enterprise. They did so by forging an American sporting identity distinct from its British antecedents, professionalizing team sports to supersede commercial rivals, seizing control of the labor process from athletes, marketing sport as part of a new culture of consumption that garnered social capital, and eventually promoting civic teams as a tourist attraction, and fueling the gentrification of neighborhoods and urban redevelopment.

Without abstract submission.

OBLIGATORY SCREENING - CRITICAL REVIEW: THE UK EXPERIENCE

McKenna, W.

The Heart Hospital, London, United Kingdom

Individuals with inherited cardiomyopathy and arrhythmia are potentially at risk from disease complications, most notably sudden death. The vast majority of patients with these conditions, however, remain asymptomatic throughout life, and do not die suddenly. Indeed, data for hypertrophic cardiomyopathy suggests that 80% or more of individuals who fulfil stringent diagnostic criteria go undiagnosed. Current recommendations for athletic participation in cases of cardiomyopathy range from legislated prohibition (Italy), conservative restrictions (USA and ESC) to individualised recommendations (UK). Current guidelines have a limited evidence base and present recommendations that make no distinction in relation to heterogeneous disease expression, ignore the clinical ability to stratify disease severity and risk and make no attempt to determine the level of risk that is acceptable to the athlete, family or team. A revisit of our current approach incorporating the views of athletes and sporting bodies is warranted, particularly as there is an increasing impetus for screening programs which will increasingly identify asymptomatic athletes, the vast majority of whom will not have severe disease markers or be at significant risk of disease complications.

LOOKING AT SPORTS: DEATH IN SPECTATORS FROM A PUBLIC HEALTH PERSPECTIVE

Katz, E.

Centre Hospitalier Universitaire Vaudois, Switzerland

Sudden cardiac death (SCD) is a natural death due to cardiac causes, heralded by abrupt loss of consciousness within one hour of the onset of symptoms. The incidence of SCD in Europe is of 1 per 1000 persons/year and the estimated number of SCD varies from 184'000 to 450'000/year in the USA. The causes of SCD differ before and after 35 years. In young athletes common SCD causes are hypertrophic cardiomyopathy, coronary artery anomalies and right ventricular dysplasia. After 35 years coronary artery disease (CAD) is the first cause of SCD. The mechanism of 80% of SCD is that of ventricular tachycardia or ventricular fibrillation, 20% are due to bradycardia or asystole. For 50% of victims SCD is the first manifestation of CAD; 15%-20% of SCD occurs in public places (airport, shopping mall, stadium), but most (70-80%) happen at home. Currently reported survival rates are poor (near 5%).

Risk factors for SCD are nearly the same as that for CAD. Anger, mental stress, cocaine and marijuana use, heavy exertion and, exceptionally, sexual activity were described as initiating events (triggers) of myocardial infarction and SCD. It was suggested that the emotional intensity of sporting events and behaviors associated with spectating such as smoking and binge drinking could trigger SCD. Soccer has often been the focus of such studies since the intensity of football games is arguably unmatched by few other sporting events. The significant increase in cardio-vascular mortality on the day of important matches have been shown in the Netherlands and Great Britain. Our group confirmed the increase of SCD in Switzerland during major soccer tournaments.

The survival in SCD is dependent of a series of critical interventions including early defibrillation. Recently automated external defibrillator (AED) for laymen use was developed and AED deployment encouraged in public places and private homes. Public Access Defibrillation (PAD) initiatives promote basic life support (BLS) and defibrillation by laymen. The survival doubled in the PAD trial and tripled in Piacenza, where public initiative was limited to defibrillation. Studies from Germany and Spain confirmed the interest of early defibrillation programs on soccer stadiums. Spectators suffering from SCD were immediately treated – this resulted in impressive survival rates (up to 62% in Germany)!

We also advise general practitioners to inform their patients and their families before major sporting events about the risks of medical non-compliance, decreased physical activity and increased alcohol and tobacco consumption. More information has to be provided by physicians and the media about practical measures to adopt in case of chest pain or cardiac arrest. Information about how to reach Emergency Medical Service (EMS) and how to perform BLS has to be broadly advertised. The reinforcement of the EMS systems and PAD development should be proposed in order to reduce the burden of SCD during major sporting events.

THE LAUSANNE RECOMMENDATIONS AND BEYOND

Meijboom, E.J., Bille, K., Figueiras, D., Schamasch, P., Brenner, J.I., Meijboom, F.J.

Centre Hospitlier Universitaire Vaudoise (CHUV), Switzerland

Introduction: The incidence of sudden death(SD) in athletes is higher (~2/100000/year) than in non-athletes (RR 2,5:1), the cause is cardiovascular in over 90%. This study reports on SCD in sport and aimed at achieving a generally acceptable PPSP endorsed by the consensus meeting(CM) of, and recommended by the IOC.

Methods: A systematic review of the literature identified causes of SCD, gender, age, underlying cardiac disease and type of sport. Methods to detect pre-existing cardiac abnormalities were discussed to formulate a feasible and safe PPSP for the CM of the IOC. (http://www.olympic.org/uk/organisation/commissions/medical/full_story_uk.asp?id=1182)

Results: SCD occurred in 1101(1966-2004) reported cases in athletes under 35 years, 50% had congenital anatomic heart disease and cardiomyopathies and 10% had early onset athero-sclerotic heart disease. 40% occurred in athletes <18 yrs, 33% <16 yrs; female/male ratio was 1/9. Sports most frequently involved were soccer(30%), basketball(25%) and runnig(15%). PPSPs, if present at all, were of varying quality and content.

Invited symposium (IS)

IS1-12 VO2 Kinetics - "Innsbruck"

VO2 KINETICS: OLD AND RECENT LESSONS FROM EXPERIMENTS ON ISOLATED MUSCLE IN SITU

Grassi, B.

Universita' degli Studi di Milano, Italy

In "normal" conditions (e.g. normoxia, absence of pathological conditions) convective and diffusive O2 delivery to skeletal muscle fibers do not seem to represent important determinants for the kinetics of adjustment of oxidative phosphorylation following increases in metabolic demand. Whereas a limiting role by pyruvate dehydrogenase (PDH) has not been experimentally confirmed, inhibition of mitochondrial respiration by nitric oxide (NO) might be partially responsible for the inertia of oxidative phosphorylation at exercise onset. The main determinants of skeletal muscle O2 uptake (VO2) kinetics, however, likely reside in the intricate interplay between the various mechanisms of energy provision at exercise onset. By acting as high-capacitance energy buffers, phosphocreatine (PCr) hydrolysis and anaerobic glycolysis would delay or attenuate the increase in [ADP] within the cell following rapid increases in ATP demand, thereby "buffering" a more rapid activation of oxidative phosphorylation. The "PCr-Cr shuttle" concept of a regulatory role of PCr or of the products of PCr hydrolysis on oxidative phosphorylation provides a mechanism which couples VO2, which occurs in mitochondria, with PCr hydrolysis occurring in the cytoplasm.

REGULATION OF VO2 KINETICS AND ITS FUNCTIONAL CONSEQUENCES

Hughson, R.L.

University of Waterloo, Canada

Our daily lives are filled with constantly changing energy demands going from rest to moderate or heavy work loads. Therefore, it is critical that we understand those factors that can limit the rate at which the energy supply system adapts to the demands. The study of

oxygen uptake (VO2) kinetics provides insight into the mechanisms regulating the oxidative supply of ATP to working muscle. The supply of O2 to skeletal muscle and the utilization of O2 is a tightly coupled process controlled by complex, and at times controversial, mechanisms. At the onset of exercise, cardiac output and local muscle blood flow increase rapidly in response to both feed forward and feedback mechanisms. Yet, the fine regulation of O2 supply is dependent on the need for precise spatial distribution within a muscle in which recruited muscle fibers are adjacent to non-recruited fibers. The increase in metabolic substrate in the active fibers must be met by appropriate O2 supply to permit oxidative phosphorylation. A new model of the interactions between metabolic substrate, O2 and enzyme activity will be presented to yield a coherent view of the complex interactions that regulate VO2 at the onset of exercise. The model will be discussed with respect to recent controversies in the literature regarding whether VO2 is controlled exclusively by O2 supply, O2 demand determined by enzyme activity and/or metabolic substrate, or some interaction between supply and demand. There are frequent observations of slower VO2 kinetics under conditions such as hypoxia that point to the important role of O2 supply in regulating kinetics, but the difficulty in showing accelerated VO2 kinetics when O2 supply is increased has caused some researchers to propose that O2 is not limiting under conditions of moderate or even very heavy exercise. Details about the supply of blood flow and O2 to working muscles of humans are becoming available with techniques including Doppler ultrasound and near infrared spectroscopy. New results concerning O2 supply again provide evidence of the tight link between supply and demand. Determining factors that limit the rate of increase in VO2 is important to athletes and to patients with cardiovascular disease because of the impact on intracellular energy state, lactic acid production and the sensations of muscle fatigue that can influence performance and daily life.

COMBINED IN SITU DETERMINATION OF METABOLIC AND MYOELECTRIC CHANGES ASSOCIATED WITH O2 UPTAKE KINETICS DURING HIGH-INTENSITY EXERCISE IN HUMANS

Perrey, S.

UFR STAPS, France

Volume of oxygen uptake (VO2) is an indirect measure of cellular respiration and energy expenditure. The abrupt rise in VO2 when moving from a resting to a dynamic exercise steady-state has been identified as VO2 kinetics. When exercise intensity is above the blood lactate threshold, the attainment of a steady-state is either delayed or may not occur, and a secondary, slowly-developing component of increasing VO2 that appears to be linked in some way to the fatigue process, is observed. The purpose of this presentation was to provide some range of perspectives concerning the muscle contractile properties and the regulation of oxidative metabolism during the slow phase of the VO2 dynamics to exercise that still remains to be explained. Combined in situ approaches in our understanding of the plausible mechanisms for the VO2 slow component seem necessary.

In an effort to gain insight into the underlying mechanism(s) mediating the slow component, a number of studies have used electromyography (EMG) as a non-invasive tool to assess muscle fibre recruitment patterns during heavy exercise. Some studies demonstrated no change in EMG parameters (Scheuermann et al., 2001), whereas others have shown that integrated EMG (Perrey et al., 2001) and the mean power frequency of the EMG (Borrani et al., 2001) may reflect changes in muscle fibre recruitment pattern during the VO2 slow component. This suggests caution in the use of EMG as a quantitative tool for assessing muscle fibre recruitment patterns during dynamic exercise. Collectively, these studies indicate however that the increased recruitment of less efficient type II muscle fibers is a major cause of the VO2 slow component. The incorporation in our lab of non-invasive muscle function tests such as the measurement of force profiles to electrical stimulation to characterise better the pattern of activation of different ﬁbre types in humans seems promising compared to biopsy samples but is rather scarce (Garland et al., 2004).

Understanding the physiological mechanism responsible for the appearance of the slow component of VO2 kinetics requires also to considere both the factors involved in the decrease of the efficiency of the ATP-producing system, and the factors involved in the decrease in the efficiency of the contractile machinery using ATP. In this way, Rossiter and colleagues (2001) proposed that ATP splitting increases during the slow component phase, causing ADP to increase and PCr concentration to fall. The observation of a slow component of PCr hydrolysis during heavy exercise suggests an increase over time in the phosphate cost of force production, whereas the O2 cost of ATP production stays the same. This issue deserves more attention in the next future for our understanding of the decreased active locomotor muscle efficiency during high intensity exercise.

Invited symposium (IS)

IS1-13 Transendothelial transport limitations in insulin resistant skeletal muscles (sponsored by Astra Zeneca) - "St. Moritz"

INSULIN AND EXERCISE INDUCED MUSCLE CAPILLARY RECRUITMENT

Rattigan, S., Kolka, C.M., Ross, R.M., Bradley, E.A., Richards, S.M., Clark, M.G.

University of Tasmania, Australia

The vascular system controls the delivery of nutrients and hormones to muscle and a number of hormones may act to regulate muscle metabolism and contractile performance by modulating blood flow to and within muscle. Development of two new techniques to investigate microvascular blood flow within muscle in vivo has provided new insights into the action of insulin and contraction in the muscle vasculature. The first technique is based on the metabolism of an exogenous substrate, 1-methylxanthine (1-MX), for the enzyme xanthine oxidase that is found predominately in the capillary endothelial cells of skeletal muscle. The amount of 1-MX metabolism determined by arterio-venous sampling across a muscle bed reflects the degree of capillary perfusion and is suitable for animal experimentation. The second technique involves contrast-enhanced ultrasound imaging of muscle using perfluorocarbon gas-filled albumin or phospholipid microbubbles. This method can provide estimates of microvascular blood volume and velocity and has been used in studies in experimental animals and in human subjects.

Results from in vivo studies using these techniques have demonstrated that insulin mediates its own access and that of glucose to muscle by capillary recruitment and an increase in bulk blood flow. The capillary recruitment however is independent from the total blood flow and is an early and highly sensitive effect of insulin. Insulin resistance of muscle may result in part from an impaired hemodynamic action of insulin. Many factors associated with the metabolic syndrome result in inhibition of the insulin-mediated capillary recruitment and include hypertension, obesity, elevated fatty acids, inflammatory cytokines, and endothelin.

Muscle contraction also leads to a rapid recruitment of microvascular flow but the mechanisms that contraction uses appear to be different from insulin. Muscle contraction can overcome the impairment of insulin-mediated capillary recruitment in obesity and cytokine induced insulin resistance. However exercise training leads to an enhancement of insulin-mediated capillary recruitment suggesting there is interaction between the processes. Further elucidation of the mechanisms and interactions between contraction- and insulin-mediated capillary recruitment will be important to provide insight into how insulin resistance can be overcome.
Neither the mechanism of insulin- or contraction-mediated capillary recruitment has been fully elucidated, but insulin action may involve endothelial factors such as nitric oxide (NO) and endothelial derived hyperpolarizing factors (EDHFs). The involvement of these factors in endothelial dysfunction associated with the metabolic syndrome provides a link between insulin resistance and cardiovascular disease.

REDUCED MUSCLE PERFUSION IN THE OBESE ZUCKER RAT

Frisbee, J.

West Virginia University School of Medicine, United States

The obese Zucker rat is a model of the metabolic syndrome, with its genesis in a leptin receptor deficiency resulting in chronic hyperphagia. Ensuing from this chronically elevated food intake, the obese Zucker rat (OZR) rapidly becomes obese, developing an increasing insulin resistance and impaired glycemic control, and a profound elevation in plasma triglyceride levels. Additionally, the OZR, following sexual maturity also develops a moderate, clinically-relevant degree of hypertension. As has been repeatedly demonstrated in human subjects afflicted with the metabolic syndrome, a crucial developing condition in these animals is a reduction in volume perfusion of skeletal muscle, both under resting conditions and in response to controlled elevations in metabolic demand. This presentation will discuss distinct elements underlying the progressive impairments to resting skeletal muscle perfusion and active hyperemia. We have previously demonstrated that the OZR exhibits a series of impairments in the ability of skeletal muscle resistance arterioles to dilate in response to both pharmacological and physiological stimuli. Further we have determined that, under reduced conditions, imposed improvements in vascular oxidant tone can ameliorate many of these constrained responses. However, the extent to which impairments to endothelium-dependent dilator reactivity contribute to reductions in skeletal muscle perfusion, or whether acute improvements in dilator responses improve muscle blood flow remain unclear. Vasoconstrictor responses, most notably in response to adrenergic stimuli, certainly appear to constrain muscle perfusion, both at rest and in response to mild elevations in metabolic demand; although metabolic influences can override adrenergic constraint on perfusion, this process is simply right-shifted to higher degrees of metabolic demand. Perhaps most compelling may be the contribution of progressive alterations to microvascular structure, at both the individual vessel and intact network levels of resolution, to the genesis of an ischemic condition, as individual resistance arterioles suffer reductions in wall distensibility and the microvessel network experiences a profound rarefaction in the OZR afflicted with the metabolic syndrome. This presentation will also encompass the effects of interventional strategies targeted at ameliorating these microvascular impairments and, by extension, the compromised perfusion levels. Specifically, these discussions of interventional strategies will focus on the effects of chronic reductions in vascular oxidant tone, treatments of hypertension and insulin resistance, and the beneficial impact of a chronic exercise regimen in OZR prior to the development of the full metabolic syndrome.

MICROCIRCULATORY FUNCTION AND INSULIN RESISTANCE

Stehouwer, C.

University Hospital Maastricht, Netherlands

Microcirculatory function and Insulin Resistance
C.D.A. Stehouwer, MD, PhD, Professor of Medicine
Department of Medicine, University Hospital Maastricht and Maastricht University, PO Box 5800, 6202 AZ Maastricht, the Netherlands. E-mail: csteh@sint.azm.nl
Abstract
Insulin resistance, hypertension and microcirculatory dysfunction are interrelated phenomena, which all, in addition, have several determinants in common, notably ageing, smoking, obesity, inflammation, and low birth weight. We propose that microvascular rarefaction and microvascular endothelial dysfunction explain in part why insulin resistance is linked to hypertension. On the one hand, there is evidence that microvascular dysfunction increases peripheral vascular resistance and thus, other things being equal, blood pressure. On the other hand, microvascular dysfunction decreases insulin-mediated glucose uptake in muscle, the latter by impairing the timely access of glucose and insulin to target tissues such as muscle. We suggest that any condition that impairs microvascular function will predispose to both insulin resistance and hypertension.

Invited symposium (IS)

IS1-14 ICSSPEE moral development in sport - "Albertville"

MORAL DEVELOPMENT RESEARCH IN SPORT: SOME PHILOSOPHICAL REFLECTIONS

Jones, C.

University of Wales Institute Cardiff, United Kingdom

The fairly gloomy conclusions of moral psychological research in sport are by now reasonably familiar. Shields' and Bredemier's early findings in particular painted a pessimistic picture of sport' affect on the moral character of those who play it. There has been much criticism of the attempts to describe empirically the relationship between sport and morality. The focus of the criticism has concentrated on a few key issues. It has been argued that all "scientific" research into morality is wrongheaded and can never achieve scientific objectivity given the inescapably normative nature of the subject under scrutiny. Other criticisms have focused on the normative commitments to deontological ethical theory implicated in the evaluations made. In this paper I aim to focus specifically on the conceptualisation of moral character implicitly and explicitly implicated in the research into sport and morality. Drawing on the valuable insight of Shields and Bredemeier, I will argue that moral character is significantly more complex than is often acknowledged. I will also argue, following Flanagan (1991) that an account of moral character, including a sport specific account, must be realistic and not compromised by opera-

tional considerations. I will sketch an alternative, non-reductive, virtue theoretically informed account of moral character and identify the implications for playing sport in a morally appropriate way.

MORAL FUNCTIONING, MORAL ATMOSPHERE, AND YOUTH SPORT: THE IMPACT OF COACH-CREATED MOTIVATIONAL CLIMATE

Miller, B.W.

Norwegian School of Sport Sciences, Norway

Most research from a sport social-psychological perspective has focused on the individual agent when pursuing questions regarding character aspects in sport (i.e., Bredemeier & Shields, 1986; Dunn & Causgrove-Dunn, 1999; Kavussanu & Roberts, 2001). The present study deviated somewhat from this perspective in that the perceptions of the coach's motivational cues were of central interest regarding moral functioning and moral atmosphere among youth football players. Participants for the study were 366 youth football players (n=242 males, n=124 females) from 34 teams in and around greater Oslo, Norway. A Norwegian version of the PMCSQ-2 (Newton et al., 2000) was used to measure perceived motivational climate. Scenario-based measures (Kavussanu & Roberts, 2001; Shields et al., 1995; Miller, 2004) were used to examine moral functioning according to Rest's (1984) model of moral action (e.g., moral judgment, reasoning, intention, and behavior) as well as both teammate and coach influenced moral atmosphere. Factor analysis of the PMCSQ-2 revealed four distinct subscales representing both mastery and performance climates: cooperative learning and important role (mastery), and unequal recognition and punishment for mistakes (performance). Canonical correlation analyses were employed to examine associations between the climate perceptions as predictor and the moral variables as criterion variables, respectively. A significant overall statistic revealed that moderate cooperative learning and important role, coupled with both high unequal recognition and punishment for mistakes was associated with overall low moral functioning and both teammate and coach influenced low team moral atmosphere. These results indicate how important coaches can be regarding youth interpretation of what is moral and non-moral in competitive sport, and how specific motivational cues perhaps may or may not affect moral functioning and team moral atmosphere. Moreover, the present findings may also be interpreted in a different manner than arguments posed by Shields and Bredemeier (1995) in that a mastery climate emphasis is essential if sport morality is desired. Specifically, it may not only be a strong mastery emphasis that is key to higher sport morality, but instead (or at the very least in conjunction with a mastery emphasis) a conscience decision on downplaying a "win at all cost" performance climate by the coach is what is needed.

DISAFFECTED YOUTH AND PHYSICAL ACTIVITY PROGRAMMES

Armour, K., Sandford, R.

Loughborough University, United Kingdom

Youth disaffection is a complex phenomenon that can manifest itself in numerous ways including disengagement from mainstream activities, engagement in disruptive or antisocial behaviour and involvement in petty crime. Disaffection is currently identified as a particular problem within schools, where it is reported that increases in the numbers of disaffected young people has resulted in higher levels of disruptive behaviour, truancy and exclusions, and low academic standards (Steer, 20000). Remedial programmes for disaffected youth tend to have broad aims that are focussed around reducing deviant behaviour, raising aspirations and promoting pro-social development (Merton & Parrott, 1999). Within this broad framework, there is an enduring belief in the value of physical activity programmes to secure a wide range of benefits for disaffected or disengaged young people (Miller, Bredemeier & Shields, 1997). Indeed, one of the key ways in which the UK government is attempting to tackle youth disaffection is through the provision of additional opportunities and facilities to enhance participation in physical education, physical activity and community sport. Yet, although high aspirations are held for the benefits of youth physical activity programmes, empirical evidence is comparatively sparse (Long & Sanderson, 2001; Morris, Sallybanks, Willis & Makkai, 2003). One of the reasons for this might be that the task of collecting credible research evidence to support claims made for individual sport and physical activity programmes is daunting. Nonetheless, there is a strong theoretical foundation underpinning the physical activity/positive youth development field, largely emanating from a number of key authors in the US, for example Burt (1998), Lawson (1995, 1997, 1999) and Hellison (1988, 1995). What is required, therefore, is longitudinal and systematic evaluation research that can build on those foundations (Sandford, Armour & Warmington, 2006). This paper, therefore, has three key objectives:

· To summarise the existing evidence base on the benefits of physical activity and sport programmes for disaffected or disengaged youth

· To report illustrative data from the first three years of a longitudinal evaluation (five years) of two corporate-sponsored programmes in the UK, both of which are seeking to use physical activity as a vehicle for enhancing young people's personal and social development

· To explore some of the methodological challenges faced in undertaking research in this field.

EFFECT OF FASCICLE LENGTH CHANGES ON THE ESTIMATION OF VOLUNTARY ACTIVATION DURING ISOMETRIC CONTRACTIONS

Arampatzis, A., Mademli, L., De Monte, G.

German Sport University Cologne, Germany

The activation level (AL) during isometric contractions has been often estimated by the interpolated twitch technique [1,2]. In this method the evoked interpolated twitch torque (ITT) normalized to the resting twitch torque (RTT). However this normalization postulate that the potential of the examined muscle to generate force in the rest and during the contraction is the same. During a contraction the fascicle length do not remain constand [3] and so the above postulation is not given. Therefore the aim of this study was to examine the influence of the fascicle length changes during an isometric contraction on the estimation of voluntary activation (VA).

Twelve subjects participated in the study. All subjects performed isometric maximal voluntary contractions (MVC) at two different ankle angle positions (75 and 90° ankle angle, knee fully extended) on a Dynamometer. Additional at each position four submaximal voluntary isometric contractions (20, 40, 60 and 80% of the preexamined MVCs) were recorded. The twitch (triple twitches) interpolation technique was used to determine the VA of the triceps surae muscle during the contractions. Further the MVCs and the twitches were repeated for 6 other ankle positions. The ankle angle was changed from 85° to 115° in 5° intervals keeping the same knee angle. The kinematics of the leg were recorded using the vicon system (8 cameras 120 Hz) to calculate the resultant moment at the ankle joint. Two ultrasound probes were used to determine the fascicle length of gastrocnemius medialis, gastrocnemius lateralis and soleus muscles at rest and during the contractions. The AL were calculated using the RTT (a) at the same ankle positions (traditional method) and (b) at an ankle position where the weighted fascicle length of the triceps surae between ITT and RTT showed the minimal differences (fascicle length consideration method).

As expected fascicle length and ITT reduced as a the level of voluntary contraction increases. At different ankle angles the fascicle length at rest and the RTTs showed also different values. From 75° to 95° ankle angle the RTTs increases and from 95° to 115° decreases. The two methods showed statistically significant differences ($p<0.05$) in the estimation of the AL wich are depended on the ankle angle. The absolute differences of the AL estimated by the two methods to the actual voluntary activation were also depended on the ankle angle and showed lower values by the fascicle length consideration method.

The changes in fascicle length during isometric contractions influence the estimation of the VA. The amount of influence is ankle angle depended. The consideration of the fascicle length changes reduce the absolute differences to the actual level of the voluntary contraction. However the differences remained in average between 3 and 8%.

BIOMECHANICAL VARIABLES IN RUNNING AND ITS RELATION TO SPECIFIC OVERUSE INJURIES

Grau, S., Maiwald, C., Krauss, I., Mauch, M., Horstmann, T.

University Clinics Tübingen, Germany

The objective clinical and biomechanical classification of overuse injuries, such as iliotibial band syndrome (ITB) and patella tendon syndrome (PTS) is of great interest to provide important information in the development of running shoes and orthotics, as well as in the understanding of overuse injuries in general. Over the years, many authors (Fredericson 2000, Orchard 1996, Khaund 2005) assumed that overuse injuries are caused by different biomechanical variables, such as the extent of pronation, increased hip adduction as well as varus forefoot and valgus leg axis. Nevertheless, scientific proof was rather poor.

Healthy male and female runners (COm, COf) and runners with ITB and PTS overuse injuries were biomecanically analyzed. The biomecanical measurements included 3-D kinematics of the lower extremity (6 camera Vicon System, 250 Hz), as well as plantar pressure distribution (emed-xt, 100Hz, 4 sensores/cm2) in barefoot running (overground) at 12km/h. 3-D kinematics was used to describe segmental frontal and sagittal plane movements. Pressure distribution evaluations included path of center of pressure (COP) in addition to loading patterns of specific anatomical regions of the foot. Statistical analysis was based on descriptive statistics as well as on ANOVA ($\alpha = 0.05$) and Tukey Kramer´s Test ($\alpha = 0.05$).

Results showed different patterns (PTS: over-pronation and medial kollapse; ITB: over-supination at stance and push-off) of overuse injuries. Moreover, kinematic variables showed more distinct differences than pressure distribution variables.

Results indicate the need for additional running shoes (besides stability and neutral shoes) to control (reduce) amount of supination, especially at push-off.

AGE-RELATED ADAPTATIONAL PHENOMENA WHILE RUNNING ON DIFFERENT SURFACES

Karamanidis, K., Brüggemann, G.P., Arampatzis, A.

German Sport University Cologne, Germany

The goals of the study were (i) to investigate whether older adults modify their running task execution to compensate for the degeneration in their leg extensor muscle-tendon units (MTUs), and (ii) to examine whether modifications in surface condition affect age-related changes in running mechanics. The investigation was executed on 30 older (aged 60-69 years) and 19 younger (aged 21-32 years) adults. In a previous study [1] we documented that the older had lower muscle strength and lower tendon stiffness in their leg extensor

MTUs. In the current study ground reaction force ([GRF] Kistler, 1080Hz) and kinematic data (Vicon, 120Hz) were recorded as the same subjects ran at 2.7m/s over three surfaces having different compliance. To calculate the rate of force generation (Fgen) we divided the average vertical force per kg body weight divided by the ground contact time [2]. The proportion of the centre of mass (COM) transport during stride cycle whilst the subjects have contact with the ground was calculated as the ratio between anterior COM displacement during ground contact and anterior COM displacement during stride cycle (Ratiodis). The gear ratio of the leg extensor muscles was calculated as the ratio (R/r) of the moment arm (R) of the GRF acting about the joint to the agonist tendon moment arm (r) [3].

Older adults had higher duty factor, lower flight time, higher Ratiodis, lower Fgen and lower maximal moment and mechanical power at the ankle joint compared to the younger ($p<0.01$). Further, older adults showed lower gear ratio at the ankle joint during the mid part of the contact phase (from 26% to 58%) by means of lowering the moment arm of the GRF acting about the ankle joint. Surface condition did not affect detected age-related changes in COM trajectory, duty factor or joint kinetics ($p>0.01$). However, when running on the soft surface, the gear ratio at the ankle joint was lower during the mid part of the contact phase (from 42% to 58 %) than on the hard surface ($p<0.01$) but these changes did not depend on subjects age.

We concluded that the older adults react to the reduced MTUs capacity by increasing safety while running (higher duty factor, higher Ratiodis, lower flight time) and benefit from a mechanical advantage for the triceps surae MTU and a lower rate of force generation. Moreover, the improvement in running mechanics and safety of the aged musculoskeletal system while running was present for all surface conditions. We suggested that older adults are able to reorganize their running strategy to adjust the task effort to their reduced MTUs capacities for a variety of mechanical environments. It appears, further, that the changes in the musculoskeletal system over human lifespan has a essentially higher effect on running mechanics than changes in surface characteristics.

MECHANICAL LOADING, RUNNING RELATED INJURIES AND FOOTWEAR CONSTRUCTION: WATH DID WE LEARN IN THE LAST THIRTY YEARS?

Segesser, B., Brüggemann, G.P., Kälin, X.

Praxisklinik Rennbahn, Switzerland

During the last decades biomechanics had a strong influence on the functional design of sport shoes. The decrease of impact forces was predominant for a long time in sport shoe research. The soft cushioning materials, however, increased the instability of the rear foot and was one of the reasons for overpronation causing typical overuse problems at the runner's lower leg and Achilles tendon. The control of overpronation by different materials and techniques was basically a compensation of the problems induced by overdimensioned cushioning systems. The medial support elements themselves lead to a lateral shift during take-off which needed to be compensated as well. Hence, the philosophy of "Cushioning –Control – Guidance" was born as a compensation strategy of different errors. It influenced sport shoe design in all brands for decades and was not able to reduce injuries effecively. Therefore, new strategies should allow natural foot movements by avoiding additional levers of the shoe in all directions. In addition to this such a new concept should support the neuromuscular informations and functions using technologies influencing muscular function optimisation (TIMO®).

LEUKOCYTE INFILTRATION IS NOT RELATED TO DELAYED ONSET MUSCLE SORENESS AFTER HIGH-FORCE ECCENTRIC EXERCISE AND INHIBITION OF COX-2 DOES NOT ATTENUATE LEUKOCYTE INFILTRATION

Paulsen, G., Fjeld, J.G., Hallén, J., Raastad, T.

Norwegian School of Sport Sciences , Norway

The mechanisms behind delayed onset muscle soreness (DOMS) after unaccustomed, high-force exercise are elusive; muscle damage and subsequent inflammation is regarded as the main culprit. Inflammation includes infiltration of leukocytes, release of numerous chemical substances and tissue swelling. This is believed to hypersensitize nociceptors and cause muscle soreness (Connolly et al., 2003). The main purpose of this study was to investigate the significance of leukocyte infiltration on DOMS.

Seventeen subjects (25 ± 2 yr, 176 ± 8 cm, 73 ± 8 kg; mean ± SD) performed 70 unilateral maximal eccentric repetitions with their elbow flexors. The subjects were divided into two groups: The Celebra group (n = 8) received celecoxib (an anti-inflammatory drug; COX-2 inhibitor; 2 x 200 mg per day for ten days), whereas the Placebo group (n = 9) received lactose pills. Medication started one hour before exercise. Infiltration of transfused, autologous radiolabelled leukocytes was measured with a gamma camera six and 20 hours after exercise. Maximal voluntary isometric torque was measured before and regularly for ten days after exercise. A visual analogue scale was used to measure DOMS, and tape circumference measurement was used to detect swelling.

Six hours after exercise the concentration of leukocytes was 43 ± 10 vs. 45 ± 11 % higher in the exercised arm than in the control arm in the Celebra and Placebo group, respectively (mean ± SEM; $p < 0.05$). Twenty hours after exercise this difference was increased to 82 ± 28 % in both groups. Immediately after exercise isometric force-generating capacity was reduced by 48 ± 4 and 52 ± 4 % for the Celebra and Placebo group, respectively. After nine days isometric force-generating capacity was still 14 ± 5 and 25 ± 5 % below pre exercise value for the Celebra and Placebo group, respectively. Two days after exercise, the Placebo group reported higher DOMS values than the Celebra group (6.4 ± 0.6 vs. 4.1 ± 0.7 mm; $p < 0.05$). The circumference of the upper arm peaked three and four days after exercise, 3.6 ± 1.1 and 2.4 ± 1.2 % above pre exercise value, for the Placebo and Celebra group, respectively. No correlations were found between the infiltration of leukocytes and DOMS, nor were there any relationships between changes in muscle function and DOMS.

DOMS does not seem to be related to neither changes in muscle function nor infiltration of leukocytes in a dose-dependent manner. The anti-inflammatory drug celecoxib was not effective in reducing leukocyte infiltration, but attenuated DOMS. Since celecoxib inhibit the COX-2 enzyme, this may indicate that COX-2 is involved in DOMS. Surprisingly, the magnitude of infiltration does not seem to be signifi-

cantly affected by the COX-2 inhibitor. However, similar findings are reported by Peterson et al. (2003) after administrating other types of anti-inflammatory drugs.

TIME-COURSE AND DIFFERENTIAL EXPRESSION OF HEAT SHOCK PROTEINS IN HUMAN SKELETAL MUSCLE FOLLOWING NON-DAMAGING TREADMILL EXERCISE: IS HEAT A MECHANISM OF ACTIVATION?

Morton, J., MacLaren, D.P., Cable, T., McArdle, A., Drust, B.

Liverpool John Moores University, United Kingdom

The exercise-induced expression of heat shock proteins (HSPs) as a cellular stress response in rodent models is relatively well defined (McArdle et al., 2001). Comparable data from human studies, however, are limited and the mechanisms contributing to the exercise-induced production of HSPs are far from understood. Although exercise-associated hyperthermia is routinely cited as a possible signal responsible for inducing an increased production of HSPs following exercise, this hypothesis has not been formally tested in human skeletal muscle. The aim of the present study was to therefore characterise the time-course of response of the major HSP families in human skeletal muscle following a running exercise protocol and to test the hypothesis that increased muscle and core temperature mediate the increased production of HSPs following exercise.

Eight healthy active males performed 45 min of running exercise at a treadmill speed corresponding to their lactate threshold. Muscle biopsies were obtained from the vastus lateralis muscle immediately prior to and at 24 h, 48 h, 72 h and 7 days post-exercise. Seven healthy active males also underwent a passive heating protocol of 1 h duration in which one leg was immersed in a tank containing hot water (45 °C). The contra-lateral limb remained outside the tank and was not exposed to heat stress thus serving as a control leg. Muscle biopsies were obtained from the vastus lateralis of both legs immediately prior to and at the time of peak HSP expression induced by exercise (observed to be at 48 h and 7 days post-heating). The exercise and heating protocol induced significant increases ($P<0.05$) in rectal (1.7±0.3 and 1.5±0.2 °C, respectively) and muscle temperature (3.8±0.8 and 3.7±0.6 °C, respectively). Muscle temperature of the control leg showed no significant change following heating (pre: 36.1±0.5, post: 35.6±0.4 °C). Exercise induced a significant ($P<0.05$) but variable increase in HSP70, HSC70 and HSP60 expression with peak increases (typically occurring at 48 h post-exercise) of 210±70%, 170±75% and 139±23% of pre-exercise levels, respectively. In contrast, heating failed to induce a significant increase in muscle content of these proteins. Neither heating nor exercise induced a significant increase in HSP27, αB-crystallin, MnSOD protein content or the activity of superoxide dismutase and catalase.

This study is the first in which the time-course and extent of HSP production in human skeletal muscle have been characterised following a moderately demanding running exercise protocol. Data demonstrate that the skeletal muscle of healthy active young males adapts to such stresses via an increased production of several HSPs (predominantly HSP70) where peak responses typically occur at 48 h post-exercise. We conclude that increases in both systemic and local temperature per se appear not to be mediating this response.

McArdle, A. et al. (2001). Am J Cell Physiol, 280: C621-C627.

EFFECT OF A FED OR FASTED STATE ON THE SALIVARY IMMUNOGLOBULIN A RESPONSE TO EXERCISE

Allgrove, J., Geneen, L., Latif, S., Gleeson, M.

Loughborough University, United Kingdom

It has been previously suggested that the nutritional status of an individual can influence the levels of salivary immunoglobulin A (s-IgA) at rest, yielding higher and more variable concentrations in fasting saliva compared to non-fasting saliva (Gleeson et al., 2004). Prolonged, strenuous exercise has been associated with changes in the levels of this antibody (Gleeson et al., 2003) however, the influence of the fed or fasted state on the s-IgA response is unknown. Thus, the present study investigated the effect of a fed or fasted state on the s-IgA response to prolonged cycling. Using a randomised cross-over design, 8 males and 8 females of mixed physical fitness, mean (SEM) age 22 (1) years, performed 2 hours cycling on a stationary ergometer at 65% of their maximal oxygen uptake on one occasion following an overnight fast (FAST) and on another occasion following the consumption of a 2.2 MJ high carbohydrate meal (FED) 2 hours before. Timed, unstimulated whole saliva samples were collected immediately before ingestion of the meal, immediately pre-exercise, at 5 minutes before cessation of exercise, immediately post-exercise and at 1 hour post-exercise. The samples were analysed for s-IgA concentration, osmolality and cortisol and saliva flow rates were determined to calculate the s-IgA secretion rate. Salivary data were analysed using a two factor repeated measures ANOVA and post hoc t-tests with Holm-Bonferroni adjustments were applied where appropriate. Carbohydrate oxidation was significantly higher ($P<0.05$) and fat oxidation tended to be lower ($P=0.06$) in FED compared to FAST. Saliva flow rate decreased during exercise from 0.50 (0.04) mL/min to 0.37 (0.03) mL/min ($P<0.05$), s-IgA concentration increased during exercise from 163 (20) to 232 (24) mg/L ($P<0.05$) but the s-IgA secretion rate remained unchanged, pre-exercise: 79 (11) µg/min, post-exercise: 74 (9) µg/min. There was a significant reduction in the s-IgA:osmolality ratio from 2.3 (0.2) pre-exercise to 1.5 (0.1) post-exercise ($P<0.05$). Salivary cortisol increased from 9.9 nmol/L (1.6) pre-exercise to 16.7 (2.9) nmol/L post-exercise ($P<0.05$). There was no effect of FED versus FAST on these salivary responses. The immediately pre-exercise values of s-IgA were 165 (27) and 161 (27) mg/L in the FED and FAST trials, respectively. The s-IgA concentration and secretion rate were found to be significantly lower in females than in males across all time points ($P<0.05$); however, there was no significant difference between genders in the saliva flow rate or the s-IgA:osmolality ratio. These data demonstrate that the nutritional status does not influence resting s-IgA or the s-IgA response to prolonged exercise. Furthermore, these data suggest a significant effect of gender on resting s-IgA levels without affecting the acute response to exercise.

HEART RATE VARIABILITY THRESHOLDS AND HEART RATE DEFLEXION POINT DURING MAXIMAL RUNNING EXERCISE IN CIRCUMPUBERTAL BOYS: ACCURATE METHODS TO ASSESS VENTILATORY THRESHOLDS?

Buchheit, M., Solano, R., Millet, G.P.

Laboratoire de Recherche Adaptations Réadaptations (APS et conduites motrices), France

Together with maximum oxygen uptake, ventilatory thresholds (VT1 and VT2) are the physiologic measures the most used to characterise aerobic fitness. To approach VTs without gas analysis, some authors have proposed to use the heart rate profile during exercise, while

determining either the so-called heart rate deflexion point (HRDP) or, more recently, the two HR variability (HRV) thresholds (HRVT1 and HRVT2). The purpose of this study is to verify the accuracy of using heart rate alone to assess ventilatory thresholds in circumpubertal boys during running exercise. 79 adolescents (aged 13.4 ± 1.3, 159.2 ± 1.41 cm and 46.8 ± 11.2 kg) took part in the study and underwent a graded treadmill test where all ventilation parameters and beat to beat HR were continuously recorded. Ventilatory thresholds were first determined from ventilatory equivalents (VE/VO2 and VE/VCO2) curves vs speed [3]. HRV thresholds were determined from the fHF.HF index (high frequency (HF) power density multiplied by the HF frequency) curve vs. speed [1]. HRDP was determined by the successive slopes methods [2]. Results show that mean HR at VT1 and HRVT1 was not significantly different (160.3 ± 12.4 vs 159.0 ± 14.5 bpm), whereas speed was higher at VT1 than at HRVT1 (8.7 ± 1.3 vs 8.4 ± 1.3 km.h-1). Coefficient correlation between speeds at VT1 and at HRVT1 was moderate (r=0.62) although significant (P<0.001). The speed difference between VT1 and HRVT1 was higher than 5% in 67.1% of the subjects. HR was significantly lower at VT2 than at HRVT2 and HRDP (185.9 ± 8.3 vs 188.7 ± 9.0 and 188.0 ± 7.4 bpm). Speeds were similar between VT2 and HRDP (11.9 ± 1.4. and 11.9 ± 1.8 km.h-1), and were significantly lower than the speed at HRVT2 (12.3 ± 1.6 km.h-1). Coefficients correlation between speeds at VT2 and at HRVT2 and HRDP were significant (P<0.001) but moderate (r=0.62 and 0.56). Compared to speed at VT2, 60.8% and 74.7% of the adolescents displayed speed differences higher than 5% at HRVT2 and HRDP. To conclude, the present study suggests that HR monitoring during running exercise in circumpubertal boys could be an interesting alternative way to approach HR and running speeds at VT1 and VT2, but, as we observed very accurate assessments only in a small proportion of the subjects, we can not recommend to replace usual VTs determinations by HRV thresholds or HRDP observation.

RELATED TRENDS IN LOCOMOTOR AND RESPIRATORY MUSCLE OXYGENATION DURING EXERCISE

Legrand, R., Marles, A., Prieur, F., Mucci, P.

Université de Lille 2, France

In healthy young subjects, the high metabolic demand of respiratory muscles could affect blood flow redistribution to these muscles, to the detriment of locomotor muscle[1]: it induce reduced leg blood flow associated with preserved O2 extraction by the muscle, leading to reduced leg muscle VO2. This "steal" phenomenon has been demonstrated in endurance trained athletes with high minute ventilation level (VE). One may wondered if respiratory muscle work could also alter locomotor oxygen delivery and utilization in non-endurance trained subjects. Although, these peoples presents lower VE and lower O2 cost of hyperpnea than endurance athletes, they have also lower cardiac output that could led to a respiratory "steal" phenomenon. One other concern is that the intensity at which this phenomenon could occur is still controversial.

Thus we investigated the potential effect of respiratory muscle work on leg muscle oxygenation in non-endurance trained subjects and searched for the range of intensity when this effect could occur.

Accessory respiratory and leg muscle oxygenation patterns were monitored continuously with near infrared spectroscopy (NIRS) in 15 healthy young men performing maximal incremental exercise on a cycle ergometer. Pulmonary gas exchanges were collected. Respiratory compensation point (RCP) was determined. Oxygenation (RMO2) and blood volume (RMBV) of the serratus anterior (accessory respiratory muscle) and of the vastus lateralis (LegO2 and LegBV) were monitored with NIRS. The breakdown point of accessory respiratory muscle oxygenation (BPRMO2), the accelerated (BP1LegO2) and attenuated fall (BP2LegO2) in leg muscle oxygenation were detected.

BPRMO2 occurred at ~85% VO2max and was related to RCP ($r = 0.88$, $P < 0.001$). BP2LegO2 appeared at ~83% VO2max and was related to RCP ($r = 0.57$, $P < 0.05$) and with BPRMO2 ($r = 0.64$, $P = 0.01$). From BP2LegO2 to maximal exercise, LegBV was significantly reduced ($P < 0.05$).

The appearance of the accelerated drop in accessory respiratory muscle oxygenation – associated with high ventilatory level - was related with the attenuated fall in leg muscle oxygenation detected with NIRS. This suggests that the high oxygen requirement of respiratory muscle leads to limited oxygen utilization by locomotor muscles as demonstrated in endurance trained subjects. The observed phenomenon was associated with reduced leg blood volume supporting the occurrence of leg vasoconstriction. These events appeared not only at maximal exercise but onward above the respiratory compensation point.

CHANGE TO ANAEROBIC TRAINING IMPROVES RUNNING ECONOMY AND HIGH INTENSITY EXERCISE PERFORMANCE IN ENDURANCE RUNNERS

Iaia, F.M. 2,1, Kolding, H. 1, Gunnarsson, T. 1, Wendell, J. 1, Rostgaard, T. 1, Nybo, L. 1, Krustrup, P. 1, Bangsbo, J. 1

1 Institute of Exercise and Sport Sciences, University of Copenhagen, 2 Faculty of Exercise Sciences- State University of Milan, Italy, Denmark

INTRODUCTION

Skeletal muscles have a great ability to adapt to changes in physical activity. Recently, Burgomaster et al. (2005) have reported a marked increase in muscle oxidative potential and cycle endurance capacity of untrained males after only six session of sprint interval training. The aim of the present study was to examine the physiological response to exercise and changes in performance as a result of a change to high-intensity training in trained endurance runners.

METHODS

Fifteen sub-elite endurance runners (mean±S.E.M; age: 34.4±1.5 yrs; body mass: 74.0±2.3 Kg; height: 180.4±2.0; experience: 6.3±1.2yrs; VO2 peak: 54.2±1.4 ml/kg/min) were matched and randomly assigned to either an experimental (EG, N=8) or control group (CG, N=7). The CG continued the training as during the period prior to the study (mainly aerobic moderate intensity training, 3-4 times a week), while the EG for a 4-wk period replaced their normal training by performing 3-4 sessions a week of high-intensity intermittent exercise (HIT) each consisting of 8-12 repeated 30-s supra-maximal running efforts separated by 3 min of rest. Before (PRE) and after (POST) the 4-wk period the athletes completed: 1) four 6-min sub-maximal treadmill running stages followed by an incremental test to exhaustion to determine VO2 max (T1); 2) Two supra-maximal intense exercise bouts to exhaustion on a treadmill (T2), 3) a 10,000-m race on a track (10K); 4) the Yo-Yo intermittent recovery test - level 2 (Yo-Yo IR2); 5) a 30-s "all out" running effort. Heart rate and pulmonary oxygen uptake were measured and blood samples were collected frequently during T1 and T2.

RESULTS

In T1, EG improved (P<0.05; Students Paired t-test) running economy (ml/kg/km) at speeds of 13.0, 14.5 and 16.0 km/h (7.3%, 5.2% and 6.4% respectively), whereas no significant changes were observed in CG at either speeds. For EG, time to exhaustion in the 1st and 2nd bout of T2POST were 24.6% and 18.0% longer (P<0.05), respectively, than T2PRE. No changes were observed in CG. Furthermore, in EG the Yo-Yo IR2 performance was 18.2% better (P<0.05) after HIT, with no significant change for CG (+4.3%). In EG the distance covered during the 30-s all-out test was 6.8% longer (P<0.05) after the training period. VO2 peak and 10K performance remained unaltered in both groups.

CONCLUSION

The present study showed that the anaerobic training improved performance during supra-maximal and intermittent exercise, and maintained the aerobic fitness and endurance performance of trained runners. Furthermore, running economy at medium and high sub-maximal intensities was enhanced. These changes occurred despite a dramatic reduction in training volume.

COMPARISON OF A MODEL PREDICTED MAXIMAL LACTATE STEADY STATE POWER OUTPUT TO A MEASURED MAXIMAL LACTATE STEADY STATE POWER OUTPUT IN ATHLETES

Neupert, E., Smith, D.J., Norris, S.R.

University of Calgary, Canada

Maximal lactate steady state (MLSS) is an important measure of athletic performance. It is defined as the the highest intensity of a constant load exercise that elicits an equilibirum between lactate accumulation and removal. Currently no consensus exists regarding the test duration of MLSS, or the criterion change in blood lactate [BLa-] that constitutes MLSS. However a minimum test duration of 30 min at the highest intensity where [BLa-] does not increase above 1 mmol/L during the final 20 min of exercise has previously been cited (1) Theoretically the attainment of MLSS could be mathematically defined as a slope of zero when [BLa-] or [HCO3-] is expressed as a function of time. The aim of this pilot study was to evaluate the observed power output at MLSS (MLSSw) in comparison to a mathematical model predicting MLSSw. Observations from a previous training study in this laboratory generated these proposed models: for [BLa-] (a) (%MLSSw = 47.393*[BLa-] slope + 100) and for [HCO3-] (b) (%MLSSw = 56.211* [HCO3-] slope – 100). The calculated slope of [BLa-] or [HCO3-] against time in a constant load ride above the lactate minimum power output (LMPO) was substituted into these equations. From these predicted results the wattage at 100% of MLSSw was calculated. Seven male trained cyclists performed an incremental VO2max test to determine maximum aerobic power (MAP) (mean MAP = 5.1 W/kg and VO2max = 60.2 ml/kg/min) a lactate minimum test to determine LMPO and three 20 - 45 min constant load rides individualized to 100 – 110% of LMPO on a Velotron Pro (Racermate Inc, Seattle). Venous blood from an indwelling catheter was sampled every 5 min during the constant load rides and analysed for [BLa-] and [HCO3-]. The hypothesis was that the slope of [BLa-] or [HCO3-] as a function of time would be zero at MLSSw. As hypothesised no significant differences at the observed MLSSw were seen (a) [BLa-] (p = 0.22) and (b) [HCO3-] (p = 0.70). Mean values of [BLa-] and [HCO3-] at the observed MLSSw (269 +/- 21W) were (5.1 +/- 0.4 mmol/L) and (20.7 +/- 0.4 mmol/L) respectively. Predicted MLSSw from the rides at >100% LMPO were 273 +/- 21W (model a) and 272 +/- 22W (model b). No significant differences were found between the observed or predicted MLSSw values for models a or b (p>0.05), R2 = 0.9485 and 0.9199 respectively. These initial findings suggest that the models for (a) [BLa-] and (b) [HCO3-] could be used for predicting MLSSw in trained cyclists.

EFFECT OF SAMPLING PROTOCOL ON RESPIRATORY DATA AND INDIRECT CALORIMETRY

Alkhatib, A., Beneke, R.

University of Essex, United Kingdom

Incremental exercise test protocols combined with measurements of oxygen uptake (VO2) and carbon dioxide (VCO2) production are widely used for performance testing and indirect calorimetry. Depending on testing equipment, VO2 and VCO2 are often sampled or averaged over 0.5 min or up to 1.0 min periods. The onset kinetics of the VO2 depends on exercise intensity (Ozyener et al. 2001). Therefore, depending on exercise intensity and sampling or averaging period, different VO2 results and a corresponding effect on VCO2 can be expected. We tested whether and how sampling or averaging of respiratory data over 0.5 min or 1.0 min affect assumptions and results of indirect calorimetry in an incremental exercise test.

METHODS: 21 healthy male subjects (age: 26.3 ± 6.0 yrs, height: 179.4 ± 8.1 cm, body mass: 74.9 ± 12.5 kg) completed an incremental load cycling test to exhaustion at 50 rpm. Starting with 1 W.kg-1 body mass power output was increased by 0.5 W.kg-1 body mass every two minutes. Three intensity domains were investigated: light 20-39 %, moderate 40-59 %, and heavy 60-85 % (ACSM Guidelines, 2000). VO2 and VCO2 data were averaged for the last 0.5 and 1.0 min of every stage of the incremental exercise test. All data are presented as Mean ± SD and tested using a repeated measures ANOVA model with averaging period as within factor and exercise intensity domain as between factor, Tukey post hoc and paired t-test. The level of significance was set at $p < 0.05$.

RESULTS: VO2 was higher ($p < 0.05$) when averaged for 0.5 than 1.0 min at heavy (3303.4 ± 650.1 vs. 3280.7 ± 643.2 ml.min-1) but not at light (1477.2 ± 207.5 vs. 1472.1 ± 195.6 ml min-1) or moderate intensity (2119.2 ± 313.5 vs. 2116.9 ± 301.6 ml.min-1). VCO2 was higher ($p < 0.05$) when averaged for 0.5 than 1.0 min at all intensity domains (light: 1204.9 ± 195.6 vs. 1172.9 ± 182.2, moderate: 1894.8 ± 317.5 vs. 1873.7 ± 305.9 ml.min-1, and heavy: 3453.3 ± 850.3 vs. 3400.7 ± 839.8 ml.min-1).

CONCLUSION: Increasing the period of averaging from 0.5 to 1.0 min resulted in an underestimation of the metabolic rate at moderate and heavy exercise intensity in the magnitude of approx. 0.1 and 0.6 %, respectively, which may be practically irrelevant. However, the latter is combined with a significant underestimation of the reliance on carbohydrate combustion of approx. 9.2 % in the light and approx. 4.9 % in the moderate intensity domain.

RELATIONSHIP BETWEEN OXYGEN UPTAKE AND OXY-HEMOGLOBIN SATURATION ON GLUTEUS MAJOR AND RECTUS FEMORIS DURING GRADED AEROBIC EXERCISE ON A NEW CARDIOVASCULAR EQUIPMENT PERFORMED IN DIFFERENT POSITIONS

Zanuso, S., Benvenuti, P., Cecchinelli, F., Ferrari, M., Quaresima, V.

Technogym , Italy

Cardiovascular machines require muscle activation that depends on movement patterns, exercise intensity and body positions. The aim of this study was to investigate the relationship between oxygen uptake and oxy-hemoglobin saturation on Gluteus Major (GM) and Rectus Femoris (RF) during graded aerobic exercise performed on a new cardiovascular equipment (CardioWave, Technogym, Italy). CardioWave machine allows a new multi-planar movement that combines hip extension, abduction and external rotation.

Local GM and RF oxidative activity has been monitored by a non invasive tissue oximeter (1) based on near infrared spectroscopy (NIRS).

Methods. Six physically active subjects (3 men) participated at the study; their mean age, height, and body weight were 37.5 ± 2.4 years, 176.8 ± 8.7 cm, 67.1 ± 11.6 kg, respectively. Adipose tissue thickness of GM and RF were 3.0±0.7 and 2.4±0.3 mm, respectively. Oxygen uptake (VO2) was continuously measured at the mouth on a breath-by-breath basis by a computerized system (Cosmed, Italy). Right RF and GM oxy-hemoglobin saturation was measured as tissue oxygenation index (TOI, %) simultaneously by a two-channel four-wavelength tissue oximeter (NIRO-300, Hamamatsu Photonics, Japan). Subjects warmed up for 10 min on a cycle ergometer (50 W; 60 rpm). Each subject performed 5 steps (Step I-V) of 6 min duration at increasing intensities defined as steps per minute (spm). Intervals of different duration (between 3 and 7.5 min) separated each step. At the end of step V, subjects performed an incremental exercise up to exhaustion (step duration:1 min; increment: 10 spm). The same protocol was performed in two positions in different days: day one (CW_1) subjects standing with trunk in neutral position; day 2 (CW_2) subjects standing with trunk in flexion.

Results and Discussion. As expected, TOI decreased in RF and GM (more consistently in RF) upon increase of spm. A high correlation was found between ΔVO2 and ΔTOI of RF (CW_1, p<0.001; CW_2, p< 0.04) and GM (CW_1, p<0.002; CW_2, p<0.01).

The pre-exercise TOI was 66.7±5 and 84.0±1.8 % in RF and GM, respectively; at exhaustion TOI was 44.5±19.1 and 74.8±6.1 % in RF and GM, respectively. The consistent TOI decrease (de-saturation) during exercise supports the hypothesis that RF and GM are actively working during aerobic exercise on CardioWave.

COMPARISON OF THE RELIABILITY OF OPEN- VERSUS CLOSED-LOOP TREADMILL RUNNING TESTS IN WELL-TRAINED RUNNERS

Laursen, P., Francis, G., Abbiss, C., Newton, M.

Edith Cowan University, Australia

Both time-to-exhaustion (Tlim) and time trial (TT) exercise tests, also referred to as open- and closed-loop exercise protocols respectively, are commonly used to examine the influence of experimental interventions on endurance performance ability. While a meta-analysis examining the reliability of open- vs. closed-loop exercise tests suggests that closed-loop reliability is reduced when compared with open-loop reliability, there are no known studies directly comparing the reliability of open- vs. closed-loop exercise tests of similar intensity and duration. The purpose of the study was to compare the reliability of open- vs. closed-loop treadmill running tests of high and moderately-high exercise intensity in well trained male distance runners. Following familiarisation tests, eight well-trained male distance runners (age 31±6 y; mass 70.4±6.9 kg, VO2max 61±8 ml.kg-1.min-1) performed in a randomised counterbalance order, eight trials in total consisting of two 1.5km TTs and two 5km TTs, and four runs to exhaustion at a speed equivalent to the average speed attained during both the 1.5km and 5km TT distances. During the TT tests, subjects were able to adjust their speed and were asked to run the distance in the fastest time possible, while during the Tlim tests subjects were asked to run for as long as possible at the prescribed running speed; reference to time was not given to the subjects in any of the trials. Reliability was assessed through calculation of the coefficient of variation (CV = SD/mean x 100%) between each of the two respective tests, while Student's t-test for pairwise samples determined differences between the test protocols and test intensities/distances. There were no significant differences between the first and second tests of the 5km TT (1167±103 vs. 1184±102s), 5km Tlim (1085±213 vs. 1086±197s), 1.5km TT (312±25 vs. 316±33s) and 1.5km Tlim (411±55 vs. 371±74s; all p>0.05). However, the CV for the 5km TT test (2±1%) and 1.5km TT test (3±2%) were significantly less than their respective 5km Tlim (11±7%) and 1.5km Tlim (10±10%) values; no differences in CV were apparent with differences in test duration or distance using the same protocol. While the mean 5km TT time (1175±101s) was significantly greater than the 5km Tlim time (1085±175s), the mean 1.5km TT time (314±29s) was significantly less than the 1.5km Tlim time (391±58s; p<0.05). In conclusion, the reliability of the time trial or closed-loop exercise test was significantly greater compared with similar time-to-exhaustion or open-looped treadmill protocols; exercise intensity or duration did not appear to markedly influence the reliability. Future studies should attempt to examine the reliability of open- vs. closed-loop tests following an exercise intervention so as to determine the type of exercise protocol that exhibits the greatest signal-to-noise ratio.

EFFECTS OF DRY-LAND VS. RESISTED- AND ASSISTED-SPRINT EXERCISES ON SWIMMING SPRINT PERFORMANCES

Girold, S., Maurin, D., Dugue, B., Millet, G.

Faculty of Medicine Jean Monnet, Saint-Etienne, France, France

This study was undertaken to compare the effects of dry-land strength training and combined resisted- and assisted-sprint exercises on 50 m freestyle swimming performance and technical parameters. Twenty-one swimmers, (10 males, 11 females), (mean ± SD, age 16.5 ± 3.5 years, height 170 ± 9 cm, weight 62 ± 7 kg, arm span 175 ± 11 cm), from regional to national level, were randomly divided into three groups: Strength (S), Resisted- and Assisted-Sprint (RAS) and Control (C). During 12 weeks, all swimmers trained six days per week, with two strength dry-land or two RAS sessions for S and RAS respectively, and a cycling training session for C. Barbells were used in strength training and elastic tubes were used to generate over-strength and over-speed in RAS training. Prior, during (6th week) and after the training period, strength of the elbow flexors and extensors was measured with an isokinetic dynamometer and speed, stroke rate, stroke length and stroke depth were recorded using an underwater video system during a 50 m sprint. After the training period, we observed a significant increase in swimming velocity in both S and RAS groups (2.8 ± 2.5%, 2.3 ± 1.3%; P<0.05; respectively), elbow flexors (39.5 ± 32.4%, 17.6 ± 13.8%; P<0.05; respectively) and extensors strength (45.5 ± 38.7%, 12.4 ± 18.7%; P<0.05, respectively). However, stroke depth decreased in both S and RAS groups (-3.5 ± 1.1%, -2.5 ± 1.2%; P<0.05; respectively). In addition, stroke rate increased in RAS (2.7 ± 0.2%; P<0.05) but not in S group. However, only slight differences between S and RAS methods were observed despite the greater specificity of RAS in swimmers. No increase in swimming velocity was observed in C. Programs combining swimming and dry-land S or in-water RAS led to a similar gain in sprint performance. This study confirmed also that these described methods are more efficient than traditional swimming methods alone.

PHYSICAL FITNESS OF DRAFTEES COMPARED WITH THEIR HABITUAL PHYSICAL ACTIVITY

Wyss, T., Marti, B., Mäder, U.

Federal Institute of Sports, Magglingen, Switzerland

Physical Fitness of draftees compared with their habitual physical activity

Thomas Wyss, Bernard Marti, Urs Mäder

Swiss Federal Institute of Sports, Magglingen, Switzerland

INTRODUCTION: The fitness test battery of the Swiss Army recruitment (TFR) is used to assign the conscripts appropriate tasks and allows monitoring of fitness development among Swiss males 19-20 years old. The TFR consists of four performance tests and a questionnaire aiming at physical activity behaviour and motivation of sport. The purpose of this study was to determine the relationship between physical fitness objectively measured by the TFR and the habitual physical activity registered by self-report questionnaire.

METHOD: 1444 draftees (19.47 ± 0.99y, 177.94 ± 6.47cm, 72.69 ± 11.74kg) performed in summer 2005 the TFR and completed the questionnaire. The TFR consisted of a progressive endurance run, standing long jump, seated shot put, and a trunk muscle strength test. For further analysis the total score, scores for each test and a dichotomous categorisation ("high-performance" versus "lower fitness level") were built. The questionnaire included 6 questions on self-reported habitual physical activity and allowed to classify the respondents as "trained", "regularly active", "irregularly active", "partially active" and "inactive". Spearman correlation coefficients were calculated to establish the relation between physical activity behaviour and the results of each of the four TFR tests. The Kappa value was calculated to quantify the magnitude of agreement between the categorisation "high performance" and "trained".

RESULTS: Draftees classified as trained (n=694) achieved 63.1, regularly active (n=127) 56.9, irregularly active (n=305) 57.3, partially active (n=238) 52.0 and inactive (n=80) 48.9 TFR-scores on the average. The total score of the TFR and the scores for each test were positively related to the habitual physical activity level, respectively (r=0.40, progressive endurance run: r=0.39, trunk muscle strength test: r=0.29, standing long jump: r=0.23 and seated shot put: r=0.20, p<0.0001). 68% of the high-performance draftees (n=519) were classified as trained by the questionnaire. 37% of the draftees with lower fitness level (n=925) were classified inconsistently as trained (Kappa = 0.284, p<0.0001).

DISCUSSION: These results suggest that in young men habitual physical activity has some promoting effects on physical fitness. Kushima et al. (1) found similar coherences in middle-aged men. As expected, the aerobic endurance is stronger related to the habitual physical activity level then explosive muscle power. Fair agreement was observed between the classifications "high performance" and "trained"; however, there seems to be a need for both assessments.

THE VALIDITY OF PREDICTING MAXIMAL OXYGEN UPTAKE FROM PERCEPTUALLY-REGULATED GRADED EXERCISE TESTS OF DIFFERENT DURATIONS

Faulkner, J., Eston, R., Mason, E., Parfitt, G.

University of Exeter, United Kingdom

The strong positive relationship between the ratings of perceived exertion (RPE) and oxygen uptake is well established. Eston et al. (2005) provided evidence that a sub-maximal, perceptually-guided, graded exercise protocol could provide acceptable estimates of maximal oxygen uptake (VO2max), which are improved with practice in physically active young males. Their study used repeated, 4-min bouts which were self-regulated at predetermined RPEs of 9,11,13,15 and 17 (Borg, 1998) in that order. However, Eston et al. did not account for the duration of the perceptually-regulated trials or indeed the influence of gender on the validity of predicting VO2max from sub-maximal VO2 values elicited at the above RPEs. An assessment of the usefulness of shorter durations of sub-maximal exertion is considered to be of practical value with regards to the time, cost and effort of such a procedure. The purpose of this study was to assess the validity of predicting VO2max from sub-maximal VO2 values elicited during perceptually-regulated exercise tests of 2- and 4-min durations. Nine-

teen physically active men and women (10 men, 9 women, age 19-23 years) volunteered to participate in two graded exercise tests to volitional exhaustion (GXT) to measure VO2max (VO2maxGXT), at the beginning and end of a two-week period. They performed four incremental, perceptually-regulated tests to predict VO2max in the intervening period. Perceptually-guided tests comprised 2 x 2-min and 2 x 4-min bouts on a cycle ergometer, regulated at intensities of 9, 11, 13, 15 and 17, in that order. Individual relationships between RPE : VO2 for RPE ranges of 9-17, 11-17 and 9-15 were extrapolated to RPE 20 to predict VO2max. For the prediction of VO2max from RPE 9-17, the trial 1 value of the 2-min protocol (mean (SD) = 43.9 (7.2)) was significantly lower (P<0.05) than the first and second VO2maxGXT values (47.2 (10.2) and 48.2 (9.4), respectively). Although predicted VO2max values from both 4-min trials were not significantly different from VO2maxGXT, the value from the second trial of the 2-min protocol (48.7 (8.1)) was a more accurate prediction of VO2maxGXT. The intraclass correlation coefficient (R) was also higher between VO2maxGXT and VO2max predicted from trial 2 of the 2-min protocol compared to both trials in the 4-min protocol (R=0.95 and 0.88 and 0.79, respectively). These results were not moderated by gender. Similar results were observed for RPE ranges 9-15 and 11-17. In conclusion, practice of a sub-maximal, perceptually guided, graded exercise protocol, particularly of a 2-min duration, provides acceptable estimates of maximal aerobic power, which are not moderated by gender.

MULTIPLE SHORT-TERM EXERCISE SESSIONS ARE SUPERIOR TO A SINGLE SESSION IN EFFECTS ON GLUCOSE HOMEOSTASIS IN TYPE 2 DIABETES MELLITUS

Eriksen, L., Dahl-Petersen, I., Haugaard, S.B., Dela, F.

Department of Medical Physiology, Denmark

Introduction

Physical training is highly recommended in the treatment of type 2 Diabetes Mellitus (T2DM). The general advice is to exercise 30 min/day at a moderate intensity. It is not known whether this amount of exercise should be performed as multiple short-term training sessions (i.e. accumulated over the day) or as a single session. Such information is important for future exercise recommendations to patients with T2DM. We tested the effect on glucose homeostasis and insulin secretion in two different exercise protocols.

Design

Eighteen male patients with T2DM (age: 59 ± 1.5 yrs (mean ± SE); BMI: 32.5 ± 1.1 kg/m2; time since diagnosis: 6.5 ± 4.3 yrs) participated in a 5-week home-based, and partly supervised (heart rate (HR) was recorded during all exercise sessions) endurance training program using bicycle ergometers. Ten patients served as a time-control group before starting the training program. Subjects were randomly assigned to a training program at 60% of VO2max for 10 min 3 times per day (3x10) or 30 minutes once a day (1x30). VO2max was determined for each subject by a stepwise incremental bicycle test. Plasma insulin, C-peptide and glucose concentrations were measured during a 3-h oral glucose tolerance test (OGTT) and insulin sensitivity was estimated using a composite measure index (ISI composite) of whole-body insulin sensitivity and HOMA (Wallace et al 2004). β-cell function was estimated by HOMA. Pre-hepatic insulin secretion rates (ISR) were indirectly estimated using C-peptide concentrations from the OGTT (Hovorka et al 1996).

Results

With both training regimens an improved aerobic capacity was observed. At each submaximal workload HR and blood lactate concentrations were decreased (P<0.01) after the training program in both training groups. In group 3x10 fasting plasma glucose (f-GLU) and 120 min GLU decreased significantly (P=0.01 and P=0.04, respectively)including a significant lower plasma glucose concentration during the OGTT measured by area under curve (AUC) 120 minutes (P =0.04) and a tendency towards a decrease for AUC 180 min (P=0.07). In group 1x30 neither GLU nor AUC improved with training. β-cell function improved by 19% (P=0.01) in group 3x10 on a background of unchanged insulin sensitivity. Both these parameters remained unchanged in group 1x30. No significant changes were found in ISR in either of the training groups. No change in any of the variables was seen in the time-control group (data not shown).

Conclusions

Based on our data, moderate intensity training performed as 3x10 min is superior to 1x30 min in effects on glycemic control in patients with T2DM. This was the case in spite of the fact that aerobic capacity increased similarly in the two groups. A possible mechanism for this finding may be that the energy expenditure associated with multiple short-term sessions may be greater than that of a single session.

ONE HOUR CYCLE TIME TRIAL PERFORMANCE IMPROVED WITH CARBOHYDRATE MOUTH RINSE: A CENTRALLY-MEDIATED MECHANISM?

Chambers, E., Bridge, M., Jones, D.A.

The University of Birmingham, United Kingdom

It has been suggested that there are oral receptors for complex carbohydrates which, when stimulated, can improve 1-h cycle time trial performance (Carter et al., 2004). To clarify and extend these observations, six male and two female endurance trained cyclists (VO2max 61.5 + 6.5 ml.kg-1.min-1; mean + SD) completed two time trials performing a fixed quantity of work (837 + 68 kJ; mean + SEM) as fast as possible. On one occasion a 6.4% maltodextrin solution (CHO) was rinsed around the mouth for 10-s every 12.5% of the trial completed while on the other occasion, a placebo (PLA) was swilled. Artificial sweetener and flavour were added to both mouth rinses to make them indistinguishable in terms of taste and texture.

Performance time was significantly improved with CHO compared to PLA (62.61 + 1.67 min and 64.67 + 1.74 min, respectively, p = 0.016) giving a significantly higher average power output with CHO (225 + 20 W and 217 + 19 W, respectively, p = 0.013). There were no differences in perceived exertion, mean heart rate or sweat loss between the two trials (p > 0.05).

The results support the previous observation that a CHO mouth rinse has a positive effect on 1-h cycle time trial performance and demonstrate that this improvement is not related to sweetness. It appears that a CHO mouth rinse enables subjects to maintain a greater power output with the same perception of effort as reported during the PLA trial. A central mechanism is proposed in which stimulation of oral CHO receptors results in activation of hedonic networks in the brain influencing central fatigue mechanisms.

EFFECTS OF MUSIC ON CEREBRAL AND MUSCLE OXYGENATION PATTERNS DURING MAXIMAL WHEELCHAIR EXERCISE

Bhambhani, Y., Malik, R.

University of Alberta, Canada

It has been well documented that listening to music during dynamic exercise such as cycling and running significantly enhances the maximal exercise responses including exercise time and maximal oxygen uptake. It is postulated that the physiological factors that cause these increases could be those that initiate motor stimulation in the cerebral motor cortex, overall oxygen transport by means of the central circulation, or peripheral factors located within the exercising muscle. In this study we used near infrared spectroscopy (NIRS) to examine the effects of music on the cerebral and muscle oxygenation responses during wheelchair exercise in order to identify whether alterations in cerebral activation or muscle oxygen extraction were responsible for the postulated improvement in peak exercise responses. Twenty healthy male volunteers (mean ± SD for age, height, body mass, and peak oxygen uptake were 24.6 ± 3.2 yrs, 169 ± 5.3 cm, 71.4 ± 5.6 kg, and 28.5 ml/kg/min respectively) completed a familiarization protocol, followed by two wheelchair exercise sessions under the following conditions: no music (control) and listening to self selected music at a tempo above 124 beats/min. Each subject downloaded music of his own choice from his personal music collection or from music websites on to an MP3 player prior to the exercise sessions. The wheelchair exercise was performed on a standard wheelchair mounted on frictionless rollers. During the test, cardiorespiratory responses were continuously monitored using a wireless metabolic cart (VMaxST, Sensormedics, CA). Cerebral oxygenation and blood volume were recorded from the left frontal lobe and muscle oxygenation and blood volume were recorded from the right biceps and triceps using dual wave NIRS instruments (MicroRunman Inc., PA). The difference in hemoglobin absorbency between the 850nm and 760nm wavelengths was an indication of oxygen extraction, while the sum of the absorbencies was an index of the total blood volume. Dependent 't' test results indicated that listening to music resulted in significant improvements ($P<.05$) in the peak values of exercise time (10%), absolute oxygen uptake (9%), heart rate (6%), ventilation rate (4%) and oxygen pulse (6%) when compared to the control condition. These changes were accompanied by increases ($P<.10$) in: cerebral oxygenation (7%) and blood volume (6%), biceps oxygenation (8%) and blood volume (7%), triceps oxygenation (9%) and blood volume (10%). The improvement in the peak oxygen uptake during the music condition was significantly correlated ($P<.05$) to the change in cerebral oxygenation but not the alterations in biceps or triceps oxygenation. These findings suggest that the improvement in peak wheelchair exercise performance as a result of listening to music is most likely centrally mediated by enhanced neuronal activation of the cerebral motor cortex.

OP1-14 Motor Learning 1/2 - "Turin DE"

THE INFLUENCE OF STRESS AND MUSCLE FATIGUE ON IMPLICIT AND EXPLICIT MOTOR LEARNING

Tallir, I., Lenoir, M., Musch, E., Valcke, M., Raab, M.

Ghent University, Belgium

According to Beek (2000), disturbing causes at the upper level of action (i.e. stress) and at the lower level of control (i.e. muscular fatigue) might result in different effects on performance when comparing implicit and explicit learning. In the present experiment an errorless/errorfull learning paradigm was used to enable the implicit/explicit acquisition of a dart throwing skill. After a pretest, the errorfull group (N=23) throwed from a progressively decreasing distance (from 317 to 257 cm), while the inverse procedure was used for the errorless group (N=21) (from 157 to 217 cm). One week after the four-day learning period (400 trials) both groups performed a transfer test, a fatigue test and a stress test (all from 237 cm). The fatigue test was preceded by a double Wingate protocol on an arm ergometer. At the beginning of the stress test participants were told they could win a significant financial reward in case of a good performance. Retrospective self-report of nervousness was administered under stressed and unstressed conditions. Hitting accuracy of the errorfull group improved from M=5.38 (maximum=15) in the first learning block to M=7.71 in the final learning block, while the errorless group evolved from M=9.67 to M=8.71, which is typical for an errorless/errorfull learning paradigm. In comparison to the scores at the pretest both groups performed equally (learning increase of 35%) at the transfer test. Performance of both groups decreased at the fatigue test, but this decrease was much less in the explicit group (5%, ns) as compared to the implicit group (20%, $p<.001$). Stress manipulation resulted in an increase of self-reported nervousness (35%, $p<.001$) and a decrease in performance (5%, $p<.05$) compared to the transfer test. However, stress did not have a differential impact on performance in both groups. Our results of the fatigue test confirmed the hypothesis of robustness of explicit motor learning to physiological fatigue, meaning that success depends on the person's ability to circumvent the (temporary) impairment induced by muscular fatigue, and thus develop alternative strategies based upon explicit knowledge. The contradiction with the findings of Poolton et al. (2005) may be due to task specificity, which calls for further research on this topic. Our results of the stress test do not show the superiority of implicit or explicit learning when performing under stress.

SPATIAL AND TEMPORAL ADAPTATIONS ACCOMPANYING INCREASING CATCHING PERFORMANCE DURING LEARNING

Mazyn, L.I., Lenoir, M., Montagne, G., Savelsbergh, G.J.

Ghent University , Belgium

Catching performance and kinematic changes were investigated across an extensive two-week training program. Participants had to catch tennis balls, approaching at a velocity of 13.1 m/s with their preferred hand in a pre, post and retention design. Compared to a control group (CoG, N=9) that not received any practice, the participants from the training group (TrG, N=8) evolved from poor to sub-expert catchers ($F2,30 = 24.261$, $p < .001$).

A permanent gain in performance outcome of the TrG (from 13% to 70% and 66% successful catches at respectively pre, post and retention test) was accompanied by some subtle changes at kinematic level. (1) Temporal consistency, i.e. within subject variability on movement time, increased together with catching performance ($F2,30 = 8.007$, $p < .005$), a finding that is characteristic to learning. (2) The interception point shifted away from the body ($F2,30 = 7.100$, $p < .005$), and hence the ball was caught more in the central visual field. According to earlier studies, such strategy is beneficial for catching performance in non-experts (see Savelsbergh & Whiting, 1988, for an overview). (3) Peak wrist velocity tended to increased as well with training ($F2,30 = 3.173$, $p = .056$), indicating a more ballistic transportation of the hand to the future interception place. This leaves more time for implementing on-line adjustments and therefore enhances the fine-tuning of the catch. These scant kinematic adjustments were argued to reflect the all-or-none characteristic of the one-handed catching task: only a minor refinement in one variable could be sufficient for enabling successful performance. Since participants already possessed some basic coordination pattern before entering the training program, this explains how only few subtle adaptations still engenders a relatively large gain in performance outcome.

The broad spectrum of individual performance curves that was found throughout the training sessions, points to the individual character of the learning process. However, it was established that novice catchers generally first adjust spatial characteristics of the catch, while a fine-tuning of temporal features occurs only later during learning. This finding of a sequential order in acquiring spatial and temporal aspects of the movement in line with earlier work (e.g. Marteniuk & Romanow, 1983) and entails relevant implications towards training methodology in sports.

DEPENDENCE OF TARGET MUSCLE ACTIVATION ON MOTOR CORTEX EXCITABILITY CHANGES

Mrachacz-Kersting, N., Sinkjaer, T.

The University of Auckland, The University of Aalborg, New Zealand

Persistent changes in synaptic efficacy (long-term potentiation – LTP) is one of the candidate mechanisms underlying motor cortex plasticity (Sanes & Donoghue, 2000). Paired associative stimulation (PAS) is a methodology that has been demonstrated to induce long lasting increases in cortical excitability through an LTP-like mechanism in the upper extremities of humans (Stefan et al., 2000; 2002; Kujirai et al., 2002).

There were two aims to this study. Initially we sought to investigate if changes following PAS can be induced in human lower limb muscles and if these changes depend on the activation state of the target muscle. Secondly we wanted to determine the time-course of this effect. This is the first study in the human lower extremity investigating PAS at both rest and in active muscles.

In 14 sitting able-bodied subjects, PAS was applied as a peripheral electrical stimulus at the common peroneal nerve (1 × motor threshold), combined with a magnetic stimulus over the area of the motor cortex associated with the tibialis anterior (TA) (120% rest threshold). The timing of the magnetic stimulus coincided with the arrival of the peripheral afferent volley at the motor cortex. Three conditions were examined; PAS at 0.2 Hz for 30 minutes while the subjects were relaxed (Condition 1) or commencing a dorsi-flexion movement (Condition 2). During Condition 3 no PAS was applied and the subjects were asked to perform dorsi-flexion movements at 0.2 Hz for 30 minutes. Sixteen motor evoked potentials (MEPs) were elicited in the TA prior to, during (at 15 min) and following the intervention and the peak to peak size of the TA MEP extracted.

The TA MEP size increased significantly (by 87%) only for the PAS intervention in the dorsiflexion condition ($p = 0.001$). PAS delivered during the relaxed condition or dorsiflexion performed on its own resulted in a slight and non-significant ($p = 0.238$) increase in TA MEP size. No significant changes in the MEP size occurred in the antagonist soleus muscle. The optimal interstimulus interval (ISI) between the peripheral and the cortical stimulus was 55 ms, though ISI's of 45ms and 50ms also produced a significant increase in the TA MEP amplitude. This is in agreement with in Vitro studies on rat hippocampal slice preparations which have indicated that there is an approximate 20 ms time window between the arrival of the afferent volley at the postsynaptic cell until the second stimulus has to be elicited (Bi & Poo, 1998).

In conclusion, results confirm that cortical excitability can be increased following a bout of PAS delivered to lower limb muscles. The effects of PAS were dependent on the order of the two stimuli, evolved rapidly and persisted after the cessation of the stimulation. As compared to hand muscles studied previously, the effects of PAS seemed to require an increased number of paired stimuli and more importantly a pre-activated motor cortex to show a significant effect.

REPROGRAMMING OF INTERCEPTIVE ACTIONS: TIME COURSE OF CORRECTIVE RESPONSES TO LARGE-SCALE PERTURBATIONS

Teixeira, L.A., Chua, R., Nagelkerke, P., Franks, I.M.

University of São Paulo, Brazil

When large-scale errors are made in the execution of an intended movement, feedback-based mechanisms are activated with the purpose of producing adjustments to the original motor program, leading to a modification in the regular pattern of limb displacement. This process has been called motor reprogramming. The time course of motor reprogramming was investigated here in an interceptive task in conditions requiring large-scale movement corrections at different moments before interception. Male and female university students (n = 24) took part in the study. They performed a task that consisted of performing a planar horizontal arm movement to intercept a top-down moving target on a monitor screen. The target was moved at a constant velocity of 8 cm . s-1, and in part of the trials,

unexpectedly for the participants, target velocity was either increased to 12 cm . s-1 or decreased to 4 cm . s-1. Target velocity was modified at different moments during stimulus displacement, producing times-to-arrival after velocity change from 100 to 800 ms. This procedure allowed us to observe the process of reacquisition of temporal accuracy from very short to long periods of time available for movement adjustments. Participants were assigned to four groups: Uni25 group, 25% probability of velocity change in a single direction (increment or decrement of velocity); Bi25 group, the same probability but uncertainty about direction of velocity change; and the other two groups were similar to the first two with the exception that they faced 50% of chance of target velocity change. With these comparisons we assessed the effect of probability of target velocity change, uncertainty about direction of velocity change, and the particular direction of velocity change on movement reprogramming, on temporal error and kinematic landmarks at the due interception moment. Analysis of movement acceleration showed that significant modifications to kinematic profile took place between 100 and 200 ms after target velocity change similarly for all groups. Analysis of temporal error indicated that the combination of high probability of target velocity change and certainty on direction of target velocity change led to improved movement reprogramming. For the other experimental conditions temporal accuracy was still poor when a period of 800 ms was allowed for correction. Movement reprogramming was observed to be a progressive process, which was more efficient when target velocity was increased than when it was decreased. These results suggest that movement correction is implemented through two phases: the first one is automatic, triggered by a direct visuomotor linkage independent of higher level demands of movement correction; and the second phase is a gradual process modulated by higher order levels of control. Effective movement reprogramming seems to be implemented only in this second phase, when voluntary feedback-based adjustments take place to change movement specifications.

THE EFFECTS OF AUDIENCE AND COMPETITION ON PERFORMANCE OF A NOVEL DART-AIMING TASK

Al-Nakeeb, Y., Lyons, M., Moreton, J., Duncan, M., Nevill, A., James, C.

Newman College of Higher Education, United Kingdom

Introduction: Several theories have attempted to explain why competition and presence of an audience affects performance (Strauss, 2002). The most popular, the drive theory of social facilitation proposed by Zajonc (1965) advocates that the presence of audience and competition increases arousal and therefore impairs the acquisition of new responses and facilitates the emission of well learned responses. However, later studies (Cottrell et al, 1968) have emphasised the role of evaluation apprehension and have shown that the mere presence of audience is not sufficient to influence performance.

Methods

The purpose of this study was to examine the effects of the presence of an evaluative audience and competition on performance of a novel task. Following practice (30 trials), twenty-four physically active young adults (12 males, 12 females; 21.70 ± 3.13 years) were assigned to one of two groups (skilled or unskilled) based on their practice scores. Each participant performed two blocks of six throws on the dart aiming task under three conditions (alone, competition and audience). Participants also completed the Jones et al.'s (2005) Sport Emotion Questionnaire following each condition to measure their state anxiety. In addition, participants' heart rate was monitored continuously during the three testing conditions to measure physiological arousal.

Results

A significant interaction ($p = 0.028$) between condition and skill level was revealed as a result of the repeated measures ANOVA. While performance of the skilled group improved under the audience and competition conditions, the unskilled group's performance deteriorated under those two conditions. Highly significant differences ($p < 0.001$) were found between the state anxiety levels under the three conditions, with the highest being under audience followed by competition then alone conditions. In addition, significant differences ($P = 0.008$) were found between heart rate during performance, with the audience condition inducing the highest heart rate followed by competition and alone conditions.

Discussion

The data suggest that performance of an aiming task in the presence of an evaluative audience or in competition by skilled performers was facilitated while the performance of the less skilled ones deteriorated. The results also indicated that performance in the presence of evaluative audience and in a competitive situation significantly increased the anxiety level and the heart rate of all performers irrespective of their skill level. The results provide further support for Cottrell et al.'s (1968) learned drive hypothesis in explaining the role of evaluation apprehension in influencing performance of motor skills.

PARAMETERS OF FOCUSED ATTENTION IN THE EEG: A COMPARISON BETWEEN SHOOTERS AND NOVICES

Finkenzeller, T., Doppelmayr, M., Amesberger, G.

University of Salzburg, Austria

The primary goal of this study was to examine shooter's aiming period to get a better understanding of the neural mechanisms associated with sustained, focused attention. Electroencephalographic activity during the preshot period was investigated in eight marksmen and eight novices for best and worst shots. According to the results of an exploratory wavelet analysis, changes in the bandpower of individually adjusted theta, lower alpha, beta 1 and beta 2 have been analyzed for the 2 seconds period prior to the shot. Additionally changes in the frontal midline theta and readiness potentials (RP's) were analyzed.

Although, well in accordance with the literature, higher theta power preceding the shot has been recorded in marksmen (Haufler et al., 2000), the repeatedly reported differences in alpha hemispheric activity (Hatfield et al. 1984; Landers et al. 1994) and differences in alpha activity between shooters and novices (Haufler et al., 2000) could not be replicated. Similarly no differences have been found between

experienced and unexperienced shooters or between good and bad shots for the RP's. However, marksmen exhibited more activation in frontal midline theta (Fm theta) as compared to novices. This result is consistent with the finding that Fm theta reflects sustained attention (Kubota et al., 2001). In the future, findings related to Fm theta might be used in neurofeedback training of marksmen.

A TEST OF THE DUAL-MODE MODEL WITH YOUNG ADOLESCENTS

Sheppard, K., Parfitt, G.

University of Exeter, United Kingdom

Introduction: Ekkekakis' (2003) dual-mode model proposes that affective responses are generated through different mechanisms. These are linked directly to the metabolic demands of the exercise intensities. Affective responses below the ventilatory threshold (VT) are influenced by the interplay of cognitive processes and interoceptive physiological cues. Responses are variable due to the way individuals cognitively process exercise cues. Above VT interoceptive cues dominate, response are homogenously negative. This pattern of responses has been explored in adults but not in adolescents. There is neither research exploring acute psychological responses of adolescents to exercise, nor the relevant underlying cognitive processes. Methods: 22 adolescents (11 boys, 11 girls; 13.3 yrs (SD=.3); BMI 19.5 (SD=2.9); VO2max 43.3 (SD=8.2) took part. Affect was measured using the Feeling Scale (FS; Hardy & Rejeski, 1989). Participants completed a graded exercise test to establish maximal aerobic power (VO2 max) and VT; followed by 3 sub-maximal protocols, set at an intensity below the VT (<VT), above the VT (>VT) and a self-selected (S-S) intensity, which was set by asking participants "select an intensity that you would be happy to sustain for 15 minutes, that you would feel happy to do regularly" (Parfitt et al., 2000). In each trial pre-exercise heart rate (HR) and FS responses were taken 5 minutes before the start of the test and immediately pre-exercise. Participants cycled for 15 minutes, maintaining a cadence of approx. 70rpm. FS and HR responses were taken in the last 45 seconds of each 5-minute period (minutes 5, 10 & 15). FS was recorded on completion, and again at 5, 10, 15 and 30 minutes post exercise. Two-factor (time x condition) fully repeated measures analyses of variance (ANOVA) were conducted on HR and FS data. Results: Condition by time interactions were recorded for both HR [F(4.8, 67) = 19.9, p<.01] and FS [F (7.1, 141.4) = 14.6, p<.01]. HR increased over time but was significantly higher in the >VT condition during exercise. The S-S condition was significantly higher than the <VT condition in the latter stages of exercise. FS remained stable and positive throughout exercise in the <VT and S-S conditions, but declined during exercise in the <VT condition. Conclusions: The patterns of affective response during and following exercise support the proposals of the dual-mode model.

INFLUENCE OF EXPECTED RUNNING DURATION OR DISTANCE ON PERCEIVED EXERTION AND ESTIMATED TIME LIMIT SCALES

Coquart, J., Raul, P., Garcin, M.

Laboratoire d'Etudes de la Motricité Humaine, EA 3608, France

INTRODUCTION

The influence of expected exercise duration on Ratings of Perceived Exertion (RPE) has been already shown (Rejeski & Ribisl, 1980). However, no study has investigated the influence of expected exercise duration or distance on Estimated of Time Limit scale (ETL). Consequently, the purpose of this study was to examine the influence of the expected running duration or distance on RPE and ETL values. SUBJECTS: 39 males (Mage = 24.4, SD = 3.8 yr; Mmass = 73.9, SD = 9.1 kg; Mheight = 180, SD = 6.2 cm) who ran regularly were recruited.

MATERIALS

Perceived effort was expressed with the RPE (Borg, 1970) and ETL scales (Garcin et al., 1999). Heart rate (HR) was recorded with a cardiotachometer (Accurex +, Polar).

METHODS

Each subject performed an exhaustive incremental test to measure Maximal Aerobic Velocity (MAV). Then, an exhaustive constant velocity test (90% MAV) was realised to determine their time limit (Tlim) and distance limit (Dlim). Next, three homogenous groups were formed. All groups performed two tests at 90% MAV during 80% Tlim and on 80% Dlim. The groups had different instructions: group 1 (G1) were expected to maintain the velocity during 60% Tlim (and Dlim), while group 2 (G2) and group 3 (G3) thought they maintained this velocity during 80 and 100% Tlim (and Dlim), respectively. During each test, RPE, ETL and HR values were collected. All tests were realised in the same conditions.

STATISTICAL ANALYSIS

RPE, ETL and HR values were compared by using a three-factor (Exercise Time Duration × Groups × Tests) analysis of variance (ANOVA). Moreover, when differences were obtained, Bonferroni post hoc tests were used.

RESULTS

The results have revealed: 1) an effect of exercise time duration on RPE, ETL and HR ($p < 0.01$); 2) significant differences between G1-G2 for RPE, and between G1-G2 and G1-G3 for ETL and HR ($p < 0.01$); 3) no effect for test (80% Tlim or Dlim) ($p > 0.05$).

DISCUSSION

Our study has shown that: 1) as expected, RPE and ETL values increased with exercise time duration; 2) moreover, a lower expected running duration or distance produced higher RPE and ETL values in comparison with a longer expected running duration or distance (i.e., these runners perceived the exercise as being harder and felt that they could endure less) and; 3) however, perceived values did not seem to be influenced by the type of test (duration or distance).

EFFECTS OF AEROBIC WATER EXERCISE ON SOMATOPHYSIOLOGICAL SYMTOMS OF DEPRESSION

Matinhomaee, H.

Azad University Of Tehran Centeral Branch, Iran

Aerobic water exercise enjoyable,pleasant,tranquilizer,with no pain and injuries (because of weigh loss),easy to do for all…and for these reasons seems to be better than other exercises to improvement depression symptoms .On the other hand effects of exercise on somato-physiological aspects of depression still are not clear .

Purpose:To determine whether aerobic water exercise(AWE)have any effect on somato-physiological symptoms of depression (SSD).

Methods:Untrained male college students (n=48,aged=23.2+_2.7years)with mild depression randomly assigned to experimental (n=24)and control(n=23)groups.All subjects were medication free and with no HPA related syndromes like chushing syndrome. Before and after 12 week (AWE) HPA changes was examined by dexamethason suppression test(DST). Tow milligram dexamethason tablets before 16 and 23 hours from blood sampling were feuded to subjects.Then plasma cortisol was measured by radio immune assay (RIA).Other (SSD)including sleep quality ,sense of healthful, sexual desire,appetite,sense of tiredness and having desire to do work and activity were assayed as described in Beck depression inventory and total weight ,lean body mass and rest heart rate were measured.

Results: plasma cortisol response to dexamethason and appetite had not significant change but other symptoms had significant ($P<0.05$)change toward improvement (SSD).

Conclusions:(AWE)and dexamethason have not effect on HPA function but have positive effects on other somato-physiological symptoms of mild depression .Thus (AWE)might be useful for diminishing and improvement of mild depression and prevention of intensification of (SSD) but we can not suggest (AWE)for improvement or treatment of HPA disorders in intensive or endogenous depression.

IDENTIFYING RELATIONSHIPS BETWEEN DECELERATION CONTROL AND INTERNAL MOVEMENT REPRESENTATIONS

Heinen, T.

German Sport University Cologne, Germany

Since the pioneering attempts of Lee (1976) to adress the problem of perception and control of (braking) action a large number of following studies focused on different aspects of deceleration control. In these studies the role of the (optical) variable tau in movement control was emphazised and attracted attention as time-to-contact-paradigm. New approaches in motor control suggest so-called perceptual-cognitive representations which are thought to form the reference system of human voluntary movements. Motor activity seems to be self organized to some degree in order to serve anticipated (sensory) effects and can be affected immediately by sensory information (Schack & Mechsner 2006). Merging both mentioned approaches it seems reasonable to assume relationships between (the use of) time-to-contact in controlling motion and the underlying perceptual-cognitive representations of movement. For this purposes and according to preliminary work (e.g. Bardy and Laurent, 1998) we focussed on analysing somersaulting in gymnastics. The major movement problem occuring in somersaulting is to land on ones feet in a defined body orientation and with a stable posture. Because the angular momentum remains constant during the flight phase, the gymnast has to use the ground contact in order to compensate the rotational movement. 120 somersaults of 20 gymnasts were analysed cinematographically (2D, 50 Hz). First, angular tau and other parameters (angular momentum, moment of inertia etc.) were calculated from the digitised datasets. Second, perceptual-cognitive representations were analysed by means of the structure-dimensional-analysis (SDA; Schack & Mechsner, 2006). Through SDA one gains information about structural aspects of the cognitive representations of each individual case. The results of the investigation show, that different strategies in controlling rotation with regard to different expertise of the gymnasts can be identified. Besides we discovered different structures of cognitive representations of each test person. Relationships between the use of time-to-contact information in controlling motion and the underlying perceptual-cognitive representation of the movement can be found. It seems reasonable that gymnasts control their somersault rotation prior to their cognitive representations with regard to their expertise level and with the use of invariant characteristics of time-to-contact information.

ACL RUPTURES IN CHILDREN WITH OPEN PHYSES - TREATMENT OPTION

Mayer, R.R. 1, Koenig, U. 2, Widmer, H. 1, Friederich, N.F. 1

1 Kantonsspital Bruderholz, CH-4101 Bruderholz, 2 Ortho-Klinik Rhein-Main, D-63067 Offenbach, Switzerland

Introduction:
ACL injuries in Children with open physes are rare but the number is lately increasing, especially due to the increase of risky trendsports. (Carving, Snowboarding, Inlineskating etc.) The strategy of treatment is still controversely discussed in the literature.
Material and Method:
Between 10/1997 and 5/2004 35 Children (mean age 12, range 10-14, 22 boys, 13 girls) with acl tear and open physes were operatively treated in our hospital.
The rupture occured during sport activity in all cases, the indication for reconstructive surgery was persisting ap instability.
Our operative technique needs a pit of 8mm in diameter on the femoral side just below the epiphyseal line. The bony block of the autologous quadriceps tendon graft with the same size is placed In this pit and fixed extraarticulary to a screw on the lateral side of the femur proximal to the physis. The tibial fixation is performed in a similar way, the free end of the quad tendon is armed with #3 nonresorbable sutures in <<baseball stitch>> technique and fixed through am 8mm transtibial tunnel to a second extraarticular screw medial and inferior to the tibial tuberosity.
In the followup Lysholm and IKDC scores were taken, as well as KT 1000 Masurements and plain x-rays. In some cases MRI were obtained.
Results: The average Lysholm Score was 95 (93-97), IKDC: 85% in group A and B. The average KT 1000 difference was 1,5mm (1-2mm) compared to the opposite side.
One patient showed a growth difference on the femoral side with an increase of femoral valgus. Tibial axis deviation did not occur. There were also no difference in leg length. 2 Patients showed enlargement of the tibial tunnel (bungee effect).
5 of 35 patients had a re-rupture in an adequate trauma in sport.
Conclusion:
We recommend children after acl rupture and persistant instability to undergo acl-reconstruction to avoid secondary intraarticular damage despite open physes.
Our technique with a quadriceps tendon autograft has an extraarticular fixation and shows no bungee effect on the femoral side. We found no growth disturbances, there was no tibial axis deformity despite of the (minimal) damage to the tibial physes. The rate of reruptures ist higher than in adults.

ACL RUPTURES IN CHILDREN: PROBLEMS AND FEARFUL COMPLICATIONS

Seil, R.

Centre Hospitalier Luxembourg - Clinique d'Eich, Luxembourg

The treatment of ligamentous tears of the anterior cruciate ligament (ACL) in children is still controversial. Considering the unfavourable natural history with a high number of secondary meniscus lesions and early signs of osteoarthritis, a long-term conservative treatment can no longer be recommended on a routine basis. With respect to the rarity of the cases, lacking medium and long-term data, the various types of proposed surgical procedures and the limited number of basic science studies, ACL reconstructions in young children (Tanner stages 1 and 2) cannot yet be proposed as a routine surgical procedure. Indications for surgery should be chosen with care and the complication potential should be considered. A precise knowledge of the anatomical specificities of the child's knee and a large experience in ACL reconstruction surgery should be mandatory when taking care of these injuries. The presentation will give a current overview of the risk of the conservative and the surgical treatment of these lesions in children.

CHILDREN ACL RECONSTRUCTION. SURGICAL TREATMENT : EXPERIENCES AND RESULT

Chotel, F., Brunet-Guedj, E., Chouteau, J., Chaker, M., Berard, J.

Debrousse Hospital / hospices civils de LYON, France

Bad results with children conservative treatment of midsubstance ACL tear, make a general consensus for surgical reconstruction. But controversies still exist about the moment and the technique to use, in order to avoid growth disturbance. Our experience with ACL reconstruction in skeletally immature patients concern 29 children. Between 2001 to 2003, 5 knee were reconstructed with a Facia Lata graft over the top at the femur and tibial trans-physeal. In 2004, we develop an new intra-articular technique ; the femoral tunnel conducted out/in, is transepiphyseal horizontal under the physis. The ACL replacement used a quadricipital autograft tendon with a patellar bone bloc. This bone is impacted with press-fit in the femoral tunnel ; and the graft get thought a transphyseal tibial tunnel. The rehabilitation program was very soft, and the knee was protected with temporary anti-recurvatum brace.
Methods
Twenty five children were injured during sport activity (10 ski, 7 football), and 4 children during traffic accident. The sex ratio was 25 males and 4 females.
The average period of time from injury to reconstruction was 19 months with facia lata, and 9 months for quadricipitale reconstruction. All patients presented instability before surgery. At time of surgery, 15 patients were in Tanner stage ≤ to 3, the average chronologic age was 12,4 ± 2 years (range, 7 to 15 years).
Twelve knee (41%) had a meniscus lesion at time of reconstruction (7 were lateral, and 7 medial); an abstention or stimulation was done 6 time, suture 6 time and partial meniscectomy only two time. For the quadricipitale technique, the femoral tunnel position was appreciated

according to Aglietti. Clinical outcomes were measured using Lysholm and IKDC scoring systems, follow-up radiographs and scanogram, and KT-1000 testing by independent examiner.

Results

All patients return to they're activity level and no instability was registered; there were no secondary meniscus lesion or meniscus surgery in both technique.

- The five patients with Facia Lata technique were seen with 1,2 to 5,6 years years follow-up ; the Lachman test gave elastic feeling but no striked stop. One patient developed a low asymmetric valgus tibial deformity without epiphysiodesis but tenodesis; it will be corrected with epiphysiodesis.

- The new technique results were evaluated in sixteen patients after one year follow-up. The computer assistance allow a good reproducibility; the mean femoral index is 63% according to Aglietti. After 1,5 years of mean follow-up, the mean Lysholm knee score was 98 (range 94 to 100) and the mean KT-1000 arthrometer side-to-side was 1,6mm (range 0 to 4). Using the IKDC evaluation form, there were 13 patients scored grade A, two grades B and one scored C. In this group, they were no significant growth disturbance.

Ccl.

The quadricipitale technique allows anatomic reconstruction, and is available in skeletal immature patients, it improved subjective and objective knee function.

IMPACT OF INTERVENTION PROGRAMS ON THE INCIDENCE RATE OF INJURIES IN BALL SPORTS: VOLLEYBALL AS AN EXAMPLE

van Mechelen, W., Verhagen, E.

VU University Medical Centre, Netherlands

While participating in sports one has the risk of sustaining sports injuries. Especially team ball sports pose a substantial risk for injury. Many reasons might attribute to this high risk, but generally it can be said that this risk is highly moderated by the presence of many players in close contact with each other. Throughout the literature one can find various studies on preventive measures against injuries. For ball sports one might find many biomechanical studies on the theoretical protective capabilities of certain sports gear, e.g. helmets, shin guards, and mouth guards. Other studies describe certain psychological aspects of player behaviour, while other describe the nature and onset of injuries and conclude with possible preventive strategies. Studies that actually study the effects of preventive measures on injury incidence in team ball sports are scarce. Based on and despite the limited information we have on this topic, there is a contemporary common idea that prevention programmes in team ball sports have great potential preventive effects.

In order to illustrate the potential benefits of such programmes one can look at preventive studies against ankle sprains. A number of studies have looked at the preventive effects of proprioceptive balance exercises against this type of injury. The majority of these studies showed positive results. Common denominator within these studies is that all were carried out within team ball sports. From a scientific point this is logical. For instance, in order to ascertain with a certain amount of confidence that such preventive exercises are beneficial for injury risk, one needs a large group of players that conduct the same exercises in a proper manner. Therefore, it is relatively easy to conduct such large scale studies within team ball sports in which all players train and compete on a regular basis. In addition in team ball sports all players complete a regular warming-up and cooling-down in which preventive exercises can be carried out without interfering too much with regular routines.

Specifically these traits of team ball sports gives prevention programmes within this setting great potential. In theory one can bundle together a number of preventive measures that can be carried out within a team setting, and for which preventive evidence exists (e.g. preventive exercises, risk perception, availability of preventive measures, screening tools). While all players are regularly exposed to this set of preventive measures the likelihood of preventive effects is high. An example of such a programme is a programme that was recently carried out in the Netherlands in volleyball and which can be transferred easily to soccer.

INJURIES IN FOOTBALL, RISK FACTORS AND PREVENTION

Arnason, A.

University of Iceland, Iceland

Football is one of the most widespread sports in the world. When studying injuries in football, three main questions are of interest: First, what is the magnitude of the problem? Second, what are the causes of injuries? Third, what can we do to prevent injuries? Many studies deal with the first question, but fewer studies have been carried out on the second and particularly the third question.

The incidence of injuries in football in elite leagues has been found to be 17-35 injuries/1000 hours for men and 34 injuries/1000 hours for women. During training the injury incidence is much lower or 2-7 injuries/1000 hours for men and 3 injuries/1000 hours for women. The most frequent injury locations are the thigh, knee, hip/groin and ankle, while muscle strains, ligament sprains and contusions are the most frequent injury types.

Various potential risk factors for injuries have been studied and some studies also test the interrelationship between different risk factors. Intrinsic factors as previous injuries, age, and gender have been documented as risk factors for new injuries. Extrinsic factors as low volume of training, a low training to match ratio, inadequate warm up and too high shoe-surface friction have also been considered to be risk factors. Injury mechanisms are of high importance and can interact with the risk factors. During recent years the use of systematic video-based methods in combination with medical information has improved our knowledge of injury mechanisms in football, particularly regarding ankle and head injuries.

Prevention of injuries is of great importance in football. However, relatively few studies have been performed on preventive measures. Some studies apply multifactorial prevention programs which decrease the possibility of identifying the most effective component of the program. Other studies focus on a specific type of injury and specific training, a single exercise or the use of specific equipment. Studies have shown that stability training or use of ankle orthosis can decrease the frequency of ankle sprains in previously injured ankles. Stud-

ies also indicate that stability training could reduce the risk of ACL injuries. In addition, eccentric strength training has also been shown to be of importance in lowering the incidence of hamstring strains.

More and larger studies are needed, that use multivariate models to compare many potential risk factors simultaneous between injured and non injured groups of players. Large studies applying multivariate models are required in order to detect weaker risk factors and relationships between risk factors. Further studies are also needed to investigate the effect of different preventive strategies.

THE INFLUENCE OF FOOTBALL CLEAT DESIGN ON JOINT LOADING

Stefanyshyn, D.

University of Calgary, Canada

Epidemiological studies have linked lower extremity injuries to high rotational resistance between shoe and surface. Torg et al. (1971, 1974) found that injuries in American football were more common under conditions with high rotational traction between the surface and shoe. A more recent prospective study (Lambson et al., 1996) on high school players reaffirmed the findings of Torg et al. They found a significantly higher Anterior Cruciate Ligament (ACL) injury rate with shoes that had higher torsional resistance. These studies suggest that shoe cleat designs with high rotational friction between shoe and surface are associated with knee injuries. However, the actual mechanism of how traction affects knee joint injury remains unknown. We hypothesized that traction of the shoe and surface influences the joint moments and loads at the knee. Therefore, the purpose of this study was to determine how soccer cleats of different designs and traction influence knee joint moments.

Twelve recreational soccer players were recruited for this experiment. All subjects performed a running v-cut with four different shoes. The v-cuts were performed by running straight ahead and then cutting at a 45° angle. All trials were performed on a sample of infilled artificial turf and were conducted at 4.0 m/s. The four different footwear conditions tested were a standard adidas running shoe and three different soccer cleats (Copa, World Cup, Trx). Eight trials per condition were collected with reflective markers placed on the right leg of the subjects. Eight high-speed cameras (240 Hz) were used to record kinematic data. Ground reaction forces were collected by a Kistler force plate (2400 Hz). Joint moments were calculated with inverse dynamics. A repeated measures ANOVA was used to compare the conditions with a level of significance set at 0.05.

There were no significant differences between shoes for the knee extension moments. However, the Copa and World Cup cleats had significantly higher knee abduction and external rotation moments than the Nova running shoes. The Copa cleats had significantly higher external rotation moments than the Trx Cleats. Knee joint loading in the transverse and frontal plane have been proposed to be associated with running injuries (Stefanyshyn et al., 1999) such as patellofemoral pain syndrome. Higher knee joint moments with the traditional soccer cleats (Copa and World Cup) may lead to higher local stress and overuse injuries in the knee joint. Also, the higher moments are likely closer to the ultimate limits of structures like the ACL. Thus, there is less room for error from unexpected perturbations during the movement, increasing the potential for acute injuries.

EPITHELIAL SODIUM CHANNELS IN HEALTH AND DISEASES

Rossier, B., CH

Without abstract submission.

ALVEOLAR NA-TRANSPORT AND HIGH ALTITUDE PULMONARY EDEMA (HAPE)

Mairbäurl, H.

University of Heidelberg, Germany

Alveolar edema results from an imbalance between fluid filtration into the alveolar space and removal by reabsorption. Hypoxia increases filtration by raising pulmonary capillary pressure and increasing endothelial and epithelial permeability allowing fluid and blood cells to access the alveoli, whereas active Na-reabsorption drives the reabsorption of fluid from the alveolar space. Hypoxia inhibits reabsorption by inhibition of epithelial Na-channels (ENaC) and Na/K-ATPase by decreasing activity and gene expression of these transport proteins. A (genetically determined) low activity of alveolar reabsorption in normoxia and further inhibition by hypoxia might cause the susceptibility to high altitude pulmonary edema (HAPE), since at some point the depressed reabsorption may not keep pace with increased filtration, which will result in alveolar edema. Na-reabsorption might even prove totally inefficient in the presence of large leaks of the alveolar barrier, which has been found to occur at very high pulmonary capillary pressures.

Na-reabsorption across the alveolar epithelium has not been measured in HAPE. Therefore Na-transport across the nasal epithelium has been used as surrogate marker based on similarities in subunit expression of ENaC in nasal, airway, and alveolar epithelium. A decreased nasal epithelial potential difference in normoxia has been interpreted to indicate a defective Na-reabsorption as a possible mechanism that might contribute to HAPE-susceptibility, but the variability in nasal epithelial Na- and Cl-transport reduces the usefulness of nasal potentials to diagnose HAPE-susceptibility. Although there are indications for an inhibition of alveolar fluid reabsorption from human lung preparations, changes in lung fluid reabsorption in vivo are not known and measurements have been performed. However, extrapolations to transport activity at the human lung alveolar epithelium from nasal potential measurements appear unreliable since at high altitude cold, dryness, and nasal infections might affect nasal mucosa Cl-secretion, fluid balance and nasal potentials when they are not determined under standard laboratory conditions.

IS1-19 Psychology of sport injuries - "Albertville"

PSYCHOLOGICAL PREDICTION ON SPORT INJURY: EMPIRICAL AND APPLIED ISSUES

Johnson, U.

Centre for Sport and Health Research, Sweden

Epidemiological studies report that the injury risk for elite football players is between 65% and 91% during one season. Thus, the chances of being injured while engaging in sport are statistically high. There has been only very modest evidence to support the assumption that acute injury is directly related to an athlete's physical characteristics. Researchers are increasingly recognizing the multifaceted pathogenesis of injuries.

While deductively derived models of post-injury responses are frequently documented in the literature, there are fewer models of pre-injury vulnerability. Thus, the purpose of this abstract is to examine a leading theoretical model that can predict the onset of a sport injury and contribute to the development of preventive interventions and strategies.

The most influential stress–injury model aimed at predicting the occurrence of sport injury was developed and modified by Williams and Andersen, 1998. It posits that individuals with personality characteristics that tend to exacerbate the stress response, with a history of many stressors, and with few coping resources will be more likely, when placed in a stressful situation, to appraise the situation as stressful. Thus, exhibit greater physiological activation and attentional disruption, leading to increased injury risk.

Several psychosocial factors seem to be related to the occurrence of sport injury. The most cited factors are high competitive trait anxiety, low self-esteem and positive or negative mood state, high life stress and life changes, and low coping skills and social support. However, research about the effect of social support on injury occurrence has not provided consistent findings.

To date, at least 6 studies about intervention strategies are primarily focused on reducing injury risk in sport settings (see Johnson, 2004). Stress management and relaxation are the most frequently used intervention techniques. All the studies claim to have reduced injuries or facilitated training without injury. Some of the studies also describe reduced stress levels and increased self-confidence as a result of the intervention. However, most studies lack a control group and do not report gender. Moreover, few intervention studies seem to be guided by theoretical models such as that of Williams & Andersen (1998).

MOOD STATES AND INJURY PREVENTION IN SPORT - EXPERIENCES FROM RESEARCH AND PRACTICE

Kleinert, J.

German Sport University Cologne, Germany

Measuring of psychological states give information about self-perception and herewith about subject-oriented action requirements. Furthermore, states are strongly connected with motivational aspects of behaviour, both as reasons and consequences of motivation. In this context psychological states are strongly connected with the occurrence of injuries in mainly two dimensions. First, mood states and perceived physical states can be related to the biomedical condition of a person. Although correlations between objective physical conditions and physical feelings of a person are mostly low, in single cases reported bad physical states could be evidence for a substantial lack of physical competence. Thus, perceived bad physical states could be interpreted as risk factors for injury. Secondly, psychological states say something about the motivation, namely the intention and willingness, for injury-related behaviour. This could be both, measures of prevention and risk behaviour.

With this theoretical background the basic question is, whether mood states and perceived physical states have relations to the injury process. This question demands a prospective methodological approach, in that psychological states are assessed more or less short term before potential injury situations. Three studies are reported, in which this demand is realised variably, depended on the organisational circumstances and empirical conditions. In all studies adjective lists have been used to assess physical feelings (questionnaire of perceived physical states - PEPS; Kleinert, 2004) so as mood and motivational states (items from different scales, especially the EZ-scale; Nitsch, 1976).

In study I 186 male and 107 female participants of the aptitude test at a Sport University were asked at the beginning of the test day on their physical states and mood states. 16 injuries (5,5% of participants) happened during the test day. Logistic regression analyses show that both physical feelings, so as high perceived physical activation, low perceived physical health state, and psychological states, so as low self confidence, high sleepiness, high sociableness, are significant predictors of injury occurrence.

In study II psychological states of 941 female soccer players were assessed at the beginning of a 3-day-tournament. The responsible physiotherapists categorised all injuries as low, moderate and high severe. In regression analyses with these injury categories as criterions, especially low perceived physical fitness, low perceived physical health, and high rated sociableness were significant predictors of injuries.

In study III weekly-assessed psychological states of 39 young male elite soccer players were compared with injury cases in the examined group. Case studies show, that mood state and physical state varied specifically some weeks before the injury occurs.

All results have to be discussed within a psycho-physiological and psycho-behavioral theoretical framework.

NARRATIVES OF A CATASTROPHIC ATHLETIC INJURY

Smith, B.

University of Exeter, United Kingdom

In recent years, qualitative researchers have in varied ways explored people's experiences of sport injury and the manner in which they have made a successful recovery from this and returned to their former sporting body-self. To date, however, few qualitative studies have

focused on those people who do not return from a sport injury and who are propelled across the border from the world of the able-bodied into the world of disability where they remain to this day. That is, a border crossing which is permanent and not transitory. Based on life history data, and against the backdrop of the narrative turn in psychology, this paper explores the stories of hope in the lives of a small group of men who have suffered a catastrophic athletic injury and become disabled through playing sport. The most common kind of hope used by the men in telling their stories as they live post-SCI is focused upon in detail. The multi-dimensionality of hope is highlighted. The ways in which three different narrative types operate to shape specific narratives of hope for these men are also illuminated to reveal the ways in which personal experiences of hope are shaped by and embedded within larger social constellations of meaning. Reactions given by sport and exercise scientists to each type of narrative and associated hope are discussed in relation to the issue of tellability and the medicalised practices tied to psychology. The implications of this dynamic process for the participants identity reconstruction as injured and disabled men are finally considered.

Invited symposium (IS)

IS1-20 Is training of reflexes possible? - "Berlin ABC"

AN OVERVIEW OF USEFUL REFLEXES WITH SPECIAL EMPHASIS ON SPORTS

Duysens, J.

University Medical Center, University of Nijmegen, Netherlands

In principle all reflexes can be useful at some point during sports but in this presentation the focus will be on the question that some reflexes may be particularly interesting in this context since they are highly modifiable and therefore can be subject to training. Although there have been claims that even the fastest reflexes can be adjusted to some extent (H-reflex in dancers) it is clear that reflexes with longer latencies are more adaptable. Of special interest are those reflexes with medium or long latency which occur in response to unexpected stimuli since they show habituation (hence plasticity), except if the subject can somehow control the stimuli. In studies on posture some of these responses have been termed automated balance correction responses and it will be argued that these are particularly important in sports situations which can induce ankle inversions. The most consistent responses occur at around 85 ms in leg muscles. It has been pointed out that similar responses are occasionally seen in man after a complete transection. However, this does not prove that these responses are entirely mediated by spinal reflexes. Rather it is argued that supraspinal pathways are important for these reflexes. There are many similarities with startle responses and it will be argued that a minor form of startle is a very functional adaptation since it provides for a brief period of freezing giving the perturbed subject sufficient time to assess the nature of the perturbation and provide an adequate response.

It is striking that these minor startle responses can be well integrated in the ongoing activities of the subject. During gait this assimilation is related to an efficient phase-dependent modulation of reflexes. The responses have been mostly studied in leg muscles. However, some recent work has used crutch walking to evaluate the responses in arm muscles after a brief unloading. These responses were found to habituate rapidly, again indicating a link with startle-induced behaviour.

The responses with the longest latencies occur at about 120 ms. These responses are still too fast to be voluntary reactions. It is argued that they represent triggered reactions and that they may be brainstem mediated reactions, which can be triggered by a cortical command (related to a visual stimulus for example). Of special interest are the recent findings that the latter type of responses may be speeded up by combining the stimuli with inputs, which can induce startle. Some authors have argued therefore that one can question the validity of the 100 ms limit used to establish the presence of false starts in various races. Furthermore, it has been suggested that these responses are basically mediated through subcortical pathways but triggered by a cortical command.

SENSORIMOTOR AND BALLISTIC STRENGTH TRAINING: SPINAL OR SUPRASPINAL NEURAL ADAPTATION?

Taube, W., Gruber, M., Beck, S., Gollhofer, A., Faist, M., Schubert, M.

University of Freiburg, Germany

Four weeks of SMT and BST were evaluated. It was ypothesized that SMT as a postural training predominantly affects propriospinal mechanisms while BST, in emphasizing voluntary movement will primarily induce supra-spinal adaptations. Therefore, a first series of experiments was designed to test this hypothesis. Changes at the cortical level were evaluated by means of transcranial magnetic stimulation (TMS), and spinal effects were assessed by means of peripheral nerve stimulation (H-reflex). Training was evaluated at rest and in the active state, i.e. in tasks corresponding to each of the two trainings: Subjects were tested during voluntary plantarflexion (PFL), corresponding to the movements required for BST and during stance perturbation on a treadmill (PER) which resembled to the motor task of SMT.

Both training interventions improved RFD and stance stability.

Corticospinal excitability was significantly reduced in tasks resembling the training condition, e.g. during perturbation following SMT and during PFL following BST. Conversely, corticospinal excitability was enhanced in the non-trained task, e.g. during PFL following SMT and during perturbation following BST. This observation of task-dependency of training effects underscores the need to consider the circumstance of any assessment. It is suggested that the actual training effect must be seen as the improved capability to modulate corticospinal facilitation between tasks.

A second series of experiments was designed to assess the relative adaptability of short (SLR) and long latency (LLR) reflexes following SMT. For this purpose fast posterior translations (PER_fast) were applied during stance on the treadmill to induce SLR and LLR in the soleus muscle. TMS and H-reflex testing again were used to assess spinal and supraspinal contribution to SLR and LLR. Training did not affect the SLR. This lack of SLR change indicates that the early component of a postural compensatory response is not affected by such a short period of training. Contrary to SLR, spinal as well as supraspinal excitability were reduced at LLR emphasizing strong neuroplasticity for later parts of the reflex response. As spinal adaptations were only observed for LLR it is assumed that supraspinal centres controlled motoneuronal transmission.

In summary our results support the claim that measurements should be taken during activity and not at rest in order to detect training related neural adaptations. We furthermore emphasize the need to measure in tasks closely related to the training condition. Moreover, challenging the system with an unfamiliar motor task may disclose a transfer of training effects to non-trained movements, thereby giving an idea of the true extent of training-induced plasticity. This implies that training affects the entire motor system and suggests supraspinal control to be relevant for spinal and transcortical reflex adaptation.

FROM OBSTACLE TO FALL? SENSORIMOTOR TRAINING HELPS FALL PREVENTION IN THE ELDERLY

Weerdesteyn, V., Duysens, J.

Sint Maartenskliniek, Netherlands

The problem of falls in the elderly has become a topic of growing scientific interest. Numerous studies on risk factors for falls and preventive strategies have been published in the past decades. The development of fall prevention interventions has usually been based on these known risk factors. Another approach would be to develop an intervention program that is based on the reported circumstances of falls. Such interventions would typically include elements like obstacle course walking, because a large number of falls in the elderly are a consequence of tripping over obstacles while walking. In order to enhance the probability of success of such intervention programs, it may help to get a better understanding of why elderly fall over obstacles. Previous studies have reported an age-related decline in the successfulness of obstacle avoidance under time pressure1. Differences between young and older adults, however, were rather limited, probably because only minor step adjustments were required. In order to further elucidate age-related limitations in obstacle avoidance skills and their relation to the risk for falling in the elderly, we have developed a new time-critical obstacle avoidance task that requires fairly large step length adjustments. In this task, participants are requested to avoid an obstacle that suddenly falls in front of the foot while walking on a treadmill. The results showed that advancing age had a detrimental effect on the successfulness on this task, which could be attributed to increased reaction times, non-optimal avoidance strategies, and smaller horizontal clearance margins. Furthermore, the successfulness on this task clearly discriminated recurrent fallers from non- or one-time fallers, which underscores the contribution of declined adaptive gait skills to the high fall incidence rates in the elderly. Therefore, a next research question was whether a new 5-week falls prevention exercise program for the elderly (with a strong emphasis on adaptive gait) could improve obstacle avoidance skills and whether this would coincide with a reduction in the number of falls. The program consisted of exercises on an obstacle course (with or without dual task and reduced vision conditions), walking exercises, and the practice of fall techniques. The effectiveness of this falls prevention program was evaluated in a randomized clinical trial. As a result of training, the obstacle avoidance success rates significantly improved, especially when there was very little time (<350 ms) to react. The improvement was mainly achieved by larger horizontal clearance margins. Most importantly, fall incidence rates of the exercise group were found to decrease by as much as 46% compared to the control group. In conclusion, an exercise program that is focused on adaptive gait skills does not only improve these skills, but also effectively reduces the risk for falling in the elderly.

OP1-16 Physiology 4/10 - "Oslo"

ACTUAL MEASUREMENT OF ALVEOLAR OXYGEN STORE CHANGES ALLOWS REDUCING VARIABILITY OF BREATH-BY-BREATH OXYGEN UPTAKE IN HUMANS

Wüst, R.C. 1+2, Aliverti, A. 3, Kayser, B. 4

1 IFKB, Vrije Univ., Amsterdam, 2 Dipartimento di Bioingegneria, Polytechnic, Milan, 3 ISMMS, Faculty of Medicine, Univ. of Geneva, Geneva, 4 ISMMS, Faculty of Medicine, Univ. of Geneva, Carouge, Netherlands

Breath-by-breath (BbB) oxygen uptake at the mouth (VO2M) is used to study aerobic metabolism of the organism. However, VO2M is hampered by poor signal-to-noise ratio and this limits the study of oxygen uptake kinetics. Variability of VO2M is due to physiological and experimental factors. One physiological factor concerns BbB variation in lung oxygen stores due to BbB variation in end-expiratory lung volume (EEVL). Variability of actual alveolar BbB oxygen uptake (VO2A) should therefore be lower compared to VO2M. To date only imperfect estimations of BbB changes in lung oxygen stores were used to correct VO2M since direct measurement of lung oxygen stores was not possible. Opto-electronic plethysmography (OEP) now allows accurate monitoring of absolute lung volume changes and therefore pulmonary oxygen stores (Aliverti et al. J Appl Physiol, 96:1464-9, 2004). Methods. To test the hypothesis that BbB variability in VO2M is for a large part due to BbB variation of lung oxygen stores, we measured, by means of OEP, VO2M and VO2A in parallel, at rest and during transients and steady state cycling exercise at 60, 90 and 120 Watt in 7 healthy subjects [mean (std) age: 35.1 (9.0) years; FRC: 4.54 (0.85) l and TLC: 7.62 (0.96) l]. In addition, in order to test the robustness of direct measurement of VO2A with OEP we asked the subjects to voluntarily change their end-inspiratory lung volume (EIVL) and EEVL between breaths to exaggerate the effects of changes in gas stores in the lung. Results. Average VO2M and VO2A at steady state were the same. Direct measurement of VO2A reduced overall BbB variability by 24% ($P<0.0001$). The difference between VO2M and VO2A was larger during transients than at steady state ($P<0.0001$). This effect was greater during on-transients than off-transients ($P<0.01$). Variance of the difference between VO2M and VO2A could be explained for 46% by BbB changes in EEVL and 9% by BbB changes in end-expiratory gas oxygen fraction. During voluntary variation of EIVL and EEVL VO2M showed increased variability and occasional paradoxical net oxygen excretion while VO2A remained stable within a physiological range. Discussion.. The main findings were that 1) by taking into account actual changes in lung oxygen stores BbB variability of oxygen uptake is reduced, 2) the impact of changes in lung oxygen stores is greater during transients as compared to steady state conditions, 3) the effect from changes in lung oxygen stores is greater during on- than off-transients, 4) about half of the overall BbB variability at the mouth is due to BbB changes in end-expiratory lung volume and 5) the OEP measurement of VO2A allows to correct for large voluntary changes in lung oxygen stores. Conclusions. Actual measurement of alveolar oxygen uptake by OEP allows greatly reducing variability in BbB measurement of oxygen consumption by the organism. These findings open new avenues for research into oxygen uptake kinetics with greater precision as up to today.

THE RECOVERY OF REPEATED-SPRINT PERFORMANCE OCCURS BEFORE THE FULL RECOVERY OF MUSCLE LACTATE AND PHOSPHOCREATINE

McGawley, K., Edge, J., Bishop, D.

University of Brighton, United Kingdom

Single and repeated-sprint protocols result in significant rises in blood and muscle lactate (La-bl and La-m), and significant decreases in muscle pH (pHm) and phosphocreatine (PCr)(1,2). High correlations have been demonstrated between the percentage restoration of power during a second 30-s sprint and the percentage resynthesis of PCr, while neither pHm or La-m recovery were related to the recovery of 30-s sprint performance(1). To date, however, no study has investigated the relationship between the recovery of muscle metabolites and the recovery of repeated-sprint performance. Furthermore, no study has investigated metabolite concentrations at a point when subsequent performance is fully recovered. The aim of the present study was to identify the relationships between performance recovery and the recovery of muscle metabolites, La-bl and oxygen consumption (VO2) following 5 x 6-s repeated-sprint exercise. Nine female soccer players (mean ± SD: age 27 ± 7 y; mass 60.5 ± 5.3 kg; VO2max 50.0 ± 3.9 mL/kg/min) performed two consecutive 5 x 6-s maximal sprint-cycle bouts (B1 and B2) on eight separate occasions. The five sprints within each bout were separated by 24 s of active recovery and the two bouts were separated by passive recovery periods lasting 5 – 14 min. Trials 1 – 6 were used to identify the least time required to recover total work done (Wtot) over a 5 x 6-s bout (time = trec). During trial 7, expired air was collected between B1 and B2 (separated by trec). During trial 8, blood samples and v. lateralis muscle biopsies were taken at rest, immediately post B1 and at the individual trec. Following trec (mean ± SD: 10.7 ± 1.2 min), Wtot recovered to 100 ± 1.05 % (B1: 18575 ± 1792 J, B2: 18579 ± 1861 J; P=0.947). La-bl was higher than at rest both immediately post B1 and after trec (11.6 ± 3.2 and 10.9 ± 4.6 vs 1.0 ± 0.5 mmol/L; P<0.001). pHm dropped during B1 (7.1 ± 0.1 to 6.9 ± 0.1; P<0.01) and recovered to 7.1 ± 0.1 at trec (not different from rest, P>0.1). La-m content was elevated above the resting value post B1 (95.0 ± 54.7 vs 14.4 ± 1.6 mmol/L; P<0.05) and dropped significantly during recovery, remaining higher than the resting value (38.0 ± 16.4 mmol/L; P<0.05). PCr was reduced to 43 ± 22 % of resting content following B1 and despite recovering to 82 ± 13 %, remained lower than baseline PCr content after trec. During recovery from B1, VO2 was unchanged (i.e., had stabilised) after 3.0 min (P>0.05). Results suggest that the full recovery of La-bl, La-m and PCr is not necessary for the recovery of 5 x 6-s sprint performance in trained, female, team-sport athletes. Instead it may be more important for pHm to have returned to baseline levels and for sufficient PCr resynthesis to have occurred to recover work in a second bout. 1. Bogdanis G., et al. (1995). METABOLIC AND MECHANICAL CONTRIBUTIONS TO THE EXERCISE-INDUCED CIRCULATORY RESPONSE

Dufour, S., Doutreleau, S., Lonsdorfer-Wolf, E., Lampert, E., Piquard, F., Lonsdorfer, J., Geny, B., Mettauer, B., Richard, R.

Service de Physiologie et d'Explorations Fonctionnelles, Hôpital Civil, France

Background. Because of its pivotal role in setting systemic oxygen (O2) delivery, cardiac output (Q) is considered as a determining factor of aerobic exercise capacity in both health (1) and many disease states (3). Both heart rate (HR) and stroke volume (SV) are direct determinants of Q adjustments during exercise and their observed responses are expected to be driven by metabolic (i.e. whole body energy demand) and/or mechanical (i.e. muscle tension) components of the exercise workload (2). Metabolic demand and muscle mechanical tension are closely coupled during whole-body exercise, making their respective drives to the circulatory response difficult to establish. As this coupling is altered in eccentric cycling, we implemented an experimental design featuring eccentric vs. concentric constant-load cycling bouts to gain new insights in human circulatory control during exercise.

Methods. HR, SV, Q, whole body oxygen uptake (VO2) and electromyographic (EMG) activity of the quadriceps muscles were determined in 11 subjects at baseline and during heavy concentric (HC), low concentric (LC) and high eccentric (HE) cycle exercises. HE and LC were designed to elicit similar VO2 (~1.15 L/min) whereas HC and HE were set at equivalent power output (270 ± 13W). Using a reductionist approach, the difference of circulatory response observed between HC vs. LC was subsequently ascribed to either the metabolic (as estimated from HE vs. HC) or to the mechanical (as estimated from HE vs. LC) component of the exercise workload.

Results. SV responses to exercise were almost exclusively determined by the whole body metabolic demand (85%), which also accounted for 75% and 66% of the Q and HR responses respectively. Muscle mechanical tension appeared to exert a significant influence on the circulatory adjustments, accounting for 25% and 33% of the Q and HR response respectively. Q and HR responses were strongly associated with EMG changes, whatever the combination of whole body metabolic demand or muscle mechanical tension.

Conclusion. Even if whole body metabolic demand is the main driving factor to the exercise-induced circulatory response, these results suggest that the circulatory adjustments to exercise are also under significant muscle mechanical tension control. Moreover, these findings support the idea that the circulatory response is adjusted to muscle activity during high-intensity cycle exercise in humans.

PHYSIOLOGICAL ADAPTATIONS TO ENDURANCE TRAINING IN ELITE CYCLISTS

García-Zapico, A., Calderón-Montero, F.J., Benito-Peinado, P.J., González-Barbera, C.

Universidad Complutense de Madrid, Spain

The purpose of this study was to describe and evaluate the evolution of physiological parameters as a control tool for training monitoring in a group of young cyclists (age 20±1.9 years; mean VO2max ~77 ml•kg-1•min-1), during one season of training, divided in two periods (winter or "volume" mesocycle and spring or "intensity" mesocycle) between the tests that they carried out in the laboratory, consisting on a ramp test until exhaustion (work load increases 25 W•min-1) and a maximal lactate steady state (MLSS) test in a cycle ergometer. The following variables were recorded at VO2max, first ventilatory threshold (VT1), second ventilatory threshold (VT2) and MLSS: load (W), oxygen consumption per kilogram body mass (VO2max in ml•kg-1•min-1; except in MLSS), hart rate (HR beats•min-1) and Lactate concentration ([La] in mmol•l-1). Macronutrients and haematological variables were also recorded during the test periods, and volume and intensity of training everyday from the beginning until the end of the study.

The physiological obtained data (463±13.4 Wats; 80.5±1.8 ml•kg-1•min-1; 62±1.7% VO2max for VT1 and 90.1±1.4% VO2max VT2) were similar to those previously reported for professional cyclists (Lucia, Hoyos & Chicharro, 2001, Mujika & Padilla, 2001). Also the values for the MLSS (255±10.6 Wats) agree with the ones reported by (Beneke, 2003). The adaptation response is represented by higher loads and VO2max (increases of ~9% of VO2max and ~8% in maximal reached Load) . Subjects improved VT1 and VT2 ($p<0.05$) after the first period (8% and 5% respectively) of training even thought the low intensity of it, focused on the performance of VT1. The MLSS performed after the first period ($p<0.05$) and remained high in the second. High levels of CK (~230 U•L-1) and Urea (37 mg•l-1) plus an insufficient Carbohydrates intake (~52%) could be responsible of the decrease of some red blood cell parameters ($p<0.05$) like the Haemoglobin values, advising of possible future overreaching processes described in similar training groups.

In conclusion, the high levels reached by the subjects after the first period of training could only be maintained in central indicators and probably improved in peripheral variables not measured in the study as previously reported for professional cyclists.

PATTERN, MAGNITUDE AND RELIABILITY OF STRAIN OF ULTRA-ENDURANCE (>24 H) COMPETITION

Lucas, S.J., Cotter, J.D., Palmer, C.D., MacKay, T., Anson, J.G.

University of Otago , New Zealand

There has been little research on the physiology of competitive ultra-endurance exercise lasting longer than one day. Ultra-endurance events such as adventure races involve substantial environmental, exertional and cognitive stresses with severe sleep deprivation. We have now studied the pattern and magnitude of cardiovascular strain and haemodynamic responses across two semi-continuous races lasting 86-120 h (2003 and 2004 Southern Traverse Adventure Race). Heart rate averaged 64% of athletes' heart rate range (HRR) for the first 12 h of both races, and 40-45% HRR thereafter (41% in 2003, n=11; 44% in 2004; n=4). Standardised exercise tests conducted before and after the 2003 race showed that the heart rate to work rate relationship was consistent but perceived exertion was elevated (reported previously). The hypervolaemic response was also large and reliable; plasma volume expanded by 24 ± 10% in both the 2003 race ($p<0.01$, n=37) and the 2004 race ($p=0.02$, n=4). Differential leukocyte count responses were less reliable. The large increases in plasma concentrations of neutrophils and monocytes early (15-35 h) in racing were apparent both in 2003 (n=11; up by 166 and 130%, respectively) and 2004 (n=4; 235 and 170%), but the 44% increase ($p<0.05$) in lymphocyte counts in 2003 was not evident in 2004 (up by 6%; $p=0.59$). The elevations in neutrophils and monocytes were still evident at completion of both races (up by 80 and 60%, respectively in 2003; 138 and 81% in 2004), whereas lymphocytes were only slightly elevated in 2003 (up by 13%, $p=0.36$) and lower in 2004 (down by 36%, $p=0.02$). Thus, neutrophilia and monocytosis responses were reliable across races and concur with findings from shorter endurance exercise and sustained military training, however the lymphocyte numbers did not consistently show the decreases reported by others following endurance exercise and sustained military training.

Heart rate data (n=3) collected in subsequent 24-h competitive and semi-controlled studies of sustained exercise indicate a similar trend. Data obtained from one athlete competing in a 24-h event and who had competed in both the 2003 and 2004 Southern Traverses, averaged 61% HHR for the first 12 h and then 35% for the remainder of the 24-h event. Heart rate data collected from a pilot study (n=2) of a 24-hour adventure race simulation averaged 60% HHR for the first 12 h and then 42% for the remainder of the simulation. Thus, the magnitude and pattern of exercise intensity appear to indicate a reliable intensity reduction, plateauing to 40-45% HRR within 24 h.

We have observed a consistent pattern of cardiovascular strain during sustained, ultra-endurance events lasting 24 hours or more. After the first 12 hours of higher intensity, athletes select a sustainable pace that they maintain for the remainder of the race, at 40-45% of heart rate range. We are currently using the 24-hour simulation to investigate the mechanisms behind this change in pace selection.

OP1-17 Doping 1/1 - "Turin ABC"

ON EDUCATION FOR NOBLE SPORTS RIVALRY

Kosiewicz, J.

Academy of Physical Education , Poland

It is possible to exert a significant and lasting influence on sportspersons' ethical attitudes; to contribute to their personal and moral transformations, as well as to their maturation taking into account the fair play principle as a momentous idea included in a superior – and the highest – moral value which is the Good in its Socratic and Platonic interpretation.

The principle of fair play constitutes some specific part of a broader moral idea of fair conduct. It concentrates on the ethos of honest play, but only in a highly reductionist meaning; namely, on moral convictions of persons connected with sport. In this sense, persons studying manifestations of the principle of fair play do not focus their attention on other forms of game – e.g. those connected with war games, gambling or other , etc. – the theory of games refers to. Neither it deals with various forms of games being present in art.

The ethical discourse concerning sports rivalry, if referred solely to the principle of fair play, does not also take into account a broader theoretical and postulative context of these forms of fair conduct which are not connected with any form of a game. Neither it takes into account other ethical theories, codices, moral ideals – both in their diachronic and synchronic, religious and non-religious interpretation – concerning Western and non-Western (e.g. Oriental) moral systems.

The discourse on the issue of noble sports rivalry should not concern solely moral reflection of the principle of fair play isolated from a broader context. It should be closely connected with moral education as such, and especially with ethics as a discipline providing a proper context for theoretical and postulative considerations on the idea of fair play, on the ethos of honest play where sport is treated as a special field of objectification of active goodness.

If there are no classes in ethics as an autonomous subject – and, additionally, classes in ethics referring to sports activity, which would take into account ethical aspects of sport, including the idea of fair play, in their curricula - in primary and secondary schools, this is the

situation when the whole burden of initial and developing education for the noble sport rivalry should, according to my opinion, rest on persons connected with sport for all (that is, school teachers of physical education, coaches, instructors), as well as with school sport, movement recreation and recreational forms of tourism constituting the basis of activities of various extra-school associations.

REMOVING DRUGS FROM SPORT: IS IT TOO LATE?

Freeman, W.H.

Campbell University, United States

The problem of removing illegal performance-enhancing drugs from sport becomes greater each year. Drug use removes the assumption of a fair platform for competition, skirts the ethic of success through diligence and devalues records that become unattainable by honest means. Even as more thorough methods of testing are developed, they arrive in the face of ever more subtle advances in the development of less-detectable substances. One recent drug regimen that produced several world champions was detected only because a competing coach turned in a sample of the drug, enabling researchers to develop a detection mechanism. Detection difficulties create suspicion of all elite performances and of great athletes. Is it possible that the detection process will never fully catch up with the cheaters? Should we give up and remove drug restrictions, especially as there are no other types of restrictions on training? If we did remove drug restrictions, on the positive side the records would no longer be questioned and the competitions would become more fair, as all athletes could use any means for improvements in performance. On the negative side, athletes never evaluate risk objectively, as the desire to win is too great. Also, advice to athletes may be questionable, as there are always coaches and medical people willing to assist in ways that put the athlete at risk. There may never be clean sport at any level. The long term impacts of drugs on sport include the drift toward androids: Athletes may become less human as they drug and genetically engineer themselves farther from normal humans. Serious risks will always be present. Medical ethics usually prevent research into the effectiveness of dangerous drugs and of extreme levels of dosages, which by definition is what athletes will choose to use, thus leaving large areas of unknown risk. The risk will shift from the danger of using drugs to the degree of using more dangerous levels or types of drugs to get ahead of a field where everyone uses drugs. Ultimately the removal of drug restrictions will result in an increased rate of athlete fatalities due to drug usage.

HOW EFFECTIVE ARE THE ANTI-DOPING CAMPAIGN?

Hanstad, D.V.

Norwegian School of Sport Sciences, Norway

Introduction

The anti-doping work is characterized by a strong development after the establishment of World Anti-Doping Agency in 1999. In the Olympic movement, where most of the tests are taken, all OF the 202 National Olympic Committees (NOCs) and all OF the 35 international federations have accepted the World Anti-Doping Code (WADC) and are undertaking anti-doping work.

But how effective is the anti-doping work? How many of these organisations are carrying out well functioning doping controls? This is the topic for my presentation.

Methods

The study is based mainly on interviews with key figures in eight different anti-doping organisations (ADOs) and in the WADA. The anti-doping organizations were the national organisations (NADOs) in South-Africa, France, China, USA and Norway, and the sport federations of athletics and rowing (Hanstad & Loland 2005). In addition, a number of sources have also been systematically examined, mainly documents regarding the World Anti-Doping Programme (WADP), statistics from individual ADOs as well as other relevant literature on anti-doping work.

Results

Among the National Olympic Committees, less than half, approximately 90 out of 202, test their athletes for drugs. Less than half of them have programmes that do not meet the requirements of the World Anti-Doping Code. The remaining 40 have their own NADOs. However, when addressing the Code requirements of registered testing pool, whereabouts information and out-of-competition testing, more committees are left out.

If the characteristics for a good NADO means ISO-certification or taking out-of-competition tests for the WADA, or have proven that they follow WADP and conduct a reasonable number of efficient controls, only about twenty NADOs can be characterized as such.

Similary, according to the WADA Code the 35 international Olympic sports federations have to meet the adopt and implement anti-doping policies and rules which conform with the Code as well. The study shows that the number of good ADOS is just as low here as with the NADOs.

Discussion/Conclusion

The real, critical question in current anti-doping work is the lack of well functioning NADOs and ADOs in the international federations. This situation has many causes, among them a lack of resources and a lack of will to give priority to anti-doping activities. The anti-doping movement need to develop strategies in this respect. The most important requirements to increase the effectiveness of ADOS are:

(i) The coordination and cooperation between ADOs, primarily between NADOs and IFs, have to be improved and made more close. (ii) Anti-doping organizations and governments need to be independent from sport. (iii) There are needs of better procedures for recruiting doping control officers and stronger educational programs.

THE TURKISH ATHLETES ATTITUDES TOWARDS DOPING. WHY DO THEY USE?

Karli, U., Polat, E., Kocak, S.

Middle East Technical University, Turkey

THE TURKISH ATHLETES ATTITUDES TOWARDS DOPING. WHY DO THEY USE?

Ünal KARLI, Ercan POLAT, Settar KOÇAK

The problem of doping has existed as long as sport has been known as a social phenomenon. Up to date, national and international sports governing bodies have put forth legislations and regulations in the anti-doping fight. In the past and now laws and penalties are constructed to dissuade the athletes from their unfair and unhealthy behaviors, but it is seen that all were useless in preventing athletes

from doping. Although athletes' beliefs and motives are known to influence their doping usage behavior, there is no deep information about subject. Therefore, the purpose of this paper was to investigate the attitudes of Turkish athletes towards doping.

In-depth interviews with the athletes were the primary source of data collection procedure. Power athletes who had experience in using illegal ergogenic aids and who are still using them in their sports life composed the subject group. The authors get in contact with 25 subjects and 11 of them accepted to be subject to the research. Semi-structured interviews were conducted to the 11 athletes who accepted participating voluntarily, and 10 of them were taken into considerations. The interview was composed of questions such as; ice breaking questions "Let's tell us about your athletic background" and "What does sports mean for you?" and main questions "What do you think about the role of doping in performances of athletes in our country and all over the world?", "What is your opinion about doping usage of the athletes?", "How many times have you experienced legal and illegal performance enhancers in your athletic life? What would you tell us about your experiences?" and so on.

After transcribing the data gathered from the interviews, three of the authors coded the data and after then, each of the coded out puts was compared. Then after all the authors consensus the data ordered under five themes which were the athletic background of the subjects and their approach to sports, the usage rate of doping and its role on athletic success, subjects experience with legal and illegal performance enhancers, doping and social life and the fight against doping.

Findings indicated that the athletes purpose on involving in sports shifted by time, while it was such a leisure activity at first now it is a profession for them. They reported that using doping is inevitable for athletic success and they believed that the usage rate of doping in Turkey and all over the world is very high. Additionally, the subjects stated that curiosity, performance enhancement, friend and coach offers were their initiating reasons for their initial experiences with doping. Also they think that the policy about the fight against doping is not fair both in national and international level. They see doping as a must to reach sportive success, but even they think so, they mentioned that their preference is that competing in a drug purified competition.

OP1-18 Health and Fitness 2/4 - "Berlin DE"

EFFECTS OF WALKING ON DESIRE TO SMOKE AND WITHDRAWAL SYMPTOMS DURING A SMOKING CUE, AND AD LIBITUM SMOKING

Katomeri, M., Taylor, A.H.

University of Exeter, United Kingdom

Failure to cope with cigarette cravings have been linked to high relapse rates among smokers attempting to quit. Recent research has shown a positive effect of walking on cravings, responses to a smoking cue (following stress), and on ad libitum smoking (Katomeri & Taylor, 2005). This study aimed to examine the effects of a 15 min walk on withdrawal symptoms and cravings, response to a smoking cue (with no prior stressor), and time to ad libitum smoking. 17 males and 13 females, aged 21.9 (SD = 2.1) years, smoking 13.7 (SD = 4.3) cigarettes daily were recruited. Following 2 hours of abstinence, smokers attended sessions involving either a brisk self-paced treadmill walk or being seated for 15 min, in a counterbalanced within-subject design. After treatment, subjects remained seated for 10 mins and then were only allowed to handle a lit cigarette. A single-item measure of desire to smoke (Tiffany and Drobes, 1991), and the seven item Mood and Physical Symptoms Scale (West and Russell, 1985), to assess withdrawal symptoms, were administered pre-, mid-, and post-treatment, and also pre and post handling the lit cigarette. A series of two-way fully repeated ANOVAs revealed a significant overall interaction effect for time x condition for all 7 MPSS items, Depression $F(2.7, 79.7)=9.5$, $P<0.001$; Irritability $F(4, 116)= 10.5$, $P<0.001$; Restless $F(3.2, 91.7)=7.7$, $P<0.001$; Tension $F(3.1, 91.3)=10.9$, $P<0.001$; Concentration $F(2.2, 64.9)=18.7$, $P<0.001$; Stress $F(2.9, 84.3)=15.9$, $P<0.001$; Anxiety $F(4, 116)=8.6$, $P<0.001$; and the desire to smoke item $F(3.0, 87.3)=39.2$, $P<0.001$, all with a Greenhouse-Glasser correction (except where df=4, 116). In all cases, post hoc t tests revealed significantly lower measures following exercise than the control condition, relative to baseline. Unlike a previous study (Katomeri & Taylor, 2005), calculated changes in desire to smoke from pre to post smoking cue were greater following exercise compared with the control condition. This may have been due to a ceiling effect for the control condition or a response to a higher exercise intensity (HRR=37.3; mean Rating of Perceived Exertion (RPE) =12.2) than reported by Katomeri & Taylor (2005)(HRR=24.1; RPE=10.9). Also, a first cigarette was smoked significantly later, $F(1,19)=8.5$, $P<.01$, following exercise (ie, 66 mins (SD=48) compared with 31 mins (SD=33) after the control condition.

COMPARISON OF THE PHYSICAL CAPACITY OF NORMAL WEIGHT AND OBESE ADULTS

Kümmerle, A., Schaar, B.

German Sport University Cologne, Germany

Obesity is a chronic disease affecting people of all ages and socio-economic backgrounds. The resulting costs for health insurances range from 3.9 to 10.33 billion per year. By 2000, the number of obese adults in Germany had risen to more than 13 million and to over 300 million worldwide. These people suffer from lack of exercise. To prevent both over- and underestimation of individual training intensity a diagnosis of the actual fitness level is required. But there seem to be deficits in knowledge about exercise testing in obese adults and in transforming standard tests for studying obesity. The purpose of this project is to compare physical capacity in obese subjects during treadmill and bicycle exercise to examine the limiting factors.

3 groups performed the same standardized test on treadmill (TM)(modified WHO) and bicycle (B) (WHO): 1. Obese (n=24, 40±8.6 years, 174.7±9.2cm, 34.3±3.1kg/m²); 2. Normal weight (n=24, 39.7±8.3 years, 177.1±9.7cm, 22.8±1.8kg/m²), 3. Students of sports science (n=20, 24.1±2.1 years, 177.7±9.2cm, 21.6±2.0kg/m²). The limiting factors and the applicability of the tests were examined to give an outlook onto

their potential modification and optimization for obese people. Body composition, BMR and maximal values for HR, lactate, VO2, RER, load and time were registered. The study was done as a quasi-experimental examination with 3 groups and 2 tests in one session.

Body composition shows a significant difference in FM only (p=0.000). No difference in BMR (p=0.362) and VO2rest (p=0.402) can be proved between the 3 groups. While EG1 differs from EG2 and EG3 in HRmax (p=0.000), Pmax (p=0.000), tmax (p=0.000), HR2mmol (p=0.000), HR4mmol (p=0.000), v2mmol (p=0.000) and v4mmol (p=0.000) on treadmill, EG1 and EG2 show no difference in bicycle results for these parameters. EG1 shows the least endurance capacity and no maximal load on TM but a significantly better performance on B. The correlation of Pmax, tmax, HRmax, v and HR at 2 and 4 mmol/l lactate indicates a clear link to both BMI and FM on treadmill in contrast to on bicycle.

Cardiac, pulmonary, vascular and muscular performance does not differ between obese and normal weight subjects when testing is executed under body weight relief. The data suggests that FM limits maximal performance and is more important than metabolic, respiratory and cardiovascular factors when stress testing is executed under full body weight. In conclusion, compared to B results the TM test is not suitable for the obese to reach maximal load so a data-based training control is hardly possible because of low performance and FM as a performance limiting factor. Further studies should focus on the modification and standardization of treadmill tests for the obese.

THE EFFECT OF EXERCISE TRAINING ON FAT OXIDATION AND INSULIN SENSITIVITY IN OBESE MEN

Venables, M.C., Heywood, B., Jeukendrup, A.E.

Human Performance Laboratory, the University of Birmingham, United Kingdom

PURPOSE: Insulin resistance is a state commonly associated with inactivity, and is a hallmark feature of disease states such as obesity and non-insulin dependent diabetes mellitus. As well as being associated with insulin resistance obese and inactive individuals have an impaired ability to oxidize lipids. The purpose of the study was to investigate whether an endurance exercise training protocol, designed to utilize high rates of fat, produced more favourable effects on both fat oxidation and insulin sensitivity than a program designed to utilise less fat.

METHODS: In a counterbalanced cross over design, eight sedentary, obese but otherwise healthy male subjects (Age 40 ± 5 y; BMI 32.9 ± 2.9 kg∙m-2) performed two blocks of endurance training at different intensities: either at a predetermined intensity eliciting maximal fat oxidation (TPCON), or at 5-min intervals of ± 20% FATmax (TPINT). Each training block lasted 4-weeks and were separated by six-weeks of no exercise. Training sessions (5 times per week) were 30-mins in week 1, increasing by 10-mins per week until each session was 60-mins by week 4. An OGTT, VO2max test, 30-min steady state exercise at 50% of pre-training VO2max and measurements of body composition were undertaken pre- and post-training. Throughout the day preceding these tests, subjects were fed a diet consisting of 50% carbohydrate, 35% fat and 15% protein, totalling ~2900 Kcal per day. Variables were compared using training type (TPCON, TPINT) x exercise (pre-, post-training) repeated measures analyses of variance.

RESULTS: No change in body weight, body mass index (BMI), waist to hip ratio (WHR) or percent body fat (%BF) was observed post TPCON or post TPINT. Average energy expenditure during the training sessions increased from ~250 kcal in week 1 to ~500 kcal in week 4 and was no different between the protocols. However average training intensities for TPCON was 44 ± 6 %VO2max and for TPINT were 25 ± 6 and 65 ± 6 %VO2max, respectively.

It was shown that fat oxidation rates were increased by 44% post TPCON (0.24 ± 0.01 vs 0.35 ± 0.03 g∙min-1), $p<0.005$ but not post TPINT and that whole body insulin sensitivity index was increased by 27% post TPCON (2.47 ± 0.26 vs 3.13 ± 0.31, $p<0.01$) but only 2% post TPINT.

CONCLUSION: It can be concluded that a short term exercise training protocol designed to induce high rates of fat oxidation, increases the contribution of fat to substrate oxidation during exercise and can significantly increase insulin sensitivity within 4 weeks.

OSTEOGENIC INDEX OF STEP EXERCISE

Veloso, A., Oliveira, C., Santos-Rocha, R.

Sport School RioMaior-Polytechnic Inst. Santarém / Fac. Human Movement-Technical Univ. Lisbon, Portugal

Step Exercise has been promoted as a low impact physical activity recommended for the improvement of cardio respiratory and muscular fitness. It allows obtaining metabolic and biomechanical stimuli, higher that those obtained during walking, similar to those obtained during jogging, but with lower risk of injury. Hundred Step sessions were observed and characterised in terms of session duration, stepping rate every 5 minutes, total number and type of movements, and number of loading cycles. Peak vertical ground reaction forces (GRF) in normalised units of body weight (BW) were obtained in previous studies (Santos-Rocha & Veloso, 2005). Using the equation proposed by Turner and Robling (2003) the osteogenic index (OI) of Step Exercise was calculated: OI (one session) = Peak ground reaction force(BW)*Ln(number of loading cycles+1). Main results were (mean±sd): OI was 11.95±0.82; peak ground reaction force (GRF) was 1.44±0.09 times bodyweight (BW); session duration was 38.6±8.3 min; rate of stepping (BPM) was 134.6±4.7 beats per minute (bpm); march was the exercise performed more often; the other movements performed more often were knee-hop, side-leg, L-step and over-the-top; number of loading cycles was 4194.1±1055.2; two regression models were determined: OI=2.182+0.073*BPM (R=0.415; R2=0.172; Sig=0.000); GRF=0.271+0.009*BPM (R=0.450; R2=0.203; Sig=0.000). OI and GRF increases significantly when stepping rate is higher than 135 bpm. A frequency of 2 to 3 sessions per week of Step Exercise might be recommended. Despite of the benefits that have been stated when Step classes are provided correctly and adapted to participants; more research is needed concerning biomechanical load, exercise prescription and injury prevention.

POPULATION-BASED STEP COUNTS IN BELGIUM: COMPARISON BETWEEN DEMOGRAPHIC VARIABLES

De Cocker, K., Cardon, G., De Bourdeaudhuij, I.

University Ghent, Belgium

Introduction: Information on pedometer-determined physical activity population levels is still sparse and only collected in a limited number of countries. No recent pedometer-based data are available of European countries. Therefore, the main purpose was to provide pedometer-determined physical activity levels in Belgian adults. Mean steps/day were compared between gender, age groups, state of professional activity and among days of monitoring.

Methods: Participants were randomly recruited out of a sample of 5000 names of 25-75 years old inhabitants of East-Flanders, Belgium. Of this sample 4067 persons were invited by telephone or mail to complete the long International Physical Activity Questionnaire and to self-monitor pedometer-determined physical activity for 7 consecutive days. Steps data were returned by 1239 participants (604 males and 635 females, mean age was 48.6 ± 13.6 years). Steps for biking and swimming were imputed.

Results: The average adult in Belgium reported taking 9655 ± 4526 steps/day. According to the pedometer indices of Tudor-Locke and Bassett 12.9 % was sedentary, 19.3 % was low active, 26.2 % was somewhat active, 21.1 % could be classified as active and 21.2 % was highly active. Steps/day differed significantly between sexes (men: 9919 steps/day vs women: 8962 steps/day, $F = 5$, $p = 0.026$), across age groups (25-35 year old: 9201 steps/day vs 36-45 year old: 10926 steps/day vs 46-55 year old: 9686 steps/day vs 56-65 year old: 9184 steps/day vs 66-75 year old: 8205 steps/day, $F = 3.3$, $p = 0.01$), between state of professional activity (employed: 9973 steps/day vs unemployed: 8908 steps/day, $F = 6.2$, $p = 0.013$) and among days of monitoring (weekdays: 9755 steps/day vs weekend days: 9433 steps/day, $F = 7.4$, $p = 0.007$).

Conclusion: This study was the single largest survey of adult pedometer-assessed physical activity in Europe in the twenty-first century. The Belgian population accumulated relatively high step levels. However, the large standard deviation was a sign of a wide distribution of ambulatory behaviour. Consistent with other studies, men accumulated more steps/day than women and steps/day were related to age.

OP1-19 Ageing 1/1 - "Turin DE"

PHYSICAL PERFORMANCE, ARTERIAL STRUCTURE AND FUNCTION IN ADVANCED AGE

Welsch, M.A. 1, Arce, A.A. 1, Dobrosielski, D.A. 1, Wood, R.H. 1, Jazwinski, M. 2

1 Louisiana State University, Baton Rouge, LA. Louisiana State University Health Sciences Center, 2 The Louisiana Healthy Aging Study, United States

Individuals with reduced physical function have an increased likelihood for morbidity, mortality, hospitalization, and poor quality of life. The six-minute walk test is a measure of physical performance that accurately predicts the onset of disability in the elderly. It was hypothesized that even in advanced age; those with the highest physical performance scores would have lower arterial thickness and greater arterial reactivity, suggestive of a healthier vasculature. PURPOSE: To examine the influence of vascular dimensions and function on the six-minute walk distance in advanced age. METHODS: Forty individuals (Age: 83±11yrs) from the Louisiana Healthy Aging Study were used for these analyses. Exercise tolerance was defined as the maximal walking distance (MWD) achieved on a six-minute walk test conducted in an internal hallway. Carotid and brachial artery dimensions (diameters, and carotid intima-media thickness (CIMT)) were measured using high-resolution ultrasonography. Average and maximum CIMT were obtained from the anterior and posterior walls of the common carotid across a marked length of 10 mm. Brachial artery peak flow velocities (BAPFV) and flow mediated dilation (BAFMD) were measured after 5 minutes of forearm occlusion. RESULTS: The average MWD was 364±122m. The average carotid vessel diameter was 8.35±0.85mm and the average and maximum CIMT was 0.94±0.06mm and 0.95±0.06mm, respectively. Brachial artery vessel diameter averaged 4.21±0.74mm. BAPFV and BAFMD were 83.63±74.13U and 2.70±2.69%, respectively. Importantly, BAPFV and BAFMD were significantly associated ($y=0.019(x)+1.728$; $r=0.48$, $p=0.001$). Multivariate analyses revealed smaller carotid vessel diameters (mean difference: 0.59mm; $p=0.026$), average (mean difference: 0.049mm; $p=0.017$) and maximum CIMT (mean difference: 0.049mm; $p=0.017$) in individuals with a MWD over 400m compared to those below 400m. Moreover, those with a MWD over 400m had greater BAFMD (mean difference: 1.74%; $p=0.005$), despite similar pre-occlusion brachial artery diameters and BAPFV. CONCLUSIONS: The lower average and maximum CIMT and greater BAFMD, in those individuals scoring above the 400m threshold on the six-minute walk test, suggests that the positive effects of physical fitness on arterial structure and function extend even in advanced age.

This research was supported by a grant from the Louisiana Board of Regents through the Millennium Trust Health Excellence Fund [HEF(2001-06)-02], and by a grant from the National Institute on Aging (1 P01 AG022064).

RELATIONSHIPS BETWEEN CAROTID-FEMORAL PULSE WAVE VELOCITY AND SPECTRAL COMPONENTS OF HEART RATE VARIABILITY IN HEALTHY OLDER MEN

Perkins, G., Owen, A., Swaine, I.L.

Canterbury Christ Church University, United Kingdom

BACKGROUND: Pulse wave velocity (PWV) is a measure of arterial stiffness which is influenced by a combination of structural and functional factors. Heart rate variability (HRV) is a measure of autonomic regulation of the heart rate. Nakao et al. (2004) have shown that brachial-ankle PWV is associated with power spectral components of HRV in 24–39 year-old men, independent of age and blood pressure. The purpose of the present study was to examine the relationships between carotid-femoral PWV (cfPWV) and spectral power parameters of HRV in 40–65 year-old men.

METHODS: Participants were healthy men (N=97). Mean age (±SD) was 50.9 (7.0) years. Body mass and height were 86.7 (12.6) kg and 1.78 (0.1) m, respectively. cfPWV and HRV were measured during supine rest. cfPWV was obtained using an automatic device (Complior) which measures transit time of pulse waves between the carotid and femoral sites. Spectral power components of HRV were derived

from a 5-min ECG recording during paced breathing. Spectral power was determined as total power (TP) and two frequency bands: high-frequency (HF: 0.15–0.45 Hz) and low-frequency (LF: 0.04–0.15 Hz) power. Resting blood pressure was measured in the seated position using a semi-automated blood pressure monitor. Resting heart rate (RHR) was derived during PWV signal acquisition. HRV data was natural log-transformed prior to analysis. Pearson's correlation was used to explore the relationships between cfPWV and spectral components of HRV. Partial correlational analysis was used to control for the effects of age, systolic blood pressure (SBP) and RHR, which are known confounders of PWV. Significance level was set at $p<0.05$.

RESULTS: Mean cfPWV (±SD) was 8.6 (1.5) m•s-1. TP, HF and LF were 1694.9 (1605.8), 435 (583.6) and 443.1 (507.0) ms2, respectively. SBP was 129.8 (11.3) mmHg and RHR was 56.9 (8.8) b•min-1. cfPWV was inversely correlated with all log-transformed spectral components of HRV (TP: r=-0.28, p<0.01; HF: r=-0.34, p<0.01; LF: r=-0.38, p<0.01). These relationships were stronger than in the partial correlations when age, SBP and RHR were controlled for (r=-0.10–0.34, p<0.01–0.31).

DISCUSSION: These findings in older men support those of Nakao et al. (2004) in younger men in that there is an association between PWV and spectral components of HRV. Furthermore, the relationship does not appear to be affected when cfPWV measurement is used compared to brachial-ankle PWV. The relationship between PWV and HRV seems to be maintained through a wide age-range in adult men. Whether there is a common link between the two variables which underlies this association has yet to be elucidated.

Nakao, M., Nomura, K., Karita, K., Nishikitani, M. & Yano, E. (2004). Relationship between brachial-ankle pulse wave velocity and heart rate variability in young Japanese men. Hypertension Research. 27: 925–931.

INSULIN RESISTANCE OF AGING: EFFECTS OF EXERCISE AND WEIGHT LOSS

Amati, F. 1+2, Dubé, J. 1, Stefanovic-Racic, M. 1, Toledo, F. 1, Goodpaster, B. 1

1 University of Pittsburgh, Pittsburgh, Pennsylvania, USA, 2 Hôpital Universitaire de Genève, Geneva, Switzerland, United States

Aging is associated with insulin resistance, which is a key factor in the development of type 2 diabetes. However, it is not clear to what degree obesity or physical inactivity underlies this 'aging effect'. Moreover, randomized trials to examine the separate effects of weight loss and exercise in older adults with insulin resistance are lacking. This study determined the separate effects of 4-months of diet-induced weight loss (WL; n=5), exercise (EX; n=8), and combined diet and exercise (WL+EX, n=9) on body composition, physical fitness and insulin sensitivity in older (68 ± 4 yr) overweight to obese (31.2 ± 3.2 kg•m-2) sedentary men and women. The EX group lost less ($P<0.05$) weight (-1.8 ± 1.2 kg) than the WL (-9.4 ± 1.6 kg) or WL+EX groups (-5.7 ± 1.2 kg). EX also lost less fat mass (-1.8 ± 1.0 kg) than WL (-7.2 ± 1.3 kg) or WL+EX groups (-4.8 ± 1.0 kg). Body composition was determined by dual-energy X-ray absorptiometry (DEXA). Physical fitness determined by maximal aerobic capacity (VO2max) using a graded exercise test, improved ($P<0.05$) in EX but not WL. Insulin sensitivity determined by a hyperinsulinemic (40mU•m-2•min-1) euglycemic clamp improved ($P<0.05$) in all three groups; however, there was no difference in the degree of improvement among EX (34 ± 11%), WL (23 ± 14%) and WL+EX (35 ± 12%). In conclusion, exercise and weight loss independently improve insulin resistance in older adults. Further studies are needed to determine the distinct mechanisms by which exercise and weight loss improve skeletal muscle insulin resistance in aging.

PERSISTENCE IN EXERCISE DECREASES WEIGHT GAIN IN ADULTS. A 30-YEAR LONGITUDINAL STUDY IN TWIN PAIRS DISCORDANT FOR LEISURE TIME PHYSICAL ACTIVITY

Backman, K. 1, Kaprio, J. 2, Kujala, U.M. 1

1 University of Jyväskylä, 2 University of Helsinki, Finland

Obesity is considered as one of the major health problems in the Western world. Lack of physical activity is one cause of weight gain. The main aim of this study was to find out whether persistent time leisure physical activity, adjusted for genetic liability and childhood experiences, protect against weight gain and other indicators of metabolic syndrome. The genetic liability to weight gain was partially controlled by investigating the effect of physical activity on anthropometric measurements in twin pairs discordant for physical activity for 30 years.

The study included 111 pairs of twins discordant for physical activity who were systematically selected from the large Finnish Twin Cohort. Physical activity discordance was initially assessed by similar questionnaires in 1975 and 1981; in both years the more active co-twin participated in higher levels of both vigorous activity and volume of activity than the less active co-twin. The outcome measurement of weight, height, self-measured waist circumference and present and past physical activity levels were assessed by a structured telephone interview in 2005. 89 pairs (40 male, 49 female, 72 dizygotic and 17 monozygotic pairs) of twins completed all parts of the interview. Paired samples t-test was used to analyse the differences in anthropometric measurements between inactive and active co-twins.

Mean age of the subjects was 58 years (range from 47 to 79 years) in 2005. There was a significant difference in the physical activity participation between initially inactive and active co-twins during 30 year follow up. Active co-twins participated in physical activity on average 4.3 MET-hours/day more when compared with inactive co-twins ($p<0.001$). 42 pairs of twins were found who remained consistently discordant for physical activity for 30 years according to the retrospective questions recorded within 5-year intervals. Within these pairs who remained persistently discordant for physical activity for 30 years the weight gain was 5.4 kg (95% CI 2.0-8.9) higher in the inactive member of the twin pair compared with the more active co-twin ($p=0.003$) during 30-year follow-up. The waist circumference was on average 8.4 cm (95% CI 4.0-12.7) greater in the inactive co-twin when compared with the active co-twin ($p<0.001$) at the end of the follow-up. The results were similar for both dizygotic and monozygotic and male and female twin pairs. This difference in change in weight and waist circumference was not seen in the twin pairs (n=47) who were not persistently discordant for physical activity for 30 years.

Even after partially controlling for genes and childhood experiences, persistent participation in leisure time physical activity in adulthood decreases the rate of weight gain and results in a smaller waist circumference. Participation in physical activity needs to continue throughout life to maintain these benefits.

INFLUENCE OF MAXIMAL POWER DETERMINANTS ON ELDERLY WOMEN PHYSICAL PERFORMANCE

Clémençon, M., Hautier, C., Rahmani, A., Cornu, C., Bonnefoy, M.

UFR STAPS Lyon, France

Background: The loss of autonomy, because of some motor disability, is revealed by dramatic functional decline particularly among elderly persons in the community. Determinants of functional limitations have been well established from several studies. Muscle power is well related to functional status and many basic activities in daily life such as walking, rising from chairs, or climbing stairs. Leg exten-

sor muscles capacities appear very important when accomplishing movements similar to those made in every day life. Power-velocity relationships obtained from force-velocity tests measured during explosive leg extension permit to measure maximal power (Pmax), optimal torque (Mopt) and optimal velocity (Vopt). Optimal velocity has been shown to be related to muscle fiber type and thus may serve as a surrogate measure for muscle fiber-type distribution (Martin et al., 2000). Thus, we consider that optimal torque and optimal velocity can give important information on quantitative (effective muscle mass) and qualitative (typology) muscular factors. The purpose of the present study was to evaluate physical performance and its relation to the production of maximal power and its corresponding determinants.

Methods

Three tests were performed to assess physical performance in 39 elderly women volunteers (83 ± 5.8 yr): walking speed, five-time chair rise time and six stair climb time. Maximal leg extension power and its corresponding determinants, i.e. Mopt and Vopt, were measured as described by Rahmani et al. (2003). To assess the relationships between impairments in leg power and its determinants and physical performance, multiple regression analyses were conducted.

Results

Participants presented a maximal walking speed of 0.85 ± 0.39 m.s-1, a five time chair rise time of 16.3 ± 7.7 s and a six stair climb time of 7.0 ± 4.0 s. Subjects produced 1.37 ± 0.78 W.kg-1 maximal leg power relative to body mass, 1.79 ± 1.21 rad.s-1 optimal velocity, and 50.75 ± 16.94 N.m optimal torque. In multiple regression analyses, maximal power and optimal velocity were better predictors of physical performance tests than optimal torque:

Conclusion

These findings, obtained in a group of very old women, showed optimal velocity to be an important determinant of physical performance. Leg power was also recognized as a predictor of physical performance. Together these two parameters explain 15% to 30% of physical performance. Force-velocity test may serve to predict disability and to design and to evaluate training rehabilitation programs. Moreover, present results give indication on the qualitative state of muscle, notably about the estimated fiber type distribution in leg extensor muscles.

EFFECT OF IMAGINED MOVEMENT SPEED ON SUBSEQUENT MOTOR PERFORMANCE

Louis, M., Guillot, A., Collet, C.

C.R.I.S., Centre de Recherche et d'Innovation sur le Sport, Université Claude Bernard Lyon I - A.I.S.T.S. International Academy of Sports Science and Technology, Lausanne, France

Motor imagery (MI) is a valuable technique for improving performance in sport. MI should reflect in every respect, including speed, the motor action that athletes actually perform. Although actual and MI durations may be identical (Decety et al., 1989), times are often found to be under- or overestimated, due to individual and task-related factors (Guillot & Collet, 2005). However, performing MI of a sequential motor action at slow/ fast speed voluntarily (compared to a baseline test) was found to elicit a decrease/ increase in the actual movement speed during the post test (Boschker et al., 2000). Based on these findings, this study was designed to check whether there was any risks to have the athletes voluntarily change the speed of their MI and what effect would that have on the real task. The study consisted of 2 MI experiments. For the 1st one, 24 sport students imagined 2 series of body movements (upper & lower) by using together internal visual and kinaesthetic imagery. They were divided into 3 groups of 8 participants each. During the pre-test, each participant performed the sequences at an initial chosen speed. They were then asked to imagine the sequences during a retention interval (450 trials). One group mentally rehearsed them at a faster speed, while the second group imagined them at a slower speed. The control group performed a neutral task. The post-test was identical to the pre-test. The 2nd experiment was similar but included 21 black belt judokas doing 1 kata on both sides for 12 MI sessions (120 trials). For the 1st experiment, movement times for the control group did not change for both upper and lower body sequences ($p>.05$), while the fast group increased their actual times ($p<.01$). No difference was found for the slow group. In the 2nd experiment, the post test times analysis showed a strong effect of MI ($p<.001$). The actual times increased for the fast imagery group ($p<.001$) and reduced for the slow imagery group ($p<.001$). This study emphasized the strong effect of MI on the actual task speed. The increase or decrease of MI speed during the retention interval is seen by a change in actual times. This effect may also occur on a motor task that does not include locomotion (upper body sequence). The results also suggest a similar outcome for a highly automatic task, even in a sport skill where the duration is already very much fixed and controlled (judo). Therefore, these results prove that the control of MI speed is a very important aspect of mental training: since it is recommended to keep MI at the same speed as the real performance, to increase or decrease it consistently could have a negative and unexpected effect on the actual performance speed. By contrast, it could also have a positive effect if MI is combined with actual skill learning, to change movement duration.

PERCEIVED SUPPORT, COGNITIVE APPRAISAL, AND PERFORMANCE

Freeman, P., Rees, T.

University of Exeter, United Kingdom

Although Sarason, Sarason, and Pierce (1990) proposed that social support might affect sports performance, there have been no explicit attempts to test this proposal upon objective performance outcome. The beneficial effects of social support are well established in general social psychology, but the specific mechanisms through which it operates are poorly understood (Saltzman & Holahan, 2002). This

study addressed these issues, and examined if cognitive appraisal is one mechanism through which perceived support exerts beneficial effects upon performance. Two path models were tested that examined if perceived support influenced challenge and threat appraisals directly, or indirectly through altering perceived situational control. In both models, it was hypothesized that challenge appraisals would be associated with better performance, and threat appraisals with poorer performance. A high-performance sample of 118 male golfers, mean age 25.4 years (SD 6.5), completed measures of perceived support, challenge, threat, and situational control before competitions. After the competitions, performance outcome was recorded. Observed variable path analysis found an excellent fit to two models. In model 1, participants with high levels of perceived support appraised the upcoming competition as more of a challenge (gamma = .64, t = 9.00) and less of a threat (gamma = -.55, t = -7.08). Challenge appraisals were associated with better performance (beta = -.20, t = -2.08) and threat appraisals with poorer performance (beta = .19, t = 2.06). Model 1 accounted for 10.2% of the variance in performance. In model 2, participants with high levels of perceived support appraised the upcoming competition as more of a challenge (gamma = .37, t = 5.03), less of a threat (gamma = -.45, t = -4.91), and had higher situational control (gamma = .56, t = 7.25). Higher situational control was associated with higher levels of challenge appraisals (beta = .50, t = 6.82), but not with threat appraisals (beta = -.17, t = -1.86). Challenge appraisals were associated with better performance (beta = -.20, t = -2.08) and threat appraisals with poorer performance (beta = .19, t = 2.06). Model 2 accounted for 10.6% of the variance in performance. The results suggest that cognitive appraisal may be one mechanism through which perceived support influences performance. Perceived support was associated directly with both challenge and threat appraisals but also indirectly with challenge appraisals through influencing situational control. Increasing perceived support may therefore influence how an athlete appraises competitive situations and lead to improve performance.

MOOD CHANGES AS A RELIABLE INDICATOR OF PHYSICAL STRESS AND OVERTRAINING

Birrer, D., Seiler, R., Baume, N.

Swiss Federal Institute of Sports Magglingen, Switzerland

Introduction: Disturbed mood states have been consistently described as sensitive markers of overtraining. Nevertheless, sport scientists have not clearly established a model to identify the early stages of overtraining. The majority of studies have used a global mood score. However, various mood factors differ substantially in their function and in their reactivity to the training load. This presentation will highlight the reaction of different mood factors to training load and different stages in the development of overtraining syndrome (OTS). Data will be presented from 3 different studies. Method and results of study 1: 6 elite male road cyclists using SRM power cranks 2 weeks prior and during a six day stage race were daily monitored with a mood measurement (BFS; Abele-Brehm & Brehm, 1986). Data was analysed on a single case basis using the cross correlation function. All 6 athletes showed a significant cross correlation between the training load and the mood states fatigue and positive activation at a lag of 1 day. No strong correlations were found for the other mood factors. Method and results of study 2: 30 male volunteers participated in a double blind study with the controlled administration of oral doses of placebo (n=10), 19-norandrostenedione (n=10) and testosterone undecanoate (n=10). During one month the volunteers underwent a rigorous endurance training program. The POMS was administered 3 times during this period. Repeated ANOVA measurements and discriminant analysis were calculated to identify mood development over time and predict group membership from mood states. Significant differences between the 3 groups were found in the mood factors vigour and fatigue. A direct discriminant function analysis matched 88% of the participants to the respective group (64% in the cross validation condition). Method and results of study 3: 35 athletes suspected of overtraining were administered the BFS. From performance analyses 13 of the athletes were diagnosed as overtrained and 22 as overreached. 26 athletes in a normal training condition administered the BFS as a control group. Data was analysed using discriminant function analysis in order to establish an instrument for future diagnosis of overtraining and to explore the role of the different mood factors in the development of OTS. The direct discriminant function ensured that all cases were correctly assigned to one of the 3 groups (1 mismatch in the cross validation condition). The mood factor depressed mood had the highest weight in the standardized canonical discriminant function followed by positive activation, fatigue and agitation. Discussion: Changes in the mood factors positive activation (vigour in POMS) and fatigue appear to be inextricably linked to the training load. Changes in these factors show an inability to cope with physical stress. In certain situations more psychologically related mood states (e.g., depressed mood, agitation, calmness) may be related to overtraining.

VISUAL SEARCH STRATEGY AND DECISION-MAKING SKILL IN YOUTH SOCCER: A CONSTRAINTS-BASED APPROACH

Vaeyens, R. 1, Lenoir, M. 1, Williams, A.M. 2, Philippaerts, R.M. 1

1 Ghent University, 2 Liverpool John Moores University, Belgium

It is widely accepted that perceptual-cognitive skills play a crucial role in sports performance (Ward & Williams, 2003). Skilled athletes develop sophisticated knowledge structures enabling them to pick up and interpret perceptual information more effectively than their less skilled counterparts, resulting in superior anticipation skill. Although these knowledge structures help guide the search for relevant visual information, researchers have recently highlighted how task, environmental and organismic constraints also shape the emergent behaviour (Williams et al., 2004). The aim in this paper is to examine differences in visual search strategy and decision-making skill as a function of task constraints in soccer.

Participants included 87 youth soccer players (13.0-15.8 yrs) varying in skill and experience (elite, sub-elite, regional level and non-soccer group). We used 33 realistic film simulations involving 2 vs. 1, 3 vs. 1, 3 vs. 2, 4 vs. 3, and 5 vs. 3 offensive situations. Performance was assessed using movement-based response measures (decision time and response accuracy) and an eye movement registration technique. As predicted, an increase in the number of players presented on screen and a higher relative proportion of defensive to offensive players increased the demands of the task, resulting in slower decision times and lower response accuracy scores ($p < .001$). Significant differences in visual search behaviour were observed between the 2 vs. 1 and 3 vs. 1 viewing conditions on the one hand and the 3 vs. 2, 4 vs. 3 and 5 vs. 3 conditions on the other. The first group of conditions is characterised by a low(er) number of fixations combined with a long(er) mean fixation duration, while more fixations of shorter duration are apparent in the latter group of simulations. Moreover, the mean fixation duration in the 3 vs. 2 condition was significantly higher than in the 4 vs. 3 and 5 vs. 3 conditions, respectively. Significant differences in performance were observed between players and non-players and across groups of soccer players matched on playing experience but differing in playing level.

Playing experience, skill level and the unique task constraints, expressed by the number of players and the relative proportion of offensive and defensive players, determined the observed search behaviour and processing requirements imposed on players in dynamic offensive team simulations. Such measures may have practical utility for the testing and training in soccer. The results provide empirical evidence supporting a constraints-based explanation of visual search behaviour.

PATTERNS IN THE DEVELOPMENT OF ELITE PERFORMANCE IN ACROBATIC SPORT

Hauw, D., Ramdani, S., Durand, M.

JE 2416 GP3S, University of Montpellier 1, France

Introduction

The aim of this study was to analyse the activity of elite athletes engaged in intensive training and in international competitions in trampolining, using a situated analysis (Clancey, 1998, Hauw & Durand, 2004). We expected to identify different types of activity underlying patterns of performance development trajectories. These patterns corresponded to macroscopic processes that athletes deployed to find the best organisation for their performance. In such acrobatic sports, athletes' activity is particularly dedicated to designing the best adjustment between the level of performance (i.e., the difficulty like the choice of number of twists or somersaults) and the way to perform it (i.e., the execution). Thus, each performance could be characterised by a particular coupling between an action that athletes perform and the situation defined by it. In order to qualify these coupling, we used a series of indicators that abstracted acrobatic performance.

Method

88 exercises performed by six elite athletes of the French national team during international competitions between 1999 and 2004 were recorded. Using the dart trainer software, we collected for each exercise (a) the number of somersaults with the adopted position, (b) the number of twists, (c) the flight time per move (sec) and its index of variation between each move for each exercise, (d) the sum of the amplitude of the horizontal distance travelled for each move on the trampoline bed. The means of these indicators for each athlete during a season were used to describe their developmental trajectories of performance and to qualify the evolution of their action-situation coupling.

Results

Three developmental patterns of activity were identified. « Building new action-situation coupling to attain the world's top-level performances » corresponded to an increasing score of each performance indicator season after season. « Optimising action-situation coupling » was characterised by contradictory evolutions of performance indicators, suggesting an activity of research into the correct steady state between action and situation. « Advancement – wander about » was characterised by wide and erratic variations of the performance indicators, suggesting a particular activity of research that does not lead to a satisfactory state.

Discussion

These results revealed different types of elite athletes' activity when engaged in the same intensive training. These activities can be described as the construction of new action and situation possibilities or as the deployment of better modalities of interaction with the situations that favour performance (Reed, 1993). Athletes' developmental trajectories also show differences in terms of paths, suggesting that their activities are based on a high level of undetermined results. Further research should be deployed in order to know how these developmental trajectories could be controlled and oriented toward performance enhancement.

SPORT: A UNIQUE IMPLEMENTATION DYNAMIC FOR TECHNOLOGIES

Manson, J.-A., Bourban, P.-E.

Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland

Sport: a unique implementation dynamic for technologies
Jan-Anders E. Månson, Pierre-Etienne Bourban
Ecole Polytechnique Fédérale de Lausanne (EPFL)
Vice présidence pour l'innovation et la valorisation (VPIV)
CH-1015 Lausanne, Switzerland

Athlete seeks the ultimate performance out of his own body, his equipment and his outfit while taking a maximum benefit from his skills and physical ability.

For this an equipment and outfit does not just need to be made of materials with the most extreme physical properties but it must also allow to transmit the "right" feeling and touch between himself and his equipment. Thus, in most cases the material has to possess a unique combination of structural and functional capabilities. Today these unique structural performances and functions are widely integrated in many sport equipments. For examples the latest tennis rackets and skies integrates these novel materials to reach the otherwise impossible combination of high stiffness, low weight and tuned damping performance.

Furthermore, the improvement of performance, perception, skill acquisition, comfort, safety and injury prediction, requires synergy between life sciences and engineering sciences. For example, by a more efficient measurement and control of sensations, body motion and by studying the influence of equipment and environment on performance or potential injury it will possible to propose technology for an improved and optimal adequacy between body, environment and performance. This is the objective of the current research programmes such as the Sport and Rehabilitation Engineering programme at EPFL (http://sre.epfl.ch) grouping key competences in cognitive assessment, psychophysics, tissue engineering, smart materials/structures, bio-sensors, multi-task control, simulation and imaging.

Technologies developed for professional sport will also impact our life quality, indeed they are in many cases established on the same generic platform as research on support system for any valid or disabled persons.

There are no doubts that the sports industry plays an important role during the implementation of a new technology to the market. In comparison to other industrial branches such as aerospace and automotive the speed of the market changes in sport equipments and outfits are very high. This puts enormous time constrains on technology adaptation and market implementation. It is well known you cannot win America's Cup or Formula 1 without the very latest advanced technology. Thus, it is not surprising that sport during last decade has increasingly positioned itself as one of the driver in research. However, it is vital to seek synergies in research and implementation strategies in order to gain maximum experience from each other's unique experience about design, material performance, durability and manufacturing concepts.

Finally, it is clearly demonstrated in recent years that sport does not just take increased use of advanced technologies it also shows an increased importance for the public economy.

TECHNOLOGY IN SPORT - ETHICAL CHALLENGES AND POSSIBLE SOLUTIONS

Loland, S.

The Norwegian School of Sport Sciences, Norway

In the paper I propose a categorization of technology in sport and present what I find to be the most significant challenges to the values of sport posed by technology.

Technology is understood as human made means to reach human interests and goals. Technology in sport, then, is seen to be human made means to reach human interests and goals in sport or related to sport.

Such technologies may have constitutive functions (skis and rackets are necessary means for skiing and tennis); they may serve goals of health and non-harm (shock-absorbing soles in shoes, and helmets and protection gear in ice hockey); and/or they may be developed with performance-enhancing intentions (aerodynamic suits in speed skating, hypoxic chambers in endurance sports). I argue that technologies intended to enhance performance are those that pose the most significant challenges to sport values.

Performance-enhancing technologies can be distinguished in at least four categories. I distinguish between body techniques (such as the Fosbury flop); sport equipment used by athletes in the performance of their sport (skis, rackets); training technologies used by athletes to prepare for performance (thread mills and strength training machines); and technologies administered to athletes outside of competition and that do not require athletic effort (advanced diet regimes, hypoxic chambers, drugs). Innovation in body techniques are generally to be admired and are ethically unproblematic. Innovation in sport equipment and training technologies usually raises questions of fairness and equality. Expert-administered technologies are the most problematic category as they often raise radical challenges to established ideas of sport performance and sport ethics.

In the final section, I propose a casuistic methodology of how deal with the ethical challenges of expert-administered technologies by examining a continuum ranging from rather unproblematic diet regimes in the one end, via hypoxic chambers, to performance-enhancing drugs and genetic technologies in the other end.

IS2-01 Alinghi: sport as driving force for people and technology (sponsored by UBS) - "Athene"

ALINGHI AS A TEAM

Karcher, C.

Alinghi, Spain

Alinghi raced to a staggering 5-0 victory against Team New Zealand on March 2, 2003, winning the most prestigious yachting trophy of all time: the America's Cup. They guaranteed themselves a place in the history books by being the first team since the inaugural race in 1851 to return the Auld Mug to Europe and on top of that for being the first team to win the Cup on a first attempt.

Alinghi's vision is "to win the America's Cup, while earning respect and recognition as a world class sports team as well as sharing our passion". And the team is well-positioned to mount a fearless defense of its title in 2007.

A summary of the steps leading up to the next America's Cup will be presented, illustrating the human and technical challenges of the competition. The Swiss-based team is made up of 21 different nationalities, all these individuals focusing on the same challenging goal. This efficient Team will depend upon the collective experience of all its members as it prepares for and faces the competition.

Technology behind the Alinghi America's cup Team

It is well recognized that the America's Cup will not be won with old technology. Thus it is not surprising that this competition has increasingly positioned itself as a driving force for research over the last decade. From the initial design of the boat up through performance analysis in race conditions, the technology used must be cutting-edge for the team to have a shot at the trophy.

To design and build a sailing boat that respects the constraining class regulation and still optimizes performance is a continual challenge. An overview of the most important constraints as well as how these rules affect design and construction of the most critical parts of the boat will be presented, illustrating the importance of continuously integrating the latest technological breakthroughs. Alinghi relies on the experience and scientific knowledge of its Design Team, as they gather and combine scientific data from research and feedback from the sailors in a unique and high-performance boat.

It is vital to seek synergy in research and implementation strategies in order to benefit fully from the unique experience of design, materials performance, durability and manufacturing that individual disciplines can contribute. Many partners are involved in the numerous steps from the concept of a new boat to its launch in competition.

TECHNOLOGY BEHIND THE ALINGHI AMERICA'S CUP TEAM

Simmer, G.

Team Alinghi, Spain

It is well recognized that the America's Cup will not be won with old technology. Thus it is not surprising that this competition has increasingly positioned itself as a driving force for research over the last decade. From the initial design of the boat up through performance analysis in race conditions, the technology used must be cutting-edge for the team to have a shot at the trophy.

To design and build a sailing boat that respects the constraining class regulation and still optimizes performance is a continual challenge. THE ROLE OF EPFL AS SCIENTIFIC ADVISOR FOR ALINGHI

Vuilliomenet, P., Manson, J.-A.

Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland

The Ecole Polytechnique Fédérale de Lausanne (EPFL) collaborated with Alinghi prior to its 2003 America's Cup victory, and this collaboration generated a strong relationship between the Alinghi Design Team and EPFL researchers. Based on this experience, the number of research topics has been increased for the 2007 campaign, leading to a massive effort in terms of scientific research and implementation strategy of new technologies.

The Scientific Advisor acts as an extension of Alinghi Design Team. Research is carried out in close collaboration with the designers of Alinghi, thus ensuring that the technological and scientific advances developed in the university can be adapted to and implemented in the very specific domain of an America's Cup boat.

The hull of Alinghi is made of a rigid, strong and incredibly light composite material referred to as a "sandwich". The production process for this composite sandwich involves several steps and variable factors that must be optimized for reliability and performance. When combined with optical fiber sensors, these composites become "intelligent."

Computational Fluid and Structural Dynamics is a mathematical approach that aims at simulating a wide range of flow conditions. Both the aerodynamic flow (i.e. the wind) around the sails and the hydrodynamic (i.e. the water) flow around the hull and appendages are considered in these simulations.

One way to improve the design of sails is to use video imaging techniques to analyze how they behave under actual sailing conditions and to extract data on how the sail, and ultimately the boat, is responding to physical conditions.

Another project aims to help the navigator by making sailing as much a science as possible. Researchers are developing a mathematical model that will be able to provide the navigator with a rational method for planning out the fastest possible course, even in the face of variable weather conditions.

It is always a challenge for a University to undertake projects of this nature and scope, because they combine long-term goals with very short term needs and decisions. A split-vision approach is needed, and this is both demanding and challenging for the partners when designing at the extreme limit. Finally, it has clearly been demonstrated in recent years that sport not only makes increasing use of advanced technologies but is also a fabulous driving force that motivates students and researchers alike.

IS2-02 Public health approaches to physical activity promotion - "Innsbruck"

PRINCIPLES OF PHYSICAL ACTIVITY PROMOTION IN PUBLIC HEALTH, THE IDEA OF HEPA EUROPE

Racioppi, F., IT

Without abstract submission.

ENVIRONMENT AND PHYSICAL ACTIVITY

van Poppel, M., den Hertog, F., van Mechelen, W.

VU University Medical Center, Netherlands

The relationship between the built environment and physical activity has received much attention in the past few years. In this presentation, a short overview of will be given of the insights gained so far. This will be put into the context of the European situation.

Furthermore, the results of a study conducted in four residential districts in Amsterdam will be presented. In this study, about 440 adult residents filled out a questionnaire about their perceived living environment, determinants of physical activity (attitude, social support and self-efficacy), and their actual physical activity behaviour. Furthermore, their height and weight were measured. Objective data on characteristics of the built environment in the four residential areas were gathered as well. From preliminary results, it appeared that the number of parking places in combination with the number of facilities (shops, restaurants, etc) have an important influence on walking and cycling. Active transport was used more often in districts with few parking places and many facilities. More results from this study will be presented. Furthermore, the relative contributions of environmental characteristics and individual factors to physical activity levels will be addressed.

HEALTH ECONOMIC CONSEQUENCES OF PHYSICAL ACTIVITY

Sørensen, J.B.

University of Southern Denmark, Denmark

Although there is ample evidence of the health benefits from physical activity, the health economic consequences have rarely been documented. This presentation will describe an analysis that was undertaken for the Danish National Board of Health. The analysis was based on a cohort study of 10.000 people who had indicated their level of leisure time physical activity. The cohort had been followed for an average of 25 years with respect to both hospital-treated illness (diagnosis) and mortality. A health economic model was developed to describe the differences in life expectancy and quality-adjusted life-years (QALYs) between individuals who were physically active and those who were physically inactive. The consequent use of health care resources was assessed in terms of gains in productivity and additional future consumption.

The model estimated that a 30-year-old physically inactive male would gain an additional 2.8 life years if he became physically active. A woman would gain 4.6 life years. Furthermore, the man would gain 2.4 years without illness and the woman 2.7 years. They would gain 3.2 and 4.7 QALYs, respectively, by becoming more physically active.

The net present value of increased production was estimated at 800-1200 Euros using the friction method and 8.667-10.400 Euros using the human capital method. The net present value of reduced consumption of health care resources due to better health was estimated at 3.600-3.860 Euros and should be off-set by the increased use of health care due to the life-years gained estimated at 2.400-3.200 Euros. In a sensitivity analysis these numbers were re-estimated using different modelling assumptions.

These health economic data provide a good basis for conducting policy scenario analysis and analyzing cost-effectiveness of interventions aimed at increasing the level of physical activity in sub-populations. The application of cost-effectiveness analysis will be illustrated based on preliminary data from an evaluation of a Danish intervention provided to elderly people. Based on the numbers of participants who start, leave, and complete the training programme the model estimates the intervention cost, the health benefits and the future consumption of health care resources. Results from such cost-effectiveness analyses can be used as a basis for assessing "value for money" and considering suitable target groups for the interventions.

SPORTS PARTICIPATION IN THE UK: THEORETICAL REVIEW AND EMPIRICAL ANALYSIS

Downward, P., Riordan, J.

Loughborough University, United Kingdom

Raising sports participation is a public policy priority. Appropriate policy requires understanding the mechanisms that promote participation. A variety of theoretical perspectives explaining participation exist, which draw upon economics, sociology and psychology (Downward, 2004). Drawing upon critical realist philosophy, this paper reappraises these theoretical perspectives and produces a synthetic account of participation in which cause reflects the interaction of human agents and social structures.

An important implication of this theoretical and conceptual review is that, for empirical analysis, focus shifts from either individual decisions, or social constraints but, instead, their interaction and suggests the need to explore causes in society 'as a property of complex and contingent mechanisms in reality…Can we get anywhere with cause if we think in this way? …by exploring and comparing cases …we might be able to say something about causes.' (Byrne, 2003 pp105-106).

This approach to empirical work is undertaken using data from the 2002 General Household Survey (GHS) that records the decision of 14, 819 adults aged 16 or over to participate or not in the last 4 weeks in 40 sports. First, a cluster analysis is undertaken to isolate groups of cases of similar behaviour of respondents using a large array of variables measuring individual and social, economic and sporting characteristics. Socially defined lifestyles are identified. 3 'fuzzy' clusters identify those with a predisposition to participating in leisure activities; those mostly in recreational activities and those in team sports or specialist activities. Logistic regression analysis is applied to each cluster to explore the individual's decision to participate. The data are weighted to account for responses being gathered within households and inference proceeds using Huber-White 'robust' standard errors.

It is argued that the results support the agency-structure model of participation. For example it is shown that there is strong evidence of interdependent demands, but distinct patterns of behaviour emerge. Whilst health appears to be important for participation in any sport (anysport) and walking generally, this is not the case for the family oriented activities of swimming, cycling and football or competitive sports. In contrast it is significant for activities such as keep-fit, weight-training and jogging. The paper thus concludes by examining the policy ramifications of these findings in connection with policy targets identified for the UK by Sport England (2004).

HIGH ALTITUDE MEDICINE: CLINICAL OVERVIEW

Bärtsch, P.

University Hospital Heidelberg, Germany

Acute mountain sickness (AMS), high altitude cerebral edema (HACE) and high altitude pulmonary edema (HAPE) are illnesses that occur in otherwise healthy mountaineers during the first days after rapid ascent to high altitude. Headache, nausea, dizziness and peripheral edema are the most frequent symptoms of acute mountain sickness (AMS). They occur with a latency of several hours after exposure to altitudes ≥ 2500 m. With adequate behaviour/treatment they normally resolve spontaneously within 1 or 2 days. They can, however, particularly with further ascent despite symptoms of AMS, progress to high altitude cerebral edema (HACE) which may, if untreated, lead to death within 1 or 2 days. The prevalence of AMS increases with altitude and with the rate of ascent. It also depends on the degree of pre-acclimatization and individual susceptibility. In most cases, AMS can be prevented by slow ascent or by acetazolamide 2x250 mg daily. Treatment consists of a day of rest with mild AMS and of descent with more severe AMS. In advanced cases, supplemental oxygen and/or dexamethasone (4-8 mg every 6 hours) is necessary to enable descent. High altitude pulmonary edema (HAPE) is a non-cardiogenic pulmonary edema that occurs after rapid ascent of non-acclimatized individuals to altitudes ≥ 3000 m. The prevalence is about 7 % in an unselected population ascending rapidly to an altitude of 4500 m and it increases to 60 – 70 % in individuals susceptible to HAPE. It is a hydrostatic pulmonary edema caused by an excessive rise of the pressure in pulmonary arteries and capillaries. Slow ascent is most effective for prevention and supplemental oxygen and/or rapid descent with early symptoms of HAPE are the treatment of choice. If these measures are not immediately possible, pulmonary vasodilators such as nifedipine (3 x 20 mg/day) or tadalafil (2x10 mg/day) can be used for prevention or initial treatment until descent is possible.

A ROLE FOR REACTIVE OXYGEN SPECIES IN THE PATHOPHYSIOLOGY OF HIGH ALTITUDE ILLNESS?

Bailey, D., Knauth, M., Bärtsch, P.

University of Glamorgan, University of Goettingen, University of Heidelberg, United Kingdom

Background: High-altitude cerebral edema (HACE) has been identified as predominantly vasogenic in origin thus implying some degree of disruption to the blood-brain barrier (BBB). Since HACE is considered the end-stage of acute mountain sickness (AMS), it is plausible that headache and nausea, its principle symptoms, may be caused by mild oedema subsequent to barrier failure. What causes barrier disruption is not presently clear despite widespread support for the "mechanical hypothesis" implicating overperfusion of cerebral capillaries analogous to autoregulatory breakthrough in hypertensive encephalopathy. However, emerging evidence suggests that free radicals may play a complementary role in what is rapidly evolving as the "chemical hypothesis" of AMS. The current presentation will describe a series of novel experiments designed to examine the source and mechanisms of free radical generation in hypoxia and subsequent implications for barrier function and susceptibility to AMS.

Experimental paradigms: We have employed various strategies designed to challenge redox homeostasis and barrier function. The first paradigm involved the experimental induction of oxidative stress and barrier disruption "prior" to hypoxia (priming strategy). Prior exposure to heat-stress and in a separate study, exercise-induced tissue damage, increased free radicals and BBB permeability confirmed as an increase in the electron paramagnetic resonance signal intensity of spin-trapped species and S100β respectively. Compared to the control trials, this paradigm increased susceptibility to AMS during subsequent exposure to hypoxia (8h at 12%O2). In the second paradigm, we tested the effects of antioxidant supplementation during an active ascent to terrestrial high-altitude (protective strategy). Compared to the placebo condition, antioxidants reduced free radical generation and susceptibility to AMS. The final paradigm combined T2 and diffusion weighted MRI with the direct measurement of free radicals in cerebrospinal fluid (CSF) following 18h passive exposure to 12%O2 (direct strategy). While AMS was not defined by any differences in barrier function or regional CSF concentration of free radicals, we did detect a selective increase in systemic oxidative stress. We also detected mild cytotoxic and to some extent, vasogenic oedema, independent of neuronal damage. This oedema may have contributed to the selective elevation in brain to intracranial volume ratio previously identified as an "anatomical risk factor" for AMS ("tight-fit" hypothesis).

Conclusions: These findings suggest that when combined with physical exercise, inspiratory hypoxia can compound oxidative stress, compromise barrier function and increase susceptibility to AMS. The pathophysiological significance of brain swelling in the setting of reduced intracranial reserve volume deserves critical consideration.

NO, THE KEY TO UNDERSTANDING THE PATHOPHYSIOLOGY OF HIGH ALTITUDE PULMONARY EDEMA

Scherrer, U., Sartori, C.

Botnar Center for Extreme Medicine, Switzerland

High-altitude pulmonary edema (HAPE) is a life-threatening condition occurring in predisposed, but otherwise healthy subjects, and, therefore, allows to study underlying mechanisms of pulmonary edema in humans, in the absence of confounding factors. Over the past decade, evidence has accumulated indicating that HAPE results from the conjunction of two major defects, augmented alveolar fluid flooding resulting from exaggerated hypoxic pulmonary hypertension on the one hand, and impaired alveolar fluid clearance related to defective respiratory transepithelial sodium transport on the other hand. Here, we will focus on the mechanisms underlying the exaggerated hypoxic pulmonary hypertension. We will provide experimental evidence for the hypothesis that an acquired and/or genetic defect of pulmonary vascular endothelial and respiratory epithelial nitric oxide synthesis and/or bioavailability may represent the central underlying defect predisposing HAPE-prone subjects to exaggerated hypoxic pulmonary vasoconstriction and alveolar fluid flooding. We will also review data based on this concept suggesting that pharmacological interventions designed to augment pulmonary nitric oxide bioavailability may be useful for the prevention of exaggerated hypoxic pulmonary hypertension and HAPE during high-altitude exposure in susceptible subjects.

Invited symposium (IS)

IS2-04 An Update of Female Athlete Triad (sponsored by Gatorade) - "Albertville"

ENERGY AVAILABILITY AND MENSTRUAL DYSFUNCTION

Manore, M.

Oregon State University, United States

This paper will review the scientific advances in the Female Athlete Triad (Triad) since the Triad was described in a position paper published by the American College of Sports Medicine (ACSM) in 1997. Initially the Triad was described as 3 inter-related clinical disorders (eating disorders, amenorrhea, and osteoporosis) observed in female athletes and other physically active girls and women. Since this first position paper, there has been much debate about the prevalence of the Triad and its underlying cause(s). Currently research indicates that low energy availability (e.g. not eating enough to match energy expenditure/needs and/or an eating disorder) is the primary underlying factor that initiates the Triad disorders. Low energy availability initiates a cascade of metabolic processes that suppress menstrual function, either completely (amenorrhea) or sporadically (e.g. oligomenorrhea, anovulation). The reduced availability of reproductive hormones, combined with high stress, high exercise training and low energy and nutrient intakes can negatively impact bone health and in extreme cases cause osteoporosis. We now know that the Triad might better be described as a spectrum that spans each of the components of the triad (low energy availability, menstrual function and bone strength) ranging between health and disease. Thus an individual athlete could present with different degrees of each of the disorders, depending on her diet and exercise habits. This paper will discuss in the energy availability issues related to the Triad and the resulting menstrual dysfunction. Currently there are no pharmacological agents that can adequately restore low bone mineral density in women with amenorrhea and/or disordered eating. The following two speakers will address eating disorders and bone health related to the Triad in detail and also discussion treatment and prevention. The new ACSM Position Stand on the Female Athlete Triad should be published in late 2006 in Medicine and Science in Sport and Exercise (MSSE).

DISORDERED EATING IN ATHLETES

Sundgot-Borgen, J.

The Norwegian School of sports science, Norway

Jorunn Sundgot-Borgen

Disordered Eating in Athletes

There is a continuum model of disordered eating (DE) ranging from abnormal eating behaviours to clinical eating disorders (EDs) such as anorexia nervosa and bulimia nervosa. Athletes with DE often attempt to lose weight or body fat by inducing a negative energy balance and or using a wide range of DE practices. Negative energy balance and energy drain occur for female athletes when the energy consumed is insufficient to cover the energy costs of daily living, exercise training and competition, building and repair of muscle tissue, menstrual function, and any additional energy costs related to life stressors, such as illness or psychological stress. DE among athletes must go beyond focusing on those who meet formal diagnostic criteria for an ED, and should include athletes who are in a negative energy balance, engage in unhealthy weight control practices that have clinical significance and that can severely compromise health and performance. Energy deficiency and DE practices impair health and physical performance. Problems result from depletion of muscle glycogen stores, dehydration, and loss of muscle mass, hypoglycemia, electrolyte abnormalities, anemia, menstrual dysfunction and loss of bone mass. Problems associated with binging and purging are also depressive symptoms, low self-esteem and anxiety. Studies have suggested a higher frequency of eating problems in athletes competing in leanness sports compared to athletes in sports focusing less on this and non athletes.

To prevent DE and EDs, the athletes have to know and practice healthy eating and make sure the energy intake cover her energy needs. Also, the team staff and parents must be able to recognize the physical symptoms and psychological characteristics indicating "at risk" for or clinical EDs.

BONE HEALTH

Meyer, N.L., Manore, M., Sundgot-Borgen, J.

The Orthopedic Specialty Hospital, United States

Female Athlete Triad Update: Bone Health

Bone strength reflects the integration of bone mineral density (BMD) and bone quality. Effects on bone strength are both indirect via hypoestrogenism and direct through substrate and metabolic hormone alterations under the condition of low energy availability. Low energy availability and subsequent reduced bone formation, and estrogen deficiency associated with amenorrhea, lead to low bone mass. Low bone mass in young athletes should not be expected, as BMD is generally 5-15% higher in athletes compared with non-athletes in the absence of menstrual dysfunction. Although there are no clear signs of low bone mass other than recurring stress fractures, an athlete who has experienced amenorrhea, had multiple occurrences of oligomenorrhea, and/or has had several stress fractures may indicate compromised bone mass. The preferred method for the assessment of bone mass is dual energy x-raw absorptiometry. The interpretation of the results is based on the normal distribution of BMD among young normal Caucasian women. According to the International Society of Clinical Densitometry, BMD results of premenopausal women, and particularly those younger than 20 years of age, should be viewed using Z-scores (average scores of healthy women of their own age) rather than T-scores (average scores of healthy young women). T-scores are used by the World Health Organization to determine risk for osteoporosis in post-menopausal women. Although the criteria for risk classification in premenopausal women vary slightly among organizations, it is generally accepted that in the young female athlete, a Z-score below -1.0 should be of concern and initiate referral to treatment. To be diagnosed with osteoporosis, a female athlete needs to present with low BMD in combination with hypoestrogenism, nutritional deficiencies, stress fractures and/or other clinical risk factors for fracture.

Treatment and Prevention

Treatment of low bone mass in an athlete with menstrual dysfunction should occur primarily through the restoration of energy balance, using a team approach (physician, sports dietitian, psychologist). Triad prevention strategies should include screening, rapid intervention in case of early signs, and education targeting athletes, parents, and coaches.

IS2-05 Testing of athletes - waste or value - "Berlin ABC"

AIMS AND LIMITS OF TESTING IN (ENDURANCE) SPORTS

Hartmann, U.

Faculty of Sport Science, Germany

It is assumed that for each sport and discipline the performance limiting factors are well known, that an exact demand profile is established and also a plan of a performance build up is existent. But mostly phenomenological descriptions of the performance demand exist: p.e. the description of a 1000m competitive race is mainly done by terms from training methodology and very rarely from physiology. Another example is the (wrong) opinion, that high lactate values attest a high anaerobic "capacity". - Those phenomenological based assumptions lead to unique views and self fulfilling opinions in test interpretation and training methodology. Under the aspect of cyclization and periodization they have an important and unlucky influence to training schedules and -programs. For a differentiate examination and interpretation for endurance performance tests and testing the following (practical) recommendations for a test evaluation could be given:

- Competition simulation test to acquire "sport specific necessities"; this test is in accordance with the structure and duration of the sport specific competition load. It is to determine the sport specific performance and its individual limits.

- Determination of the "maximal oxidative" (aerobic) performance (VO2max test); this test part contains of multiple steps, each with a short duration and a rapid increase of the load (vita max test) to estimate the real and absolute VO2max.
- Determination of the "maximal glycolytic" (anaerobic) performance (estimation of lactate formation rate; (VLAmax)); the test is characterised by a short duration, a supramaximal load for a very short time (5–10 s) for estimating the VLAmax.
- Determination of the endurance performance ability ("endurance capacity"); long duration of each step (minimum 5 min, if possible even longer) and a small increase of the load; aim of this test part is to estimate that what is called "endurance" or those metabolic conditions which are close to the metabolic „steady state / maxLass" conditions.
- If possible a computer based simulation for interpretation of the given test results should be done.

Many of the (common) laboratory test procedures and the way how they are used are partly or in total not fulfilling the basic quality criteria in performance testing! The „simple" transfer of laboratory findings, as it is momentary existing in practice, is not very helpful and deserves an evaluation and sophisticated studies! But it would be necessary to give up the existing point of view and proceedings, after what by the help of a single (metabolic) test an abundance of questions according to the (correct) training load should be answered! Only as good as we feel up and as we are willing, to evaluate existing points of view in a critical way!

PSYCHOLOGICAL DIAGNOSTICS AND EVALUATION IN ELITE SPORTS

Amesberger, G.

University of Salzburg, Austria

Interventions in sport psychological programmes should be based on diagnostic information. Nevertheless the discussion on diagnostic processes highlighting the effect on interventions is not that comprehensive (Duda, 1998; Strauß & Tenenbaum, 2003;Tenenbaum & Strauß, 2006).

The presentation focuses different aspect of diagnostics, evaluation and ethical problems in testing and assessing.

There are four main reasons for diagnostics: (1) to efficiently and accurately asses the characteristics of athletes, (2) to create hypothesis about appropriate intervention methods (3) to measure the progress of behavioural changes and (4) to gather professional information for research, development and teaching (see Etzel et al., 1998, 425). Measurements in order to guide and evaluate sport psychological training will be discussed by examples from different projects:

- Anamnestic Interview
- Quantitative Questionnaires (mental skills, self-esteem, locus of control, mood, ...): Computerized psychological testing
- Objective tests (reaction time, concentration, tracking, peripheral awareness, anticipation, …)
- Biofeedback

One of these projects is "Challenge 2008": In order to prepare the Austrian soccer team for the European Championship 2008 about 40 players have been selected for additional individual training. Among other individual supports all players are psychologically tested and those how want, get supports in sport psychological training. Results and specific problems will be reported.

Another Project: Starting with 2006 in Austria all elite athletes sponsored by Top Sport Austria for sport psychological training take part in an evaluation project on the outcome of psychological training. The method of this evaluation will be presented and ethical problems of handling the results will be discussed. The interest of coaches in psychological diagnostics increased in resent years. But there are serious reasons for sport psychologists to be very carefully and to act professionally with diagnostic information in order to keep the athletes rights and dignity as a main goal of psychological ethic codes. In this case diagnostic and assessment are not means to find out the truth about the character of an athlete but to enhance the personal potentials.

THE USE OF SUB-MAXIMAL AND MAXIMAL YO-YO INTERMITTENT ENDURANCE TESTS IN SOCCER

Krustrup, P., Mohr, M., Heiner-Møller, A., Krustrup, B., Poulsen, A., Bangsbo, J.

Institute of Exercise and Sport Sciences, Denmark

A series of recent studies have used the Yo-Yo intermittent endurance level 2 test (Yo-Yo IE2) in order to evaluate the intermittent exercise performance of male and female elite soccer players at different playing positions, competitive levels and seasonal periods. The maximal version of the Yo-Yo IE2 lasts for 4-25 min and consists of 2x20 m shuttles performed at gradually increasing speeds, interspersed by 5-s periods of recovery. In relation to playing position, Yo-Yo IE2 performance was observed to be better ($p<0.05$) for elite female midfield players (1656±121 (±SEM), n=16) than for goal keepers (775±182, n=4), defenders (1331±77, n=14) and attackers (1347±207, n=6). It has also been found that Yo-Yo IE2 performance varies markedly between competitive levels both for female and male players. Yo-Yo IE2 performance was 24% better ($p<0.05$) (1654±100, n=18) for the best than for the fourth best (1338±98, n=16) team in the Danish female top-league. The performance of recreational male players, sub-elite male players and Scandinavian elite male players was 834±55 m (n=35), 1551±101 m (n=14) and 2692±83 m (n=20), respectively. The test has also been used to study the effect of sub-elite and recreational soccer training. A group of untrained subjects improved ($p<0.05$) their Yo-Yo IE2 performance by 98% during a 6-month period with 2 weekly soccer training sessions (982±119 vs. 496±43 m, n=15). Likewise, a sub-elite male team improved ($p<0.05$) performance by 21% during a 2-month pre-seasonal preparation period (1551±101 vs. 1283±130 m, n=14). A sub-maximal version of the Yo-Yo IE2 test lasting 4 min (600 m, elite female players) or 6 min (920 m, elite male players) has recently been introduced. This test utilizes heart rate recordings during, and in recovery from, a given number of shuttles. A few studies have investigated the reproducibility and validity of the sub-maximal Yo-Yo IE2 test. In one study, heart rate was measured during two 6-min tests performed 3 days apart. The end-test heart rates were 164±5 and 165±5 b.p.m., respectively, with a CV value of 1.4%. A recent study showed that %HRmax after 4 and 6 min is correlated

with Yo-Yo IE2 test performance (r=0.80 and 0.75, respectively, p<0.05, n=19-32). For the Danish national male team, a significant correlation was observed between %HRmax after 6 min of the Yo-Yo IE2 test and the peak values for high intensity running performed by the midfielders in a 15-min (r=0.75, n=17) and 45-min period (0.77, n=11). Five weeks prior to Euro 2004, end-test HR of the Danish national team players (n=18) was 177±2 b.p.m, but decreased (p<0.05) to 173±2 b.p.m. after 2 weeks of intense training (n=18). Sixteen of 18 players had a decrease in end-test HR during this period. In summary, the maximal Yo-Yo IE2 test appear to be a sensitive tool to evaluate the intermittent-exercise performance of male and female soccer players at different playing positions, playing standards and in various seasonal periods. A sub-maximal version of the test may be used for frequent, non-exhaustive testing.

GREATER LEG LACTATE EFFLUX VERSUS PYRUVATE EFFLUX DURING STEADY-STATE CYCLING IN BOTH NORMOXIC AND HYPEROXIC CONDITIONS

Stellingwerff, T., LeBlanc, P.J., Hollidge, M.G., Heigenhauser, G.J., Spriet, L.L.

1 University of Guelph, 2 McMaster University 3 Brock University, Canada

During intense exercise it is believed that lactate is the major by-product of carbohydrate metabolism to leave the muscle. However, a recent study reported similar rates of net lactate and pyruvate efflux from leg muscles during cycling at 65% VO2peak. We examined this issue by measuring the major fates of pyruvate in leg muscle: 1) oxidation via pyruvate dehydrogenase (PDH), 2) reduction to muscle lactate, 3) lactate efflux, 4) pyruvate accumulation, and 5) pyruvate efflux. We also examined these five fates while subjects breathed both normoxic and hyperoxic air. Hyperoxia decreases muscle glycogenolysis, which results in decreased pyruvate and lactate production and decreased muscle lactate efflux. PURPOSE: To quantify the fates of muscle pyruvate and compare the rates of pyruvate and lactate efflux, during steady state cycling under normoxic and hyperoxic conditions. We hypothesized that; 1) lactate efflux would be greater than pyruvate efflux regardless of inspired O2 content, and 2) breathing 60% O2 would decrease pyruvate production leading to decreased pyruvate and lactate efflux as compared to 21% O2. METHODS: Seven active male subjects cycled for 40 min at 70% VO2peak on two occasions while breathing 21 or 60% O2. Arterial and femoral venous blood samples and blood flow measurements were obtained throughout each trial, and muscle biopsies were taken at rest and following 10, 20 and 40 min of exercise. RESULTS: On average, during normoxic exercise, we found a 4.7-fold greater rate of leg lactate efflux as compared to pyruvate efflux (4.7 ± 1.1 vs.1.0 ± 0.1 mmol/min/leg). During hyperoxic exercise, muscle glycogenolysis was reduced by 16% which translated into a significant 15% reduction in total pyruvate production (60%: 735 ± 85 vs. 21%: 870 ± 86 mmol/leg) and decreased pyruvate efflux over 40 min of cycling. Decreased pyruvate production with hyperoxia had no effect on pyruvate oxidation (PDH activity) (60%: 3.02 ± 0.50 vs. 21%: 3.03 ± 0.39 mmol/wet muscle/min) or muscle pyruvate accumulation, but decreased (P<0.05) muscle lactate accumulation by 22%. Leg lactate efflux was also reduced in hyperoxia but remained higher than pyruvate efflux (1.8 ± 1.0 vs.0.7 ± 0.1 mmol/min/leg), although the ratio of lactate to pyruvate efflux was decreased to 2.5. CONCLUSION: Contrary to a recent study, we found greater rates of lactate efflux, as compared to pyruvate efflux, regardless of inspired O2 content. A greater rate of pyruvate reduction to lactate and eventual lactate efflux out of contracting skeletal muscle, versus direct pyruvate efflux, may serve to maintain cytoplasmic redox state (NAD+/NADH) during exercise. Hyperoxia decreased total pyruvate and lactate production by 16 and 56% respectively. This larger decrease in lactate production vs. pyruvate production seemed to have a greater effect on decreasing lactate efflux, as there were relatively smaller decreases in pyruvate efflux during the hyperoxic trial.

CAFFEINE REDUCES EFFECTS OF HYPERTHERMIA IN CENTRAL FATIGUE DURING EXERCISE IN THE HEAT

Del Coso, J., Estevez, E., Baquero, R., Mora-Rodriguez, R.

Universidad de Castilla-La Mancha, Spain

Introduction

The combination of dehydration and hyperthermia induced by prolonged cycling in the heat reduce maximal knee extension force (2). The attenuation in maximal force production with hyperthermia is associated with a reduction in central activation drive (2). When hyperthermia is prevented by the ingestion of a carbohydrate electrolyte solution (CES) cycling power is longer maintained (1). Moreover, caffeine supplementation increases central activation drive (3). However, it is unknown if caffeine could counteract the effects of prolonged exercise in the heat in the CNS despite sustained hyperthermia. The purpose of this study was to evaluate if the ingestion of fluid (to reduce hyperthermia), carbohydrate (to supply extra energy) and/or caffeine (to act as a CNS stimulant) will progressively reverse the effects of dehydration and hyperthermia on maximal leg force.

Methods

Seven endurance-trained and heat acclimated males volunteered for this study. They pedaled at 63% VO2max (176±15W) in a hot-dry environment (36ºC; 29% rh) during 120 min in six different double-blind trials: 1) no fluid ingested (DEH); 2) caffeine supplementation (CAFF; 6mg/kg BW); 3) rehydrating 90% sweat loss with water (WAT); 4) rehydrating with water+caffeine (WAT+CAFF); 5) rehydrating with a 6% carbohydrate-electrolyte solution (CES) and 6) rehydrating with CES+caffeine (CES+CAFF). Immediately before and after each trial right knee maximal isometric voluntary contraction (MVC) and central activation ratio (CAR; superimposed electrical stimuli) were measured. In addition, muscle contractile function was assessed via tetanic electrical stimulation (EL). Data were analyzed using ANOVA.

Results

The no-fluid trials (DEH; CAFF) induced to hyperthermia (39.0ºC) while fluid ingestion maintained rectal temperature at 38.3ºC. After 120 min of exercise MVC declined 76 N in DEH, 39 N with WAT and less in the rest of trials (14, 20 N and 14 N increase in CES, WAT+CAFF and CES+CAFF, respectively; P<0.05). Of note during the CAFF trial MVC decreased 14N despite hyperthermia. The reductions in CAR (index of CNS drive) followed the trend of MVC; (r= 0.52 between MVC and CAR; P<0.01). EL evoked muscle contraction force was not reduced after 120 min of pedalling in any of the trials.

Discussion

In agreement with previous data (2) prolonged exercise inducing hyperthermia reduced MVC. This reduction was mainly due to a reduction in CAR (decreased central drive) since force evoked by EL was unchanged. The effects of fluid, carbohydrate and caffeine on the

preservation of MVC after exercise seemed additive. CAFF (6 mg/kg) counteracted the effects of hyperthermia on MVC preserving CAR which suggests an important role of CNS stimulants for heat induced fatigue.

VO2 KINETICS DURING HIGH INTENSITY CONSTANT EXERCISE : A FOURTH PHASE?

Leclair, E., Thevenet, D., Cretual, A.l., Prioux, J.

UFR STAPS Nantes, France

Introduction: During a continuous exercise at high and constant intensity, a VO2 decrease before exhaustion has been observed (Nummela and Rusko, 1995; Perrey et al., 2002). The aim of this study was to verify the VO2 kinetic fourth phase existence and the involvement of respiratory muscle fatigue in this phenomenon. Methods: Seven endurance trained males (19.6 years (0.4)) performed 5 field-tests until exhaustion: 1) an incremental test to determine their maximal oxygen uptake (VO2max-58.6 ml.min-1.kg-1 (1.4)) and maximal aerobic velocity (MAV-18.5 km.h-1 (0.2)), 2) a 100% of MAV constant exercise (tlim100(1)), 3) 4) and 5) in a randomized order, 2 constant exercises at 95% of MAV (tlim95(1) and (2)) and a second tlim100 (tlim100(2)). Running speed was maintained constant thanks to an examiner on bicycle that the subject followed. This examiner was provided with mp3 reader which gives imposed time every 20 meters. Moreover, a second examiner took care of the subject position on a level with the bicycle and of lap time. The cardio-respiratory values were averaged on a 2s period. Data were analysed with Matlab® software and a single exponential model was applied to VO2 kinetics. A kalman filter was used in order to detect the changes of model relatively to VO2 kinetic. When a series of changes was detected at the end of VO2 kinetic, the software applied a linear phase after the third phase described. Respiratory muscle fatigue was appreciated using maximal inspiratory and expiratory pressures (Plmax-PEmax) measure. This measure was realized by the same examiner during each constant load exercise at rest, then 3 minutes, and 24 hours after the end of the test. In each case, Plmax and PEmax were measured 5 times respectively at residual volume and at total pulmonary capacity. Results: Our study results highlight a VO2 decrease before exhaustion for 3 of all subjects. No significant difference was found between each tlim100 and between each tlim95. Plmax and PEmax mean values do not present significant differences between each condition. Conclusion: In our study, tests results allowed us to highlight a VO2 kinetic fourth phase for 3 of our 7 athletes while running speed was maintained constant. VO2 decrease observed cannot be explained by a running speed decrease and Plmax and PEmax measures results do not show significant variation. Moreover, tidal volume and respiratory frequency kinetics are not linked to a ventilation decrease. In this way, the respiratory muscle fatigue hypothesis seems to be rejected.

SEX DIFFERENCES IN MUSCLE ENERGETICS DURING INCREMENTAL KNEE-EXTENSOR EXERCISE IN 9-12 YEAR OLD CHILDREN

Barker, A.R., Welsman, J.R., Armstrong, N.

University of Exeter, United Kingdom

There is strong evidence indicative of sex differences in the muscle metabolic response during high intensity and at maximal exercise, but not during submaximal intensities in pre/early pubertal children. The purpose of this study was to examine whether during knee-extensor exercise to the limit of tolerance, sex differences were evident in the intramuscular metabolic response, as determined by 31P-magnetic resonance spectroscopy.

Eighteen girls (mean age 10.6 y, height 1.41 m, body mass 36.3 kg) and 15 boys (mean age 10.8 y, height 1.43 m, body mass 35.0 kg) completed a single leg knee-extensor incremental exercise test to exhaustion whilst lying prone in the bore of a whole-body scanner (Philips 1.5T). Following 2 min rest for baseline measures, masses were added to a custom designed ergometer at 0.5 kg·min-1 to ensure exhaustion occurred in ~8 min. Dynamic changes in phosphocreatine (PCr), inorganic phosphate (Pi), Pi/PCr and intracellular pH were resolved every 1.5 s via a 6 cm 31P transit-receive surface coil placed under the subjects' right quadriceps muscle. Spectra profiles were averaged every 30 s and determination of 31P metabolites was performed using jMRUI. Each subject's Pi/PCr and pH profiles were plotted against power (W) for subjective determination of intracellular thresholds (ITPi/PCr and ITpH). Potential between sex differences in muscle metabolic parameters were explored using independent Student t-tests. Values are reported as mean ± standard deviation (SD).

At rest no significant sex differences in metabolic concentrations were present ($P>0.05$). Peak power achieved at maximal exercise was not significantly different between sexes (14.5 ± 3.2 vs. 13.9 ± 3.6 W; $P=0.582$). However, the boys displayed a significantly lower increase in Pi (286 ± 59 vs. 372 ± 90 %; $P=0.004$), decrease in PCr (51 ± 12 vs. 39 ± 18 %; $P=0.039$) and increase in Pi/PCr (0.94 ± 0.33 vs. 1.95 ± 1.28; $P=0.006$) compared to girls at end exercise. End exercise pH tended ($P=0.058$) to be lower in girls (6.92 ± 0.11) compared to boys (6.98 ± 0.05). The power outputs at the ITPi/PCr and ITpH displayed no sex differences ($P>0.05$), but the girls demonstrated significantly ($P<0.05$) greater changes in Pi/PCr and pH as a function of work rate following the ITs.

These results suggest that in response to incremental exhaustive exercise, sex differences in the quadriceps metabolic response are clearly discernible during the region of high-intensity exercise. Although quadriceps muscle peak power was comparable between sexes, the intramuscular metabolic perturbation was greater in girls following the ITs, resulting in a greater anaerobic component and subsequently a higher accumulation of Pi, PCr degradation and intracellular acidosis at end exercise. Mechanisms relating to the delivery of and/or utilization of oxygen at the myocyte may be compromised during high intensity/exhaustive exercise in young girls.

SKELETAL MUSCLE OXYGENATION TRENDS, MOTOR UNIT RECRUITMENT PATTERNS AND TIME-LIMIT AT POWER OUTPUT CORRESPONDING TO VO2MAX FOLLOWING MAXIMAL LACTATE STEADY STATE IN CYCLISTS

Lajoie, C., Polasek, N., Gurd, B., Kowalchuk, J.M., Grenier, S., Serresse, O.

Laurentian University and University of Western Ontario, Canada

The primary purpose of this study was to investigate the mechanisms involved in the upward trend in pulmonary O2 uptake (VO2; i.e. VO2 slow component) while exercising at a constant workload corresponding to the Maximal Lactate Steady State (MLSS). We hypothesized that the progressive rise in VO2 at MLSS is the result of an increase in motor unit recruitment and O2 utilization at the level of the exercising muscle. Moreover, to better understand the mechanisms that limit endurance capacity, immediately following MLSS, subjects were asked to pedal until exhaustion (T-limit), at a power output expected to elicit VO2max. Along with measures of pulmonary VO2 and blood lactate concentration, surface electromyography (sEMG); mean (MPF) and median (MDPF) power frequency, and near-infrared spectroscopy (NIRS)-derived measures of deoxy- (HHb), oxy- (O2Hb) and total-hemoglobin/myoglobin (HbTOT), were recorded from the vastus lateralis of 12 trained cyclists (VO2max = 63.3 ± 8.6 ml/kg/min) when cycling for 1 hour at MLSS and at T-limit. As expected, VO2 increased ($p<0.05$) by 13% from 10 to 60 min at MLSS (final VO2 represented 78% VO2peak) and increased ($p<0.05$) further at T-limit (time-to-fatigue; 91 sec), although subjects could only achieve a maximum value corresponding to 81% of the VO2peak. NIRS-derived HHb increased by 36% ($p<0.05$) relative to its initial response throughout the MLSS, with an additional increase of 11% ($p<0.05$) during T-limit. After increasing rapidly at the onset of exercise within the first 10 min, HbTOT rose more gradually ($p<0,05$) between 10 min and 45 min, and remained steady for the remainder of the MLSS. During the subsequent T-limit period HbTOT tended to decrease, but not significantly. During MLSS, O2Hb remained relatively constant throughout the MLSS, but decreased ($p<0.05$) by 20% during the T-limit. sEMG demonstrated an increase ($p<0.05$) in muscle fiber conduction velocity as showed by a 12% and 16% increase in MPF and MDPF respectively at MLSS, whereas at T-limit, MPF and MDPF remained unchanged compared to the MLSS 60th min. These findings lend further support to the theory that the VO2 slow component derives mostly from local events occurring within the exercising muscle, by change in motor unit recruitment type and an increase in HHb, independent of lactate accumulation (4.65 ± 0.97 mmol/L at 10th min to 4.9 ± 1.1 mmol/L at 60th min of MLSS). Failure to reach maximal VO2 during the very heavy constant workload (i.e. Tlim) may represents a limitation of the circulatory system to deliver adequate amount of O2, rather than the muscles capability to utilize O2.

Oral presentation (OP)

OP2-02 Training and Testing 2/7 - "Turin ABC"

KINEMATIC MATCH ANALYSIS IN BEACH SOCCER

Trauner, T., Lederhilger, B., Schwameder, H.

University of Salzburg, Austria

Beach soccer is a young and growing sport with 20 national teams currently in Europe. It is played barefoot on a sand-pitch (38x28m) with 4 players and a goalkeeper in each team. The specific format (three periods of 12 min each, free substitutions, free kicks without barrier, 'always a winner' and high goal average) make the sport dynamic and attractive for the spectators (www.beachsoccer.com). A game lasts about 1 hour with an average playing time of 36±8 min per player.

The scientific research regarding kinematic characteristics and game activities in beach soccer is limited. Beach soccer is often compared with soccer and therefore it is important to know whether or not the specific demands and training programs for soccer can be transferred to beach soccer.

The purpose of the present study was to analyse paths, type of locomotion, velocities and game activities of the Austrian and Swiss beach soccer national teams (17 players total) during two games. Heart rate and lactate profiles were collected simultaneously (Lederhilger 2006). Furthermore, the results were compared with data from soccer (Reilly 1993, Müller & Lorenz 1996, Sainz & Cabello 2005) and basketball (McInnes et al, 1995).

Two stationary digital video cameras were used to film the players' locomotion. The estimated center of mass was manually digitized and transformed into position-coordinates. A third digital camera traced all the players' actions with the ball. The results of the two games and teams were averaged.

The mean distance covered was 3.1±0.6 km with an average velocity of 1.5±1.2 m/s. On average the players' locomotion were: 47% walking (1.5±0.3 km / 27±6 min), 41% jog trotting (1.3±0.2 km / 8±2 min), 11% running (0.3±0.1 km / 1±0.5 min) and 1% sprinting (40±20 m / 5±3 sec) of the total distance. There was a change of type of locomotion every 3 s with an average distance of 5 m. 12% of all movements were higher than 4m/s and players covered 4% of total distance in ball possession. On average a player performs 142±62 different actions with the ball: 36% ball receptions, 11% shots on goal, 14% dribblings and 39% passes.

Compared to soccer beach soccer shows shorter total distances, more frequent changes in locomotion, in ball possession (Reilly 1993, Sainz & Cabello 2005) and higher percentage in walking and jog trotting (Müller & Lorenz 1996). McInnes et al (1995) reported similar values for basketball. According to these results as well as regarding heart rate and lactate production (Lederhilger 2006) the profile in beach soccer was found to be different from soccer and, consequently, specific training programs and scientific studies have to be established to improve the efficiency of this new sport.

THE EFFECT OF A ONE-PIECE COMPETITION SPEED SUIT DURING THE SWIM-CYCLE INTERACTION OF A SPRINT DISTANCE TRIATHLON

Peeling, P., Landers, G.

The University of Western Australia, Australia

This study investigated the thermoregulatory response to wearing a one-piece competition speed suit (Rival Force, Rosebery, NSW) during the swim-cycle (SC) interaction of a sprint distance triathlon. Eight highly trained, male triathletes completed three separate laboratory sessions comprising one graded-exercise test, and two SC sessions. Each SC included a 750 m time trial paced swim followed by 30 min of cycling at an intensity corresponding to 95% of the lactate threshold. Throughout each SC testing session, the athletes were required to wear either regular cut, standard swimming bathers only (SCB), or the one–piece competition speed suit (SCS). The 750 m swim was conducted in a 25 m outdoor pool heated to 27.75 ± 1.35°C. Data was collected for the athlete's swim time, stroke rate (SR) and stroke length (SL). Subsequent cycling was performed on a wind-braked cycle ergometer inside a climate regulated chamber set to 30.05 ± 0.83°C and 60.45 ± 1.03 % humidity. Such conditions are similar to those experienced by the elite men competing at world championship races. Eight hours prior to each SC session, subjects were required to swallow a telemetric temperature measurement pill (CorTemp™, HQ Inc, Palmetto FL). At the conclusion of the swim and for the duration of the ride, the temperature pill, in association with a series of skin thermistor leads allowed the determination of core temperature (Tc), and skin temperature (Tsk). Blood lactate (BLa), heart rate (HR) and ratings of thermal comfort (RPE) were also collected during the cycle discipline. The SCS swim time (10:04.97 ± 0:58.65) was significantly faster ($p<0.05$) than SCB (10:25.45 ± 1:01.33). This time improvement incurred no between group differences in SL, SR, BLa or RPE ($p>0.05$). During the 30 min cycle, the power output between SCB (279.03 + 40.54 W) and SCS (279.13 + 38.73 W) were not significantly different ($p>0.05$). Furthermore, there were no differences between the recordings of Tc, Tsk, HR, BLa or RPE ($p>0.05$). The use of a one-piece Rival Force speed suit during the swim leg of a triathlon may be beneficial in improving an athletes swim time as a result of a reduced passive drag through the water. Additionally, it was shown that the speed suit has no effect on an athletes' thermoregulatory response during a SC interaction. Hence, wearing the suit in extreme environmental conditions does not place the athlete at a greater risk of incurring a heat related illness. Further investigation is warranted however, in the assessment of how this response continues during the subsequent running discipline.

DROP JUMPING ABILITY IMPROVEMENT INDUCED BY BACKWARD-DOWNHILL PLYOMETRICS

Kannas, T., Amiridis, I.G.

DROP JUMPING ABILITY IMPROVEMENT INDUCED BY BACKWARD-DOWNHILL PLYOMETRICS

Kannas Th and Amiridis IG

Laboratory of Neuromuscular Control and Therapeutic Exercise, Departement of Physical Education and Sports Sciences at Serres, Aristotle University of Thessaloniki

In the interest of improving jumping ability, we are interested to define an optimal training method for increase plantarflexors performance. According to their force-length relationship, these muscles produce their greater force at extremes angles towards dorsiflexion (Kawakami et al, 1998). It is hypothesized that backward plyometrics on decline ground are more efficient than classic plyometric training on a plane. Thirty six male students (age=18.7±0.6years, mass=77.68±9.01kg, height=180.9±9.3cm) were divided into Decline (150) Group (DG, n=13) Plane Group (PG, n=11), and Control Group (CG, n=12). DG and PG performed 12 training sessions (3sessions/week, 4 weeks) including 10 sets (2min rest between sets) of 10 consecutive maximal jumps. Before and after training, jumping ability was tested using Drop Jumps (DJ) from 20, 40 and 60cm performed on a Kistler (9821C, Switzerland) force plate (1000Hz). Ground reaction forces and take off velocity of the best performance using two jumping (bounce DJ and counter DJ) techniques were analyzed. Bipolar surface electrodes (Motion Control Inc., USA) were used to determine Electromyographic (EMG) activity of Rectus Femoris, Semi-Tendinosus, Tibialis Anterior and Medial Gastrocemius (MGAS). Analysis of Variance (ANOVA) with repeated measures was conducted to determine the changes in the jumping ability ($p<0.05$). After training, regardless of jump height, Ground Reaction Force (GRF) during the bounce DJ, but not the counter DJ, was greater for the DG. Similarly, take-off velocity during all DJ significantly ($p<0.05$) improved for the same group. Oh the other hand, after training, GRF and take off velocities remain unaltered for the PG. No differences were noted after training concerning EMG activities of all muscles examined for both experimental groups. However, only for the DG, the ratio of iEMG of MGAS during the concentric phase/total iEMG was significantly ($p<0.05$) increased after training. It is concluded that, downhill backward plyometric training could improve jumping ability, especially during fast DJ. Neuromuscular adaptations seem to be presented very early after this specific training. Athletes and trainers have to take into consideration these observations in order to improve jumping performance and reactivity of the calf muscles.

SUITABILITY OF MAXIMAL ECCENTRIC STRENGTH TRAINING IN ATHLETICS

Scholz, K.

German Sport University Cologne, Germany

Motivated by the German crisis in the athletic sprinting and jumping events the present study tries to shed some light on the question, whether or not maximal eccentric strength training (MEST) is or should be used in athletic training. In addition, practicable ways of producing such high force eccentric loads in daily training are compared and evaluated. Besides reviewing the literature, the study features interviews on MEST with renowned scientists, athletic national coaches, and physiotherapist from Germany.

Athletics is characterized as a sport that produces maximal demands on the neuro-muscular system. Muscles like the hamstrings (,the adductors, etc.), which are not extensively used eccentrically in daily life, have to produce very high forces in sprinting and jumping (as biomechanical and medical date indicates).

For this study MEST is defined as a training, where the athlete, employing maximal voluntary effort, tries to stop an overpowering outer resistance that moves at medium speed. In research studies this resistance is usually produced by computer-controlled isokinetic strength training machines. But these are usually not accessable for day to day training, because they are expensive and difficult to use.

A first session of MEST is usually followed by severe D.O.M.S. and a loss of muscle force, mainly caused by disruptions on the molecular level. These effects are much smaller after a second session or a longer training phase of MEST (repeated bout effect). But the initial

destructions – occuring especially in fast muscle fibres – can also be interpreted as a trigger for adaptations. In the long run, there seem to be hints that MEST strengthens the intramuscular connective tissue and the passive filaments within the muscle cell. The number of contractile proteins after MEST might by increased via hypertrophy, hyperplasia, and/or the seriell addition of sarcomeres. Excitation-contraction coupling is effected by the disruption connected to MEST and an increased total excitation and a change of neural excitation patterns might be part of the adaptation process.

From a funtional point of view muscle pain, acute loss of muscle force, increased short-term injury occurance and overtraining are possible negative effect of MEST. Increased eccentric and relative strength, decreased long-term injury occurance, improved force transmission and increased contraction velocity could be positive effects.

It is concluded that there seem to be good reasons to include MEST in an athletic preparation phase. Manual resistance seems to be the most practical option to produce maximal eccentric loads in daily training. Repetitions should be started from maximal preactivation. Training volume experts and respective literature typically mention 1 to 3 sets of 1 to 8 repetitions.

Practical ideas for implementing MEST into athletic training have been demonstrated on a video-CD.

IS VERTICAL JUMP HEIGHT A VALID INDEX OF MUSCLE POWER?

Markovic, G., Jaric, S.

Faculty of Kinesiology, University of Zagreb, and University of Delaware, Croatia

Introduction

Explosive movements like vertical jumps have been often applied in assessment of both rapid movement performance and muscle power (P) (2,4). However, relatively moderate relationships between the recorded performance and directly assessed P question the validity such an approach of assessment of P (1). We believe that this problem could be the result of differential influence of body size on P compared to rapid movement performance (3). Thus, the aim of this study was to test the hypothesis that the performances of rapid movements represent body size independent indices of P.

Methods

Physical education subjects (n = 159) were tested on various vertical jump and leg extensor strength tests. Both jump height and average power were calculated from the ground reaction force during jumping. The relationship among various indices of P calculated from vertical jump tests, vertical jump heights, leg extensor strengths and body size indices, both before and after the normalization of strength and power tests for body size (i.e. division with mass0.67), were calculated using a Pearson product moment method. The corresponding inter-correlation matrices of all selected variables were factorized using principal components factor analysis (PCA).

Results and Discussion

The PCA applied on all vertical jump measures, leg extensor strength tests and body size indices revealed a complex and inconsistent structure of the three extracted principal components were the jump height and P loaded different components, while muscle strength and power partly overlapped. When the indices of muscle strength and power were normalized for body size using theoretical predictions of geometric similarity (i.e. divided by mass0.67), a simple and consistent structure of principle components was in line with the hypothesis. Specifically, the recorded height and P calculated from the same jumps loaded the same components, separately for the jumps predominantly based on concentric and jumps based on rapid stretch-shortening cycle of leg extensors. The third and fourth extracted principal components represented leg extensor strength and body size, respectively.

Conclusion

We conclude that the recorded height of vertical jump can be considered as a body size independent index of P. If supported by similar results obtained from other rapid movements, the finding that the performance of rapid movements assess the same physical ability as properly normalized tests of P could be of exceptional importance for designing and interpreting the results of batteries of physical performance tests, as well as for understanding some basic principles of human movement performance.

EFFECTS OF A BICYCLE SPECIFIC STRENGTH ENDURANCE TRAINING WITH AND WITHOUT VIBRATION

Kleinöder, H., Remppel, T., Yue, Z., Mester, J.

German Sport University Cologne, Germany

Effects of a bicycle specific strength endurance training with and without vibration

Kleinöder Heinz, Remppel Titus, Yue Zengyuan, Mester Joachim

Institute for Training Science and Sport Informatics, German Sport University Cologne, Germany

Introduction

Vibration training is performed in many sports since positive effects on various factors such as speed, maximal strength, strength endurance could be shown (cp. e.g. Issurin et al 1999). Especially strength endurance is important in many cycling disciplines. Cyclists usually train this ability on a ergometer against variable resistance. A new approach is to add vibration to the above described typical training on a specially developed vibration ergometer.

Methods

30 male persons (sport students, 1.84 cm +- 6.2 cm, 77.5 kg +- 5.6 kg) were equally randomized in 3 groups. These consisted of 2 training groups (1 with and 1 without vibration) and 1 control group. Both training groups performed 8 strength endurance training units in 4 weeks on a Cyclus 2 Record ergometer by Avantronic. Each training unit lasted 31 min (i.e. 5 min warm up (80 watt, 90 rpm), 3 times 5 min training (60 - 70% individually adjusted, 50 rpm), with 3 min active regeneration in between (80 watt, 90 rpm) and 5 min cool down (80 watt, 90 rpm). During the 3 training intervals the vibration group trained with 4 mm amplitude and 30 Hz frequency. A 2 min ergometer test and 3 strength tests (isometric and dynamic) of bicycle specific muscles (m. quadriceps femoris, m. biceps femoris und m. triceps surae) were performed at the beginning and the end of the training period.

Results

T-tests were performed to establish changes within and between groups. The vibration group improved significantly from pre-test to post-test in the 2 min test, 2 isometric strength tests (leg extensors and calves) and the dynamic test for the calves. The conventional training group showed significant improvements only for the 2 min test and 1 isometric strength test (leg extensors). Between both training groups significant differences occurred for the leg curl strength test (dynamic and isometric) in favour of the vibration group. No significant differences could be found for the control group. Individually there were high scores of improvement for various test esp. for the vibration group.

Discussion/Conclusion

The results show that the training on the vibration bicycle has potential which should further be developed in order to find out guidelines for the appropriate training load. Since it was the first approach and training conditions were safety-oriented, the results are quite promising as well as the positive feedback of the vibration group. Therefore training against different resistances, with different duration and different intervals need to be tested in the near future.

CO-INGESTION OF PROTEIN AND LEUCINE STIMULATES MUSCLE PROTEIN SYNTHESIS IN YOUNG AND ELDERLY MEN

Koopman, R., Verdijk, L.B., Manders, R.J., Gijsen, A.P., Wagenmakers, A.J., van Loon, L.J.

Nutrition and Toxicology Research Institute Maastricht (NUTRIM), Maastricht University , Netherlands

Aging is associated with a progressive loss of skeletal muscle mass, which is attributed to a disruption in the regulation of skeletal muscle protein turnover, which results in a chronic imbalance between muscle protein synthesis and breakdown rate. Knowledge of differences in responses of young and elderly subjects under normal daily living conditions are of crucial importance to our understanding of the etiology of sarcopenia and are currently lacking in the literature.

Purpose: We investigated the response to the ingestion of carbohydrate with or without protein and free leucine following simulated activities of daily living (ADL) on whole-body protein balance and mixed muscle protein synthesis rates. Methods: Eight elderly (75±1 y) and eight young (20±1 y) male subjects were randomly assigned to 2 trials in which they consumed either carbohydrate (CHO) or carbohydrate, protein and free leucine (CHO+PRO+leu) after performing 30 min of standardized ADL activities. Primed, continuous infusions with L-[ring-13C6]phenylalanine and L-[ring-2H2]tyrosine were applied, and blood and muscle samples were collected to assess whole-body protein turnover as well as fractional protein synthetic rate (FSR) in the vastus lateralis muscle over a 6 h period. Results: Plasma insulin responses were significantly higher in the CHO+PRO+leu trial than in the CHO trial in both the young and elderly subjects ($P<0.05$). Whole-body phenylalanine and tyrosine fluxes were significantly higher in the young versus the elderly ($P<0.01$). Protein balance was negative in the CHO trial, but positive in the CHO+PRO+leu trial in both groups. In the CHO trial, muscle FSR was significantly lower in the elderly compared with the young subjects ($P<0.05$). Mixed muscle protein synthesis rates were significantly greater in the CHO+PRO+leu compared with the CHO trial in both the young (0.082±0.005 %∙h-1 vs. 0.060±0.005 %•h-1, respectively; $P<0.01$), and elderly subjects (0.072±0.006 %∙h-1 vs. 0.043±0.003 %∙h-1, respectively; $P<0.01$), with no differences between groups. Conclusion: Co-ingestion of protein hydrolysate and leucine with carbohydrate following ADL activities improves whole-body protein balance and increases muscle protein synthesis rates to the same extent in young and elderly men.

THE EFFECT OF ANTIOXIDANT VITAMIN SUPPLEMENTATION FOR 4 WEEKS ON OXIDATIVE STRESS AND IMMUNOENDOCRINE RESPONSES TO PROLONGED CYCLING

Davison, G., Gleeson, M.

Loughborough University, United Kingdom

Antioxidant supplementation may modulate systemic cortisol and IL-6 responses to prolonged exercise (Fischer et al. 2004). It is unclear if such effects are also associated with a reduction in the magnitude of immunodepression. The aim of the present study was to examine the effects of daily antioxidant supplementation (vitamin C 1000 mg/day and vitamin E 400 IU/day) on cortisol, IL-6, oxidative stress and neutrophil functional responses to prolonged exercise. Twenty healthy males cycled for 2.5 h at 60% VO2max after 4 weeks of placebo (PLA, n = 10) or antioxidant (AO, n = 10) supplementation. Blood samples were taken before supplementation (Baseline), immediately pre, post and 1h post-exercise (Rest, Post-Ex and 1h Post-Ex, respectively). Results, presented as means (standard deviation), were analysed with 2-way ANOVA. There was a significant post-exercise increase in plasma free 8-isoprostane but this was not different between groups (interaction $P = 0.609$). A significant trial x time interaction was observed for plasma cortisol concentration ($P = 0.008$) and the post-exercise increase above baseline was greater ($P < 0.05$) in the PLA compared with AO group. Furthermore, 1-way ANOVA on each trial independently revealed a significant increase post-exercise in the PLA group ($P < 0.05$) but no effect of time in the AO group ($P = 0.392$). The values were 415 (174), 352 (165), 702 (274) and 620 (371) nM in the PLA group and 455 (87), 465 (66), 573 (202) and 451 (144) nM in the AO group at Baseline, Rest, Post-Ex and 1h Post-Ex, respectively. Plasma IL-6 was significantly increased post-exercise ($P < 0.001$) to a similar extent in both groups (interaction $P = 0.167$). The values were 1.2 (0.3), 5.4 (2.8) and 4.9 (2.0) pg/ml in the PLA group and 1.6 (0.6), 4.0 (1.8) and 3.7 (1.6) pg/ml in the AO group at Rest, Post-Ex and 1h Post-Ex, respectively. Blood neutrophil count was significantly increased ~ 4-fold post-exercise ($P < 0.001$) but was not different between groups (interaction $P = 0.459$). The neutrophil in vitro bacteria-stimulated elastase release per cell was significantly decreased post-exercise ($P < 0.001$) to a similar extent in both groups (interaction $P = 0.423$). The values were 428 (163), 144 (55) and 134 (44) fg/cell in the PLA group and 407 (90), 147 (61) and 185 (48) fg/cell in the AO group at Rest, Post-Ex and 1h Post-Ex, respectively.

These results suggest that 4 weeks of AO supplementation may blunt the cortisol response to a single bout of prolonged exercise independently of changes in oxidative stress or plasma IL-6 concentration. Furthermore, it was not effective at modulating the exercise-induced neutrophilia or depression of neutrophil function. It is possible that greater IL-6 responses are required (as observed with the

longer exercise protocol used by Fischer et al. 2004) in order for AO supplementation to modulate IL-6 and immune function changes with exercise.

GENETIC POLYMORPHISM AND INDIVIDUALIZATION OF YOUNG ATHLETES' NUTRITION

Topanova, A., Ahmetov, I., Mozhayskaya, I., Dondukovskaya, R., Golberg, N.

St Petersburg Research Institute of Physical Culture, Russia

Genetic individuality of the person determines the features of the optimum diet preventing development of diseases and promoting maintenance of a high level of working capacity. The D allele of ACE gene is known to be associated with hypertension, left ventricular hypertrophy, heart attack and vascular hypertrophy. The Ala allele of the common Pro12Ala polymorphism of PPARG gene is associated with a 25% reduced risk for type II diabetes. The effect of this polymorphism is probably mediated by increased insulin sensitivity, which may be secondary to more efficient suppression of free fatty acids release from fat tissue, where PPARG is exclusively expressed. As to PPARA genetic polymorphism, the C allele carriers had greater progression of atherosclerosis than did G allele homozygotes [1]. Uncoupling protein-2 and -3 are mitochondrial proteins expressed in skeletal muscle, an important site of thermogenesis in humans. The Val/Val genotype of the UCP2 polymorphism was positively related to type II diabetes [2]. The UCP3 TT genotype was associated with a higher atherogenic profile and modified the risk for the development of type II diabetes [3]. The purpose of the present study was to reveal the risk of development of metabolism diseases by detecting genes polymorphisms for correction of young athletes' nutrition.

Young bicyclists (n=61, aged 13-16) were participated in the study. DNA was extracted from mouthwash samples. PPARA G/C, PPARG Pro12Ala, ACE I/D, UCP2 Ala/Val and UCP3 -55C/T polymorphisms were determined by PCR and restriction enzyme digestion.

We found that the frequencies of risk alleles for metabolism diseases such as D allele of ACE, C allele of PPARA, Pro allele of PPARG, Val allele of UCP2 and TT genotype of UCP2 genes were 43.4%, 19.7%, 87.2%, 46.7% and 8.7%, respectively. Genotypes distributions amongst young athletes were similar to that observed in other reported groups of the European population. In conclusion, the group of high risk of development of metabolism diseases was identified amongst young athletes, for which the diet was corrected. Applying the genetic data for athlete's diet correction is believed to prevent metabolic diseases and enhance their physical performance.

NUTRITIONAL INTERVENTION IN TRACK AND FIELD JUMPERS, MIDDLE DISTANCE RUNNERS AND DECATHLETES

Torres, A., García, A., Garrido, G.

Faculty of Physical Activity and Sport Sciences (U.P.M.), Spain

Introduction

Track and field events require the development of different motor skills: race walking, running, jumping and throwing. Single events need the development of one of them; decathlon is a multi-event and is the most complex athletic activity.

Diet composition was analyzed in elite athletes competing in three different events: jumpers (J), middle distance runners (MD), and decathletes (D). After this evaluation an individual nutritional report advice was given to each of them. To verify possible changes after this intervention a new diet composition evaluation was performed (one month later) in a group of them chosen randomly. The goal of this study was to compare different nutritional patterns in athletes competing in different events (J, MD and D) and verify possible changes in dietary practices after intervention.

Methods

Subjects were 25 Spanish young elite athletes (9J, 8MD, 8D). Age=22.9(3.9), 23.3(5.7), 22.9(4.3)yr, ht=178.5(0.1),173.3(0.1),185.4(0.0)cm;wt=70.1(10.7),59.9(8.6),80.7(10.2)kg;BMI=21(1.9),19.8(1.6),23.4(2.3)kg/m2 respectively. Diet composition was estimated by food weighing (Mettler-Toledo 1g accuracy) for a 5 day period. During the same 5 day period, athletes completed a 24h activity questionnaire to estimate physical activity level (PAL). Our intervention was to provide a diet composition report with individualized advice to improve diet quality. A random group of them (n=7) repeated diet composition evaluation by food weighing for 5 days in the same training period.

Results

Comparison data between the three groups: energy intake Kcal/day (2544[668]; 2425[567]; 3076[433]) was similar in J, MD and D and we found a negative energy balance (740 Kcal) according to estimated energy requirements (EER) by DRI's (2002).

EER were significantly lower in MD 3124(135) than the other two groups due to a lower body weight. Protein expressed as % energy intake (18.0 [2.0] vs 14.1[1.7]) and relative to weight (g/Kg) (1.8[0.3] vs 1.3[0.4]) were significantly higher (p≤0.001) in D vs J.

Comparing D to MD, energy intake was significantly higher in D at lunch (p≤0.01) and dinner (p≤0.05). Fat (g) (109[27] and 82[23]) (p≤0.05) and cholesterol (mg) intakes (512[114] and 278[88]) (p≤0.001) respectively, were also significantly higher.

Marginal intake with respect to the recommendations (DRI's) for: calcium (J), magnesium (J,MD,D); vitamin E (J,MD) and folate (J,MD) were detected.

After intervention we found a lower percentage of energy from fat (34% vs 28%) and reduced cholesterol (mg/d) content (401 vs 352). Micronutrient intakes (Ca, Mg, vitamin E and folate) were still suboptimal after intervention.

Discussion/Conclusion

The negative energy balance found in each group leads us to question the validity of the EER formula used for this population.

A simple dietary report is not an effective intervention for improving diet composition. More in depth strategies are probably needed combined with a closer relationship with athletes to effect changes in diet quality.

MUSCLE GLYCOGEN SYNTHESIS WITH COMBINED GLUCOSE AND FRUCTOSE INGESTION AFTER EXHAUSTIVE EXERCISE

Wallis, G.A., Hulston, C., Mann, C., Roper, H., Tipton, K., Jeukendrup, A.E.

University of Birmingham, United Kingdom

Restoration of muscle glycogen after exercise is crucial to the recovery of endurance exercise capacity. Systemic carbohydrate availability has been suggested as a major limitation to muscle glycogen synthesis in the early post-exercise recovery period (< 8 h) (1). Compared to when only one form of carbohydrate is ingested (e.g. glucose), carbohydrate delivery from ingested carbohydrate solutions can be increased during exercise with combined glucose and fructose ingestion (2). Whether ingestion of large amounts of this combination of carbohydrates can have a similar benefit to muscle glycogen synthesis after exercise is unknown. Therefore, the effect of combined glucose and fructose (GF) ingestion on short-term (4 h) post-exercise muscle glycogen storage was compared to glucose only (G) ingestion. On two separate occasions, 7 endurance trained men performed an exhaustive glycogen depleting exercise bout followed by a 4 h recovery period. Muscle samples were obtained from the vastus lateralis muscle ~30 min after exercise. Immediately thereafter, and at 30 min intervals for the next 4 h, subjects ingested carbohydrate solutions containing G (90 g/h) or GF (G, 60 g/h; F 30 g/h). Further muscle samples were obtained at 1 and 4 h after the first drink was consumed. Post-exercise muscle glycogen concentrations were similar between the trials (G, 115±25 mmol/kg dm; GF, 103±16 mmol/kg dm; P>0.05). Total glycogen storage over the 4 h recovery period was 165±30 and 150±26 mmol/kg dm for G and GF respectively (P>0.05). Accordingly, mean muscle glycogen synthesis rates did not differ between the two conditions (G, 41±8 mmol/kg dm/h; GF, 38±7 mmol/kg dm/h; P>0.05). Venous plasma glucose and serum insulin responses during the recovery period were similar in both conditions, although plasma lactate concentrations were significantly elevated during GF compared to G (by ~0.8 mmol/l, P<0.05). In conclusion, immediate and regular consumption of carbohydrate promoted rapid muscle glycogen synthesis during the initial hours of recovery from exercise. Moreover, muscle glycogen storage was equally effective when glucose alone or combined glucose and fructose were ingested simultaneously during post exercise recovery.

EFFECTS OF HIGH-INTENSITY TRAINING ON MCT1, MCT4 AND NBC1 EXPRESSION IN SKELETAL MUSCLE IN RATS

Thomas-Junius, C., Bishop, D., Moore-Morris, T., Mercier, J.

Laboratoire de Physiologie, Bvd Henri IV, 34 060 Montpellier, France

A large part portion of lactate and H+ removal from skeletal muscle is mediated by the monocarboxylate transporter (MCT) proteins : MCT1 and MCT4 [2, 3, 6]. Recently it has been shown that lactate/H+ cotransport is increased when MCT1 is expressed together with the sodium bicarbonate cotransporter (NBC) in Xenopus oocytes [1]. NBC [5] and MCT1 and MCT4 [2, 3, 6] are expressed in the skeletal muscle of rats and humans. However, while MCT expression has been reported to increase with contractile activity [2, 3], no data are currently available for NBC. Due to their functional cooperation, we hypothesized that both NBC and MCT expression would be regulated by physical activity, and that there would be a relationship between their expression. Furthermore, as high-intensity exercise induces large changes in metabolic process and these transport proteins are involved in pH regulation [4], we investigated the expression of NBC and MCTs after high-intensity training.

24 Male Wistar rats performed an incremental test to exhaustion on a treadmill inclined to 15o (starting at 10 m/min with increments of 3 m/min). They were then matched on time to fatigue and randomly assigned to the control or high-intensity training group. Training consisted of 6 (1st wk) -12 (5th wk), 2-min intervals (interspersed with 1 min of rest) performed 3x/wk for 5 wk. The intensity of the intervals was initially set at 80% of the peak speed reached during the incremental test and was increased by 10% each week. MCT1, MCT4 and NBC1 expression were measured by Western blotting in soleus (predominantly oxidative) and EDL (predominantly glycolytic) muscles. Results were analysed with student t-tests and Pearson product moment correlations (P<0.05).

After high-intensity exercise training, compared to controls, the expression of MCT1, MCT4, and NBC1 proteins increased significantly in the soleus (P<0.01), with no significant change in the EDL. Only MCT1 expression was correlated to NBC1 expression in the soleus (r=0.53, P<0.01).

These results suggest that 1) high-intensity training altered MCT and NBC1 expression and with a fiber-type specificity; 2) NBC1 expression is related to MCT1 expression in oxidative, but not glycolytic, muscle. In consequence, we can speculate that lactate transport could be facilitated by NBC in oxidative skeletal muscle. Transporting bicarbonate into the muscle would then help to suppress the build up of intracellular H+ and maintain the pH gradient required for continued MCT1 activity.

THE MECHANO-SENSOR FOCAL ADHESION KINASE (FAK) GOVERNS THE SLOW OXIDATIVE EXPRESSION PROGRAM IN ANTI-GRAVITATION RAT SOLEUS MUSCLE

Durieux, A.C., Desplanches, D., Freyssenet, D., Flück, M.

University of Bern, Switzerland

Background & Significance: Maintenance of skeletal muscle function critically depends on the mechanical stimuli. The basic mechanisms underlying mechanosensation and its integration into a phenotypic muscle response are not understood. In this regard, the mechanically-induced expression and activation of the costameric protein tyrosine kinase FAK and its role in myogenesis suggest that FAK operates as a governor of the contraction-dependent myocellular program of muscle fibers [1, 2].

Hypothesis: We hypothesized that overexpression of FAK in the anti-gravitational soleus muscle induces the expression of transcripts related to the slow-oxidative program in a loading-dependent fashion.

Methods: The right soleus muscles of 3-month old female Wistar rats were transfected with L19-tagged FAK via gene electrotransfer [3]. Transfection of the left soleus muscle with the L19-tag alone served as internal control. Overexpression of FAK protein vs. the contralateral soleus was evaluated immunochemically as described [2]. Changes in muscle loading were induced in the hindlimb suspension-reloading model [4]. Transcript levels alterations were monitored with custom-available cDNA microarrays as described in [4].

Results: Seven days after gene transfer, overexpression of FAK was detected in 20% of soleus muscle fibers and on the level of total protein in cage control and suspended animals. Concomitantly, enhanced mRNA levels of numerous factors associated with the oxidative metabolism as well as voltage-gated membrane-depolarization were noted in the FAK-transfected muscles of cage controls. The effect on gene expression of oxidative factors was reduced after 7 days of unloading when overexpression of FAK was diminished vs. cage controls. With 1 day reloading, FAK-transfected muscles were 12% heavier than contralateral control and FAK protein levels were enhanced. Concomitantly, numerous factors involved in myogenic control and protein turn-over were up-regulated.

Conclusions: The combined application of transcript profiling technology and somatic gene transfer highlights that skeletal muscle is an excellent model to map signaling pathways in vivo. The data imply that FAK is part of a mechano-sensory cascade which conditionally integrates mechanical loading and contractile activity of soleus muscle into mitochondrial biogenesis and protein turnover.

REGULATION OF MUSCLE FIBER TYPE COMPOSITION BY GENE POLYMORPHISMS

Ahmetov, I., Glotov, A., Lyubaeva, E., Glotov, O., Astratenkova, I., Druzhevskaya, A., Fedotovskaya, O., Rogozkin, V.

St Petersburg Research Institute of Physical Culture, St Petersburg State University, SSC RF Institute for Biomedical Problems, Moscow. , Russia

Human skeletal muscle demonstrates a remarkable plasticity, adapting to a variety of external stimuli. However, there exists a large variation in the magnitude of adaptability between individuals. Such variability partly explains the marked differences in aspects of physical performance between individuals (all individuals have different capacities to perform aerobic or anaerobic exercise, partly depending on their muscle fiber composition), as well as the relationship of skeletal muscle fiber type composition to certain chronic disease states, including obesity and insulin resistance. In untrained individuals, the proportion of slow-twitch (ST) fibers in the vastus lateralis muscle is typically around 55% (range 5-90%) and their conversion to fast-twitch fibers under several conditions is limited, indicating that muscle fiber type composition is determined by individual genetic program. The purpose of the present study was to investigate the association between gene polymorphisms and muscle fiber type composition of untrained subjects.

Samples of m. vastus lateralis of 43 young healthy men were obtained with the Bergstrem needle biopsy procedure. The immunoperoxidase technique was employed for immunohistochemical identification of myosin isoforms. Fiber distribution was expressed as a ratio of the number of fibers of each type in a section to the total number of fibers. DNA was extracted from mouthwash samples. Genotyping for 13 muscle- and cardiovascular-specific genes (PPARA intron 7 G/C, PPARG Pro12Ala, PPARD +294 T/C, PGC1A Gly482Ser, ACE I/D, eNOS 4a/b, ACTN3 R577X, AMPD1 C34T, UCP2 Ala55Val, UCP3 -55C/T, CnB 5I/5D, TSHR D727E, IGF-I CA-repeat promoter) was performed by polymerase chain reaction (PCR) and restriction enzyme digestion. Detection of eight polymorphisms of another 7 genes (REN G/A, AGT M235T, AGTR1A/C, AGTR2 C/A, BKR2 T/C, MTHFR C/T, ADBR2 A/G and C/G) was performed by using multiplex PCR with subsequent hybridization on the biochip. Mutations were discriminated by analyzing fluorescence intensities from separate units on the biochip.

We found that GG-PPARA, TC-PPARD, DD-ACE and C-AGTR2 subjects had significantly higher percentages of ST fibers than CC-PPARA (53.5±2.4% vs 38.5±2.3%; P=0.014), TT-PPARD (61.9±2.7% vs 46.0±1.8%; P=0.0001), II-ACE (56.6±2.5% vs 44.9±3.3%; P=0.008) and A-AGTR2 (54.8±2.3% vs 44.4±2.3%, P=0.0026) subjects, respectively. Furthermore, mean percentages of ST fibers in Gly/Gly PGC1A, CC AMPD1, Val/Val UCP2, CC UCP3 homozygotes were slightly higher than in Ser/Ser, TT, Ala/Ala and TT homozygotes, respectively, but this correlation was nonsignificant. In conclusion, PPARA G/C, PPARD +294 T/C, ACE I/D and AGTR2 C/A polymorphisms were associated with muscle fiber type composition of m. vastus lateralis in untrained males, which may be a mechanism for the association between the PPARA, PPARD, ACE and AGTR2 genotypes and physical performance.

RELOCALIZATION AND UPREGULATION OF HSP70 AFTER MUSCLE DAMAGING ECCENTRIC EXERCISE

Bayer, M.L., Paulsen, G., Ugelstad, I., Hallén, J., Kalhovde, J.M., Raastad, T.

Norwegian School of Sport Sciences, Norway

Heat Shock Proteins (HSPs) are upregulated in cells exposed to stress, playing an essential role in assistance to maintain and regain cellular homeostasis. Earlier, we have shown a translocation of HSP27 to myofibrillar proteins immediately after high-force eccentric exercise (Paulsen et al., 2005). HSP70 is the main stress-inducible member of the HSPs and of interest if this type reacts similar to HSP27, i.e. translocating to the site of damage. Therefore, the aim of this study was to investigate the HSP70 response to muscle damaging eccentric exercise. In particular, we wanted to examine HSP70 localisation (cytosolic vs. myofibrillar-bound) at different time points after high-force exercise.

Eleven healthy male students (27.5±3.5 yr, 180±8 cm, 82.6±6.4 kg) performed a leg workout, consisting of 300 maximal isokinetic eccentric repetitions with the quadriceps muscle. Biopsies from m. vastus lateralis were collected 30 minutes, 4, 8, 23, 95, and 167 h after exercise from both the exercised and control leg. Muscle samples were homogenized and analyzed applying ELISA (cytosolic fraction), western blot (WB; myofibrillar fraction) and immunohistochemistry (cross sections).

Thirty minutes after exercise, there was a shift in the HSP70 localisation from the cytosolic (18±2% decrease) to the myofibrillar fraction (314±88% increase). This was supported by immunohistochemistry, showing scattered HSP70 stain in the exercised muscle. Thereafter, HSP70 in the cytosolic fraction rose to 194±40% of control muscle 23 h after exercise. This increase was still persistent after one week. In the myofibrillar fraction, HSP70 further increased to 979±240% of control 95h after exercise, remaining elevated one week after exercise. ELISA and WB results were supported by an increased number of HSP70 positive fibres on cross sections (24±8% of counted fibres 95 h after exercise). Moreover, we report a significant correlation between acute reduction in force-generating capacity and the later increase in HSP70 levels in cytosolic ($r=0.77$, $p<0.05$) and myofibrillar fraction ($r=0.94$, $p<0.05$).

The decreased levels of cytosolic HSP70 and a concomitant increase in myofibrillar bound HSP70 immediately after exercise suggests a rapid relocalisation of HSP70. The relationship between changes in muscle function and the following HSP70 response indicate that HSP70 is upregulated proportionately to the degree of muscle damage. Thus, the subsequent upregulation of HSP70 in both the cytosolic and myofibrillar fraction indicates need for cellular protection in general and at the site of damage. We suggest HSP70 to be actively involved in refolding, chaperoning and transporting of newly synthesized proteins.

Paulsen et al. (2005) Rapid Hsp27-response to high-force eccentric exercise. The 10th annual ECSS, Belgrade.

SHORT-TERM EFFECTS OF NORMOBARIC HYPOXIA AND EXERCISE ON ANGIOGENIC/VASCULOGENIC GROWTH FACTORS AND ENDOTHELIAL PROGENITOR CELLS

Wahl, P., de Marées, M., Schmidt, A., Bloch, W., Mester, J.

German Sport University, Germany

Introduction

In competitive sports high altitude training is used to increase EPO concentrations and the number of erythrocytes and thus to improve O2-transport capacity in blood. Additionally hypoxia seems to be a powerful stimulus for angiogenesis because like EPO, vascular growths factors (e.g. VEGF), are also controlled by HIF-1α.

For many years the prevalent view was that the formation of new blood vessels in adults can only occur by angiogenesis, i.e. the sprouting of existing blood vessels. Today numerous studies showed that bone marrow derived progenitor cells (EPCs), released to the circulation, can contribute to regeneration and formation of new blood vessels, a process called vasculogenesis [1]. Recently, several groups were able to show the stimulating effects of exercise on EPC mobilization [2]. Hypoxia could play an important role in mobilizing EPCs from bone marrow. Up to now, it is unknown, what kind of exercise (duration/intensity) under what kind of environmental conditions induces (level of altitude) a vascular adaptation by mobilizing EPCs and which changes in angiogenic/vasculogenic growth factors are associated.

Methods

Seven subjects participated in this study. Each subject was exposed to five different conditions for 90 minutes. Condition 1: Normobaric hypoxia (2000m); Condition 2: Normobaric hypoxia (4000m); Condition 3: cycling exercise at sea level; Condition 4: cycling exercise under normobaric hypoxia (2000m); Condition 5: cycling exercise under normobaric hypoxia (4000m). Blood samples were taken pre training, 0h and 3h after altitude/exercise. Angiogenic/vasculogenic growth factors (EPO, VEGF, IL-6, IL-8, IGF-1) were measured by ELISA. The blood samples were also used for migration assay of EPCs.

Results

EPO (2000m, 4000m) and IL-6 (NN, 2000m, 4000m) showed a significant increase 3h and 0h after exercise respectively. For IL-6, IL-8 and VEGF no changes were measured. The migratory activity of EPC was not stimulated after various treatments. There was no correlation between any growth factor and the migration of EPCs.

Especially the combination of hypoxia and exercise should have induced, according to the current state of knowledge, a mobilization of EPCs. Although there was an increase in EPO and IL-6 concentrations no changes in migratory activity of EPCs were observed. It appears as if the exercise stimuli were not intense enough to mobilize EPCs or other additional factors, not determined in this study are responsible for mobilization.

ANALYSIS BETWEEN DECOMPENSATED GLOBAL MUSCULAR STRETCHING AND PROPRIOCEPTION ACTIVITY IN THE POSTURE AND EQUILIBRIUM CONTROL

Cairo, S., Ceciliani, A., Ghiretti, M., Tentoni, C.

Faculty of exercise and Sport Sciences of Bologna University, Italy

Aim of this study was to check the efficacy of 3 different activities for postural and balance control improvement. The first activity was represented by the Decompensated Global Muscular Stretching (DGMS) using Pancafit®, the second one by Proprioception activity (using Prokin 324®, Trial equilibrium-board, Fitball – tapis-roulant Aimachine®) and the third one by the fusion of the 2 preceding activities.The working hypothesis was that the combination of 2 different activities (DGMS and Proprioception), could be more effective than one single activity.

Methods: In each group there were 8-9 volunteers (17 female and 19 male) aged from 20 to 37 yrs (av.24.6).The activities that were carried out were the following: Experimental group: both DGMS and Proprioception activity (P.A.);Group1:onlyDGMS activity;Group2:only P.A.; Group3:no activities at all. Each group practised for 10 training sessions (1 hour each) 2 times a week.

The following tests were performed: postural test (surface e.o. r=0,30 e.c. r=0,35 p<0,05 and length e.o. r=0,60 e.c. r=0,60 p<0,05) with Correckta BR/2034; Vertical Barrè test (r=0,56 p<0,05); Fukuda Test (r=0,65 p<0,05); Proprioceptivity Prokin test (r=0,64 p<0,05) .

The collected data were analysed by the T-student test. Data distribution were analysed by the kurtosis,asymmetry,average,SD (av.+3DS, av.-3DS).

Analysis:data analysis,showed that group1 had obtained the best results in all the tests. Experimental group and group2 had even worse results in the Fukuda test. Group3 didn't show improvement in any test. In the proprioceptivity test, the group1 showed less improvement, than the group2 and the experimental group. In the Vertical Barrè test the group1 showed the most improvement compared with the other groups. In the Fukuda test only the group1 showed improvement. Group3 didn't show any improvement.

Data analysis show us that the DGMS is the best method for the recovery of the postural and balance control. The single P.A. does not resolve problems of postural nature but helps only the control of the equilibrium. That means that the improvement of such control has repercussions, in the sense of the assimilation of negative habits adaptations denied to you, on the posture.

That is demonstrated by the worsening in the test of Fukuda.

ConclusionsDGMS activity seems to be the first step in any activity of functional re-education. The importance of the reduction of the muscular retractions is the turning point in encouraging a correct posture that acts as inevitable condition for the other methods. Probably the mixed group didn't improve as much as we expected, because the DGSM activity has not been enough or has been compromised by the P.A. that has not facilitated the reduction of the muscular retractions.

RECONSTRUCTION OF TALAR OSTEOCHONDRAL LESIONS WITH MOSAICPLASTY FROM THE KNEE JOINT

Leumann, A., Valderrabano, V., Pagenstert, G., Hintermann, B.

Lower Extremity Orthopaedics, Switzerland

Introduction

Osteochondral talar lesions are frequent injuries in ankle sprains and may lead to persistent pain, constriction of range of motion, sports stop, or even degenerative joint disease. Many surgical therapies have been described for talar osteochondral lesions treatment: chondrozyte transplantation, mosaicplasty, retrograde drilling, microfacturing, and others. However, despite this variety of methods, no mid- and long-term results in the modern treatment of talar osteochondral lesions are available.

Methods

Between 02/2000 and 10/2005 22 patients with a symptomatic osteochondral talus lesion Berndt and Harty grade II-IV were treated with a mosaicplasty (Hangody et al. JBJS 2003). The osteochondral grafts were harvested at the ipsilateral knee joint. The analyzed variables were: pain (VAS, 0-10), AOFAS hindfoot score for functional assessment (points 0-100; Kitaoka et al. FAI 1994), clinical examination of donor side morbidity, arthritis grade (x-ray), chondropathy grade (Outerbridge I-V), magnetic resonance imaging and diagnostic arthroscopy.

Results

22 patients with an average follow-up of 4 years and one month were evaluated after reconstruction (range: 4-72 months; average age 34 years (range: 19-51 years old)). The lesions measured in average 1.8 cm2 (range: 0.25-9cm2). 2/3 were located on the lateral edge of the talus, 1/3 on the medial side. 2.5 cylinders were used in average (range: 1-6) between 4.6 and 12.7 mm in diameter. Six patients (27%) showed postoperative knee pain that needed further treatment. Nine patients (40%) showed concomitant chronic ankle instability that was corrected in the same operation. Further results will be discussed at the conference.

Discussion

The ideal therapy for talar osteochondral lesions remains unsolved. One of the options is the reconstruction with autologous bone-cartilage transplantation (mosaicplasty) from the knee joint as described in this report. Although long-term results are lacking concerning function, pain and secondary osteoarthritis, "knee-to-talus mosaicplasty" showed restricted results, and – in the opinion of the authors – causes significant donor side morbidity.

THE PERCUTANEOUS SUTURE FOR THE RUPTURE OF THE ACHILLES' TENDON IN A MODIFIED TECHNIQUE - A USEFUL ALTERNATIVE FOR AVOIDANCE OF DAMAGE OF THE SURALIS NERVE-

Baraliakos, X., Meyer, O., Mieles, A., Godolias, G.

St. Anna Hospital Herne, Germany

Introduction:The percutaneous suture of the ruptured Achilles' tendon, as described by Ma et al. is a useful alternative surgical technique for this indication. The benefits and disadvantages of this technique, as compared to the open suture technique or also the primary functional (conservative) treatment has been reason for discussions of the 'adequate' treatment of this injury since several years.

Objectives: In this prospective study, we analysed the clinical outcome of the percutaneous rupture of the Achilles' tendon in athletes, as described by Ma et al. Furthermore, we developed a modified technique with variation of placement of the incisions in order to minimize the intraoperative risk of damage of the suralis nerve. For performance of the suture, an unbowed needle was used as a further technical variation to the techniques described in the literature.

Materials and Methods: Overall, 93 athletes with rupture of the Achilles' tendon have been treated in our clinic between January 1998 and December 2003. All injuries occurred during warming up or full exercise. All athletes were treated by using the percutaneous technique; the first 23 (24.7%) were treated with the original technique and the other 70 (75.3%) with the modified technique, as proposed in this study. Follow-up examination was performed after a mean of 29 months (range 19-33 months)

Results: Overall, 84/93 (90.3%) of the athletes reported a 'good' or 'very good' clinical and functional outcome at follow-up. Full activity levels could be reached after a mean of 18.3 weeks and 81/93 (87.1%) of the athletes reported similar activity levels as before injury. Intraoperative damage of the suralis nerve was found in 7/93 (7.5%) and in 3/93 (3.2%) of the athletes when using the original technique and the modified technique, respectively, and recurrence of hypaesthesia was seen in 9 of these 10 patients (90%). Achillodynia during exercise was reported in 14/93 (15.1%) of the athletes. There was no athlete complaining functional dysfunction postoperatively. However,

rerupture of the Achilles' tendon occurred in 3/93 (3.2%) of the subjects and had to been treated with open suture surgery. Overall, no infections, no wound healing failures and no thrombosis occurred in any of the patients.
Conclusions: Percutaneous suture of the ruptured Achilles' tendon of the athlete is a very promising alternative, as compared to the open surgical technique. By using the modification proposed here, the risk damage of the suralis nerve can be considerably decreased.

EXPOSURE IN ALPINE SKI RACING - REASONS FOR KNEE INJURIES AND OTHER SEVERE TRAUMAS

Spitzenpfeil, P., Lipfert, S., Burger, S., Waibel, K.-H., Hartmann, U.
TU Munich, Faculty of Sport Science, Germany

INTRODUCTION
From the very beginning alpine ski racing has been regarded as a sport characterized by high exposure (Crim 2003). Apart from the classic anterior cruciate ligament (ACL) injury, an increase of complex injuries coupled with nearby-joint fractures of the lower limb, such as tibial condyle fractures, have been observed lately. Results on injury mechanisms or causal relationships, however, are not available at this time. Most previous studies were more concerned with statistical analyses of accidents in recreational skiing or biomechanical relationships regarding ACL-injury (Greenwald et al. 1997; Pecina 2002). Until this day there is a lack of extensive multidisciplinary studies on complex knee joint injuries including nearby-joint fractures. Based upon previous studies (Spitzenpfeil et al. 2005) this paper tries to focus on causes and consequences of overbalance situations for potential knee injuries by analyzing video recordings of downhill races from 1999-2003.
METHODS
Video tapes of nearly all elite downhill and super giant slalom ski races of the winter seasons 1999/2000 until 2002/2003 were digitized, compressed and stored. Based upon our previous studies a scheme of four overbalance categories (minor instabilities, major instabilities, almost crash, crash) was further developed and transferred into a SIMI Scout project. Additionally a new scheme of categories was developed to analyze crashes and their respective progression.
Additional data obtained for each overbalance situation were processed using the software SPSS to receive frequency counts. Comparisons were made between this data and that obtained in the previous studies.
RESULTS AND DISCUSSION
An increase of overbalance situation from 1999 (21%) to 2003 (49 %) could be detected. It is more dramatical in men than in women. The category "minor instabilities" recently occurs more frequently than crashes and almost crashes. Concerning potential reasons for ACL-injuries 20 % of the observed situations would fit into typical injury mechanisms like "phantom foot" (6%) or "boot induced" (20%). Dominating terrain for "phantom foot" related situations was the straight gliding phase facilitating the cause "false cutting". Detailed data concerning the progression of crashes will be presented at the congress.

IS2-06 The World Antidoping Code: from implementation to future challenges - "Athene"

INTERNATIONAL STANDARDS FOR LABORATORIES

Saugy, M.
Swiss Laboratory for doping analyses, Switzerland

The purpose of the International Standard for Laboratories is to ensure production of valid test results and evidentiary data and to achieve uniform and harmonized results and reporting from all accredited laboratories.
All laboratories are certified under the ISO 17025 rules. The World Anti-doping Agency has the duty to control the efficiency of the Laboratory network. External round tests are organized in order to improve the overall system and to be sure that the detection methods are fitting for the purpose defined in the World Anti-doping code. The chain of custody for any anti-doping sample must be strictly followed in order to prevent any formal discredit of a result. In some case, a second opinion on an adverse analytical result can be requested to assure an optimal result management. Research and development in the doping analyses are now formally part of the accreditaion scope of the accredited laboratories.
These international standards have been created in order to guaranty to the athletes similar treatment of their biological sample from the analytical point of view all over the world.

INTERNATIONAL STANDARD FOR TUE, A MEDICAL APPROACH OF THE FIGHT AGAINST DOPING

Garnier, A., CH

Without abstract submission.

INTERNATIONAL STANDARD FOR THE PROHIBITED LIST, THE VIEW OF INTERNATIONAL FEDERATIONS

Alonso, J.M.

Inernational Association of Athletics Federations, Spain

The Prohibited List (List) was first published in 1963 under the leadership of the International Olympic Committee. Since 2004, as mandated by the World Anti-Doping Code (Code), WADA is responsible for the preparation and publication of the List. The List is a cornerstone of the Code and a key component of harmonization. It is an International Standard identifying Substances and Methods prohibited in-competition, out-of-competition, and in particular sports. Substances and methods are classified by categories (e.g., steroids, stimulants, gene doping). The use of any Prohibited Substance by an athlete for medical reasons is possible by virtue of a Therapeutic Use Exemption. Guidelines for the annual review and consequent publication of the List are outlined in the Code. The agreed process for the annual consideration of the List includes three meetings (see timeline below) of the WADA List Committee with a draft discussion List being published and circulated for consultation in June, following the second meeting.At its third meeting, the List Committee, in September, following full and proper consideration of the submissions received from the consultation process, recommends the new List to the Health, Medical and Research Committee which in turn makes recommendations to the WADA Executive Committee. The Executive Committee at its September meeting finalizes the List. The updated List is published by October 1 and it comes into effect on January 1 the following year.

CHANGES IN PUBLIC PERCEPTION OF DOPING IN SPORT IN SWITZERLAND 1995-2004

Kamber, M., Stamm, H.P., Mahler, N., Lamprecht, M., Marti, B.

Federal Office of Sports, Magglingen, Switzerland

Objective:

To assess the changes in the public awareness of doping in sport and its prevention issues over a period of 9 years in Switzerland and to compare some of the results with the answers from a survey with top level athletes.

Design:

The surveys were carried out with population-based representative telephone surveys in the years 1995, 1998, 2001 and 2004 as well as with a written questionnaire for top level athletes in 2006. The core questions in the telephone surveys remained the same throughout the observation period. The topics covered doping and ethics in sports. The time to conduct the telephone surveys was always late summer and fall and there was never any particular media attention to doping issues during these periods. The questionnaires had eight (1995), twenty-five (1998) twelve (2001) and nineteen (2004) items. The questions were pretested for each run on a smaller number of respondents. The questions concerning doping and ethics were embedded in the telephone surveys of 1998, 2001 and 2004 within broader surveys about the respondents' physical activity behavior. The survey with top level athletes was carried out at the end of 2005 and beginning of 2006.

Setting:

Population of Switzerland and top level athletes in the Swiss registered control-pool.

Participants:

1201 (1995), 800 (1998), 1535 (2001) and 2114 (2004) respondents between 18 to 74 years old, selected by stratified random sampling and top level athletes (2006).

Main Outcome Measures:

When asked about the main problems in sports (survey of 2004).

Invited symposium (IS)

IS2-07 Physical activity promotion through primary care - "Innsbruck"

REDUCING RISK FACTORS BY EXERCISE IN GENERAL PRACTICE

Fritz, T., SE

Without abstract submission.

A QUALITATIVE APPROACH TO THE DEVELOPMENT OF PHYSICAL ACTIVITY PROMOTION IN PRIMARY CARE

Bize, R., Cornuz, J., Martin, B.

Federal Office of Sports, Magglingen, Switzerland

Introduction: A number of physical activity promotion models for primary care have been developed in Switzerland over the last few years. None of them has however been taken up by general practitioners on a wider scale.

Objective: To assess opinions, beliefs and behavior of a sample of Swiss physicians regarding physical activity (PA) promotion in a primary care setting, in order to develop, together with the results of focus groups interviews, a widely acceptable concept and the material for PA counseling in this particular setting (written booklets for patient, manual for physicians training, and a prescription form).

Methods: We conducted a qualitative study with semi-structured interviews among 16 physicians in the French speaking part of Switzerland. Nine were primary care physicians (GPs), four were mainly involved in preventive medicine, and three mainly involved in the field of physical activity.

Results: The main themes that were explored are presented below.

Screening for sedentary lifestyle and counseling practices - History regarding physical activity is consequently taken with new cases, but not in a systematic manner. Counseling is more likely to be delivered if other cardiovascular risk factors are present.
Counseling techniques - According to some interviewees, more emphasis should be put on well-being as a motivational tool, rather than on disease prevention.
Barriers to counseling - Lack of time, lack of reimbursement, lack of clear guidelines
Interventions advocated by GPs for PA promotion in a primary care setting – Screening for sedentary lifestyle, booklets accompanying physician counseling, patient orientation to structured fitness programs or to specially trained counselors.
Effectiveness of counseling – Most physicians describe themselves as rather pessimistic in their perception of counseling effectiveness.
Management of the numerous prevention topics – Practical continuing education directed to motivational interviewing skills and topic-specific tools are requested.
Conclusions: In order to find wider acceptance in primary care settings, the conception of physical promotion should take into account physicians' attitudes and expectations, address their perceived barriers (lack of time, reimbursement and clear guidelines) and try to improve their self-efficacy in physical activity counseling. Such an approach is currently being developed jointly with the Swiss College of Primary Care Medicine. Its feasibility, acceptance and use, will be further tested among a sample of family physicians.

EXERCISE ON PRESCRIPTION (EOP) - DANISH EXPERIENCES

IS2-08 High altitude training - "St. Moritz"

ALTITUDE TRAINING: IS HIGH-HIGH OR HIGH-LOW BETTER THAN LOW-LOW?

Friedmann, B.

University Hospital Heidelberg, Germany

Altitude training is frequently performed by elite endurance athletes assuming that an increase in total hemoglobin mass (red cell volume) and/or muscular adaptations, both of which are typical for altitude acclimatization, might outlast the altitude sojourn and cause an improvement in sea-level performance. The results of controlled studies on the effects of classical altitude training with living and training at moderate altitude (High-High) are equivocal. Especially in elite endurance athletes, there is a lack of scientific evidence for High-High being superior to equivalent training at sea level (living low-training low, Low-Low). It was reasoned that reduced training intensity at altitude due to the decrement in aerobic capacity has detrimental effects on sea level performance. Therefore, living at moderate altitude and training at low altitude (High-Low) was introduced as an alternative form of altitude training to acquire the advantage of altitude acclimatization without the need to adapt the training program to hypoxic conditions. As there are only a few natural sites where High-Low can be performed with reasonable daily travelling altitude rooms and hypoxic tents are often used for the realization of High-Low. However, the findings of a few controlled studies investigating the effects of this training regimen on sea level performance are controversial while the results of only one study which compared the effects of High-Low with High-High suggest that High-Low is superior to High-High.
Some methodical problems exist for all altitude training regimens. Especially, randomized controlled studies with a sufficient number of elite athletes (VO2max of at least 70 ml/kg*min) are difficult to perform and are therefore lacking. Furthermore, in most studies on the effects of training at altitude, little or no attention was paid to the fact that there is a great inter-individual variation in the reduction of performance and heart rate at equivalent exercise intensities compared to sea level. It seems possible that in some studies sea-level performance was not improved because of suboptimal training during altitude exposure. One essential question is which endpoint should be used in altitude studies. In elite athletes it has to be performance capacity in a discipline which is also chosen in competition. VO2max – which undoubtedly can be increased by an augmentation of total hemoglobin mass – has frequently been used as a measure for performance capacity. However, VO2max is only one component for performance in endurance sports and performance at the maximum steady state intensity, exercise economy and anaerobic capacity must also be considered. Therefore, time trials might be the most suitable tests. As only few studies meet some of these criteria further investigation is needed to answer the question if High-High or High-Low is better than Low-Low.

POTENTIAL MECHANISMS ACCOUNTING FOR PERFORMANCE IMPROVEMENT BY HIGH-HIGH OR LOW-LOW

Bärtsch, P.

University Hospital Heidelberg, Germany

Classic high altitude training and the training modality Live-High-Train-Low (LHTL) both lead to ventilatory acclimatization and to an increase in red blood cell mass (RBCM), given that the exposure to hypoxia is ≥ 14 hours at an ambient PO2 equivalent to at least 2500 m in LHTL. Double-blind controlled studies of erythropoietin administration demonstrate that a 10 % increase of RBCM leads to a 7 % improvement in VO2max. Thus, if living at real or simulated high altitude leads to an increase of RBCM in the order of 10 %, a significant effect on aerobic performance can be expected, while ventilatory acclimatization is most likely not relevant for sea-level performance. Additional effects have been suggested to account for an improved sea level performance after LHTL or classic high altitude training, such as improved anaerobic capacity due to increased buffer capacity and increased mechanical efficiency due to preferential carbohydrate utilization in hypoxia. The results of various studies, many of which were uncontrolled, yielded controversial results. Furthermore, buffer capacity can also be increased by high training intensity at low altitude and the relevance of both proposed mechanisms for sea level performance has not yet been clearly established.

TRAINING IN HYPOXIA FOR SEA LEVEL PERFORMANCE: POTENTIAL MECHANISMS AND EVIDENCE

Vogt, M., Angermann, M., Graber, F., Flück, M., Hoppeler, H.

University of Bern, Switzerland

Altitude training is very popular among endurance athletes. It is used to increase endurance exercise performance or to prepare for competition at altitude. Although well controlled studies showed increases of performance determining variables, endurance athletes in general respond very differently to acute altitude exposure and to altitude training. For example there are individual differences in the altitude dependent decrement of maximal oxygen consumption and exercise performance as well as in the response to hypoxia challenges.

Mechanisms which lead to this individual response are not well known. To search for possible muscular factors explaining individual differences of the acute performance decrement at altitude we recently tested Nordic combined skiers under simulated hypoxic conditions corresponding to an altitude of 3200m. High decrement of maximal oxygen consumption at altitude was associated with high intramuscular lipid content and low myofibrillar density in deltoideus muscle. These results suggest that ultrastructural characteristics of skeletal muscles may explain at least to a part the altitude dependent loss of aerobic performance in trained athletes.

Currently, there are two seemingly opposite training paradigms proposed to use altitude (or hypoxia) as an ergogenic aid. Beside "live high – train low" by which an improvement of the oxygen transport capacity is expected, the concept of "live low – train high" has also received attention. For this latter regime, athletes train under simulated or natural hypoxic conditions, while recovery time is spent at sea-level or normoxia. Several studies show that aerobic and anaerobic endurance performance can be improved with "live low – train high". Molecular analysis reveals that a transcription factor called Hypoxia-Inducible Factor 1 (HIF-1) acts as a master gene in the regulation of hypoxia dependent gene expression. In human skeletal muscle "live low – train high" induces the expression of glycolytic enzymes, antioxidative enzymes, the angiogenic factor VEGF, myoglobin as well as the increase of capillarity and mitochondrial content in parallel to the induction of the HIF-1 system. In trained human skeletal muscle, these adaptations cause a shift of substrate selection to an increased oxidation of carbohydrates as well as to an improvement of the conditions for transport and utilization of oxygen.

We gained experience with using hypoxia in the training of top-level athletes. This training mode may have practical implications of using hypoxia as an ergogenic aid.

IS2-09 Decision making in collective sport - "Albertville"

ASSESSING COLLECTIVE DECISION MAKING IN SPORT BY A POSTERIORI METHODS: CASE STUDY IN TEAM HANDBALL

Lenzen, B. 1, Theunissen, C. 2, Cloes, M. 2

1 University of Geneva (Switzerland), 2 University of Liège (Belgium), Switzerland

Team sports provide a big challenge in term of decision making for players and pupils, coaches and teachers, and researchers. Most of the research on decision making in sport has been conducted in connection with expertise, and the majority of researchers working on cognitive expertise have adopted an information-processing framework for studying decision making in simulated settings. In contrast, we prioritized a posteriori methods within the framework of the ethnomethodologic approach of situated action. Three aspects of this theory are of particular interest for research on decision making in sport: (a) the relation between planning and action; (b) the perception-action coordination; and (c) the distinction between first person and third person representations. The first one is expressed by the distinction between strategy and tactics in team sports. The second one results in the recommendation that perception and action should be coupled for the analysis of performance. Finally, the third aspect deals with the risk of confusion between the frame of reference of the decision maker and the one of the scientist studying him or her, and means to reduce it.

Aiming to demonstrate the interest and the validity of a posteriori methods for exploring the relation of knowledge and action to the particular and ever-changing circumstances of complex sport situations, we submitted six elite female handball players to self-confrontation interviews about two previously played and video recorded championship matches. Players were notably asked the following questions: (a) Can you describe what happened at this moment (the moment illustrated by a previously selected video sequence)? (b) Which information did you take into account? (c) What was the principle that you applied? (d) What is the origin of this principle?

Findings emerging from the qualitative analysis of players' retrospective verbalizations may be distinguished depending on whether they (a) provide help understanding how subjects make decision in already studied simulated settings or (b) prefigure novel variables that can be used for further model specification. We describe as non-situated elements those referring to strategy, which influence players' decision making independently of the context of the game situation (e.g., visual cues, offensive/defensive tactical concepts) and as situated elements those which depend strongly on the context of the game situation (e.g., auditory/tactile cues, knowledge about oneself's weakness/strengths, knowledge about teammates' weakness/strengths, knowledge about the opponent's usual play, difficulty of the match). The latter deal more deeply with the collective aspects of the decision making process. These situated elements need to be further addressed before models in decision making can be applicable to real-world sport settings, in a way to develop on this basis more effective training and teaching sessions.

DECISION-MAKING OF ELITE RUGBY PLAYERS IN GAME SITUATIONS

Mouchet, A.

Université Paris XII, France

We are interested by complexity and subjectivity in the decision making of elite rugby players in game (Mouchet, 2005a). An interbreeding method contributes to enlighten the private and public dimensions of decisions, by articulating the player point of view and the researcher point of view (Mouchet, Bouthier, in press). We do in case studies a data triangulation between:

- Player's conceptions about the general movement of the game, with a semi-steered interview before the match.
- Actions description in a game sequence extracted of the match and chosen by the researcher. We use video-computer analysis.

- Subjective lived of the player in the considered actions with an "explicitation interview" (Vermersch, 2004) after the match. This interview is the most important, because it allows us to accede to the details of the action by the player's own logic. We can understand by the player's point of view the meaning of his game situation elaboration, and his decisions.

The major results underline many points about the decision making activity.

- Players' subjective relations to shared elements of the team, as game project often elaborated by trainers.
- Peculiar and subjective mobilization of the different sources of influence, as decisional background which includes for example the player's experience in other situations or strategies defined for the match.
- Flexibility in the decisions which are emergent or more deliberated. It's often depends of the defence pressure on the ball bearer. This flexibility can be considered as factor of creativity, and is interesting for the articulation between strategy and tactics (Mouchet, 2005b).
- Subjectivity in the attention dynamics of the ball bearer. For instance in his own construction of configuration of play.

Methods and results allow us to draw some tracks for training. We try to mobilize verbalisation for the development of players' competences, and for the construction of a common repository in the team.

FOOTBALL PLAYERS' MENTAL REPRESENTATIONS OF GAME SCENARIOS: DOES EXPERTISE COUNT? A PSYCHOLINGUISTIC INVESTIGATION

Gygax, P.

University of Fribourg, Switzerland

In order to progress through a competitive sporting event, athletes need to build a mental representation of the event. The information included in such a representation will determine an athlete's behavioural and mental responses. In this paper, we present two studies exploring the mental representations of Swiss football players at different levels of expertise, when presented with textual information. In Study 1 (off-line), 1st Division and 5th Division players were asked to write about performing in competitive scenarios after being provided an introductory sentence constraining the scenario. The results were analysed using a recurrent category coding system. Most importantly, the results showed that players of less expertise were more self-oriented and included more emotional content in their mental representations. In Study 2a and 2b (on-line), we presented players of three different levels of expertise with different scripts (National League, 1st Division and 5th division), constructed with the information provided in Study 1, and measured the participants' reading times focussing on the orientation of focus (self-orientated vs other-oriented) and sentences with an emotional valence. Although we found differences between 1st Division players and 5th Division players, suggesting that 1st Division players' mental representation more easily includes others and less readily includes emotions, we found that National League players were very similar to 5th Division players in their mental representations of game scenarios. It is suggested that although the results from the 5th Division and the National League were similar, different cognitive processes underlie the construction of the players' mental representation.

MATHEMATICAL MODELS IN SPORT PHYSIOLOGY

Quarteroni, A., D'Angelo, C.

EPFL (Ecole Polytechnique Fédérale de Lausanne), Switzerland

Physical exercise involves extremely complex physiological processes. For instance, it is known that several biochemical phenomena with a number of chemical reactants take place during efforts such as running, swimming and almost all sport activities. They are highly interdependent, and the way they interact changes with respect to workload and other physiological parameters. Performing an accurate analysis of sport physiology based on individual characteristics is therefore a difficult task. Due to the intrinsic interest of such analysis for a number of applications, for instance in the pharmacological study of drug administration, we propose some mathematical models, aiming at obtaining relevant informations about the response of the body to the effort condition.

The main actors among the physiological processes sustaining exercise are

1. the biochemical reactions in skeletal muscle;
2. the substrate (oxygen, glucose, lactate, . . .) transfer between blood and tissues;
3. the cardiovascular feedback with respect to the arterial pressure and substrate concentrations (i.e. the baroreflex and chemoreflex effect).

We describe suitable models for these three phenomena and show how they can be coupled together. The coupled models can describe the autoregulation effects

that typically affect the cardiovascular system and the metabolism of tissues. Our approach involves lumped models as well as distributed models.

Lumped models feature several compartments that describe different parts/organs of the human body (skeletal muscles, blood vessels, other tissues, ...).

The variables of such models are averaged quantities on each compartment rather than spatial distributions, so that the computational cost of simulation is reduced. To apply the model, the identification of unknown parameters related with metabolism and biochemical reactions is required: typically they are obtained by optimization techniques.

Distributed models are proposed for flow analysis and chemical transport processes in blood vessels. They is able account for the geometry of vessels or tissues; on the other hand, they have a more pronounced computational cost. We show some examples of the use of the so-called 1D models for analysing blood flow and mass transport, and of more complex 3D/1D models.
Some typical applications will be discussed as well.

BODY FIXED SENSORS AND THEIR APPLICATION IN SPORT SCIENCE

Aminian, K., Favre, J.

Ecole Polytechnique Fédérale de Lausanne, Switzerland

Camera based motion capture, force-plate and instrumented walkway are the most commonly used system for movement analysis. Systems using these technologies are available on the market, but they provide information for a limited period of time and could be used only in a closed environment. In order to overcome limitations of these technologies, some investigators attached sensors on body segments to measure kinetics or kinematics features. Body fixed sensors (BFS) have several advantages. First, they allow mobile and outdoor motion capture. Second, they can provide information over extended periods of time. Third, frequency sampling is higher and several hundred hertz can be reached with existing datalogger. Finally, BFS approach is very similar to sensory system used in human movement control.
Here we review the use and application of the main BFS such as goniometers, foot pressure sensors, accelerometers, earth magnetic sensors and gyroscopes in human ambulatory monitoring. We outline the advantage of new technologies based on BFS and particularly the possibility to perform field measurement and during the actual condition of the subject. The relevance of intelligent computing and its potential to enhance those features hidden in biomechanical signals are reviewed. An emphasis is made to show the results produced by these sensors when used alone and new possibilities offered when the information from different type of BFS are fused. We provide some applications related to sport science where BFS are used to improve athlete performances, training or rehabilitation. The first application is the assessment of spontaneous physical activity in order to provides valuable information about posture allocations (sitting, standing, lying, walking, …) and allowing a better evaluation of moving ability and energy cost of the subjects. The second application concerns the 3D evaluation of body segments and joints. 3D knee function obtained in this way gives many outcomes for ligament rupture evaluation before and after surgery. The third application is related to jump performance where our results demonstrate that a simple ambulatory system provide a precise analysis of the principal parameters of the vertical jumps such as velocity, force, power, height, takeoff. Finally, using BFS, we provide a new approach to estimate multi-segment joint coordination during cyclic movement such as walking.
Based on these results, we believe that new technologies using BFS are well adapted for field measurement in sport science and provide outcomes which can be used for training, rehabilitation and physical activity monitoring.

FUNCTIONAL COMPOSITE MATERIALS FOR IMPROVED FEEL AND CONTROL

Fischer, C., Bourban, P.-E., Michaud, V., Manson, J.-A.

Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland

High-end alloys and polymer composites are extensively used in sporting goods. Recently, the development and integration of "smart"- and "active" materials into composite structures have been a major topic of interest. These novel materials could improve the human-material interaction and thus provide better feel and comfort when practicing sports involving an equipment.
To illustrate this concept, it is generally accepted that classical design changes that cause an increase in damping will cause corresponding reductions in stiffness and strength. Thus, the integration of adaptive materials into composite structures to better control vibration and stiffness represents an area of considerable interest. Structures based on well-established "smart" systems (e.g. containing predeformed shape memory alloy (SMA), electro-rheological (ER) and magneto-rheological (MR) fluids) provide means of modifying vibrational properties via external stimuli in a wide range of applications. To avoid the need for an external power source, a material that changes its properties according to the loading conditions would be ideal. Such behavior is characteristic of shear-thickening fluids (STFs), which show a marked increase in viscosity beyond a critical shear rate. In the framework of this project, we have shown that the incorporation of a tailored STF into sandwich structures simultaneously lead to stiffness and damping changes of the structure under certain dynamic loading conditions. Such properties are thought to be very interesting for highly deformed structures such as alpine skis, and a first attempt to integrate STFs into skis showed promising results.
Beyond the activities focusing on materials development, we have recently developed a methodology to determine the influence of several characteristics of a sports equipment on the athletes' perception, in the perspective to assess the influence of novel materials on the users' "feel and control". Using alpine skis as a case study, this method has shown to provide a tool that relates the subjective evaluation of the athlete to the intrinsic mechanical and dynamic properties of sports equipment.
This project is part of the Sports and Rehabilitation Engineering program (SRE) at EPFL, and is being carried out in collaboration with scientists from the Brain Mind Institute (BMI).

BODY PLETHYSMOGRAPHY AT HIGH ALTITUDE (4559 M): NO EVIDENCE FOR INTERSTITIAL PULMONARY EDEMA IN MOUNTAINEERS WITH AND WITHOUT ACUTE MOUNTAIN SICKNESS

Schendler, G., Luks, A., Menold, E., Berger, M.M., Bärtsch, P., Swenson, E.R., Dehnert, C.

University Hospital Heidelberg, Germany

Blood gas analysis and measurement of vital capacity (VC) have yielded indirect evidence that acute mountain sickness (AMS) is associated with mild interstitial pulmonary edema.
Since interstitial pulmonary fluid accumulation should also alter pulmonary compliance and airway resistance especially in the smaller airways, the aim of our study was to perform extensive pulmonary function testing by body plethysmography and compliance measure-

ment. After baseline measurement at low altitude, 34 healthy subjects ascended to 4559 m within 24 h and were tested 2-4 h (HA-day1), 20 h (HA-day2) and 44 h (HA-day3) after arrival. Severity of AMS was assessed by Lake-Louise-score and ESQ-C-score, additionally chest radiographs were taken to diagnose HAPE at each time point.

HAPE was diagnosed by clinical examination and chest x-ray in 4 subjects, which were excluded from the further analysis presented here. AMS was diagnosed in 16 (53%) of the 30 remainder subjects. None showed any sign of HAPE. Pulmonary function testing showed no differences between low altitude and measurements at high altitude for total lung capacity, vital capacity, forced expiratory volume in the first second, airway resistance, and dynamic and static compliance. Differences from low altitude were found in peak expiratory flow at HA-day1, HA-day2 and HA-day3 and for mid-expiratory flow at 75% of vital capacity at HA-day1 (ANOVA, post hoc t-test, $p < 0.05$). There was no correlation in any parameter of pulmonary function testing and severity of AMS.

The fact, that lung volumes, airway resistance, and pulmonary compliance are unchanged at high altitude indicates that no relevant interstitial fluid accumulation occurred in these subjects. The lack of correlation of AMS-scores and pulmonary function testing suggests that the development of AMS is not associated with interstitial pulmonary fluid accumulation and that the reported deterioration in gas exchange efficiency in AMS must have some other cause.

EFFECT OF COLD WATER IMMERSION ON CORE BODY TEMPERATURE, MUSCLE FUNCTION, AND LOWER LIMB BLOOD FLOW FOLLOWING PROLONGED ENDURANCE CYCLING IN THE HEAT

Peiffer, J., Abbiss, C., Peake, J., Nosaka, K., Suzuki, K., Laursen, P.

Edith Cowan University, Australia

The benefits of cold water immersion as a means of aiding recovery from prolonged exercise in the heat has been, to date, largely anecdotal. PURPOSE: This study was conducted to examine the influence of cold water immersion on indices of muscle function, body temperature and femoral blood flow following prolonged cycling in the heat. METHODS: Ten well-trained male cyclists (Age: 27+/-7 yrs, Height: 181.1+/-6.4 cm, Weight: 77.9+/-6.6 kg, %body fat: 8.5+/-2.7%, VO2max: 61.7+/-5.0 ml/kg/min, Peak power: 343+/-24 Watts) completed two exercise trials consisting of 90min cycling at a constant power output (64+/-3.6% peak power) followed by a 16.1km time trial in the heat (32DegC, 40% relative humidity). Following the trial, subjects were assigned in a randomized crossover fashion to complete either 20 min of cold water immersion (CWI; 14DegC) or control condition (CON) consisting of sitting in a thermo neutral room (~21DegC; 40%rh). Rectal temperature (Tre) was measured continuously throughout the duration of the trials with values averaged every 5 min. Femoral artery and vein diameter (FAD and FVD, respectively) were measured at the right femoral artery bifurcation (FAB) and right mid-thigh (RMT) using ultrasonography, and maximal voluntary contractions (MVC) and electrically stimulated (1sec, 80volts, 100Hz, square wave) MVC (SMVC) were performed pre-exercise, 5 min post-exercise, 45 min post-exercise (5 min post CWI) and 90-min post-exercise. All data were analyzed using a repeated measures ANOVA with significance set at $P<0.05$. RESULTS: Tre was significantly lower in CWI (37.1+/-.7DegC) versus CON (37.4+/-.7DegC) at 55 min post-exercise which persisted throughout the remainder of the trial ($P<0.05$). MVC and SMVC decreased significantly from the pre-exercise values at all time points for both CWI and CON trials ($P<0.05$). MVC and SMVC were significantly less at 45 (218+/-57.4 vs. 234.8+/-48.3, 208.7+/-58.7 vs. 212+/-59.8 N*m) and 90 min (218.6+/-57.4 vs. 234.8+/-48.3, 212.7+/-59.8 vs. 242.6+/-45.0 N*m) in the CWI vs. CON condition ($P<.05$). While FVD at FAB was not significantly different at any of the time measurements in the CWI versus CON condition, the FAD at FAB was significantly decreased 90 min post-exercise in the CWI vs. CON trial (0.68+/-0.09 vs. 0.74+/-0.11 cm; $P<0.05$). FVD at RMT was significantly decreased in the CWI vs. CON trial at 45 min post-exercise (0.87+/-0.15 vs. 0.95+/-0.16 cm; $P<0.05$), but no significant differences were observed between the CWI and CON trial for FAD at RMT . CONCLUSION: 20 min of cold water immersion (14DegC) following prolonged cycling in the heat significantly lowered Tre. Decrements in MVC and SMVC were apparent for up to 45 min post CWI. Decreases in FAD and FVD may affect blood flow to and from exercised muscle which could have negative consequences for acute muscular recovery. It does not appear that cold water immersion is effective for a short-term recovery from exercise in the heat.

TIME COURSE OF MUSCULAR, CONNECTIVE TISSUE AND NEURAL ADAPTATIONS TO UNILATERAL LOWER-LIMB UNLOADING

de Boer, M., Seynnes, O.R., Maganaris, C.N., Narici, M.V.

Manchester Metropolitan University, United Kingdom

Unloading of the musculoskeletal system leads to muscle wasting and weakness both in humans and in lower mammals (1). Although the mechanisms behind the loss in muscle function are not fully understood, muscle atrophy only partly explains the decrease in maximal voluntary strength (2). Recently, simulated microgravity has also been shown to leads to tendinous adaptations (3) represented by a decrease in tendon stiffness. This phenomenon could potentially contribute to the loss of muscle function by affecting the length tension relationship of the muscle-tendon unit. Although the quantitative changes of muscle mass to unloading are reasonably well known, the question of whether these adaptations precede, follow, or take place pari passu with those of the tendon has never been addressed. Hence the appreciation of the size and speed of the changes affecting both tissues seems fundamental to understand the mechanisms involved in muscle weakness associated with prolonged inactivity.

In the present study, neuromuscular and tendinous adaptations to 23 days of unilateral lower limb suspension (ULLS) were assessed in 9 healthy men (aged 18 to 20 yr). Measurements were performed on day 14 and 23 of ULLS.

Knee extensors (KE) MVC, measured at 80 deg (optimum angle) of knee flexion, decreased by 25% ($p<0.001$) within 14 days of ULLS and did not decrease thereafter. Maximal voluntary activation, based on twitch interpolation, decreased by 4.1% ($p<0.05$) after 14 days and did not decrease thereafter. KE CSA, determined by magnetic resonance imaging at the distal 6/10 of femur length, decreased by 8.1% ($p<0.001$) after 14 days and by 14.0% ($p<0.001$) after 23 days. Patellar tendon stiffness and Young's modulus decreased by 21.1% and 21.5% ($p<0.05$) respectively, after 14 days and by 39% and 41% ($p<0.05$) respectively, after 23 days. The similarity between changes in tendon stiffness and Young's modulus indicated that the deterioration in tendon stiffness was due to changes in tendon material and not dimensions. Expressed as rate of daily loss, the decline in tendon material properties (Young's modulus) was 1.8%/day compared to a rate of loss of KE CSA of 0.6%/day. The results show that muscle atrophy and decreased activation accounted at best for ~3/4th of the decrease in torque, while the decrease in tendon stiffness accounted mainly for the remaining loss of MVC by having the muscle fascicles operate on a shorter length.

In essence, these findings indicate for the first time that the tendinous adaptations to unloading are about three times faster than those of skeletal muscle. We expect these diverse time courses to be reflected in differences in collagen and myofibrillar protein synthesis rates which are currently being investigated.

ORAL ADMINISTRATION OF VITAMIN C JEOPARDIZES TRAINING EFFICIENCY IN RATS AND IN HUMANS

Gómez-Cabrera, M.C., Domenech, E., Romagnoli, M., Borras, C., Arduini, A., Viña, J.

Catholic University of Valencia; University of Valencia; University Polytechnics of Valencia, Spain

Introduction

Physical exercise generates reactive oxygen species (ROS) (1). These are generally considered as harmful to the cells and thus supplementation with antioxidant vitamins is recommended (2). However, results from a number of laboratories indicate that ROS are signals (3) which serve to up-regulate the expression of a number of genes (4). In this work we tested the hypothesis that supplementation with vitamin C decreases training efficiency by interfering with the cellular signalling network that leads to cellular adaptations to exercise.

Material and methods

Animals

Thirty six male Wistar rats were randomly divided into 3 groups: rest (n=12), exercised (n=12) and exercised but treated with a daily dose of vitamin C (n=12). The dose used was equivalent to 500 mg per kg of body weight (5). Endurance-trained animals were exercised 5d/wk during 6 weeks. After the last training session an endurance test was administered to each rat. The time to exhaustion was recorded for each animal.

Humans

Subjects were randomly divided into three experimental groups: rest (n=6), exercised (n=5) and exercised but treated with a daily dose of vitamin C (1g) (n=5).Each subject participated in two experimental tests (before and after eight weeks of training). After the initial VO2max test all the subjects underwent a regular exercise programme of 3d/wk for 8 weeks on a static bike.

Results

Training increased VO2 max in humans by 30% but this was prevented when subjects were supplemented with vitamin C (P≤0.05). In the animal model training increased the maximal running time from 100 minutes to approximately 300 minutes (P≤0.01). This was prevented by supplementation with vitamin C. To provide a molecular explanation for this inconvenient effect of vitamin C, we tested the antioxidant and the mitochondriogenic pathways. We found an increased expression of the genes for MnSOD and Gpx with the exercise that was completely prevented by supplementation with vitamin C. The mitochondriogenic pathway that we have studied is: PGC-1→ NRF-1→ mTFA → Citrate Synthase. All these factors were up-regulated by training and all of these adaptations were prevented by vitamin C administration.

Conclusion

A major conclusion can be drawn from these experiments: small increases in the level of oxidants produced by exercise have favourable effects because they increase catalytically the antioxidant defences and the mitochondrial content. Preventing these hormetic (6) effects is inconvenient to the cell and therefore supplementation with vitamin C prevents the adaptation of the cell to oxidative stress and lowers the training efficiency.

EFFECTS OF HYPOXIA ON EXERCISE-INDUCED DIAPHRAGMATIC FATIGUE IN HIGHLY TRAINED ATHLETES EXHIBITING EXERCISE-INDUCED ARTERIAL HYPOXEMIA

Athanasopoulos, D., Vogiatzis, I., Zakynthinos, S., Georgiadou, O., Golemati, S., Kostikas, K., Koskolou, M.D., Garagouni, C., Wagner, H., Wagner, P.D., Roussos, C.

University of Athens, Greece

Diaphragmatic fatigue occurs in highly trained athletes during exhaustive exercise. Since approximately half of these athletes also exhibit arterial hypoxemia during exercise (EIAH), we investigated the effects of different degrees of arterial hypoxemia on exercise-induced diaphragmatic fatigue in this population. Eight cyclists (mean±SD: VO2max: 65±7 ml/kg/min) randomly completed one hyperoxic (FIO2: 0.26), one normoxic and two hypoxic (FIO2: 0.17 or 0.13) 5-min exercise tests at intensities equal to a:90±7%, b:85±10%, c:80±8%, d:67±8% of normoxic maximal work rate, respectively, designed to produce the same ventilation at each FIO2. Bilateral phrenic nerve stimulation was used to determine reduction in twitch transdiaphragmatic pressure (Pdi,tw) during recovery. Mean exercise arterial oxygen saturation varied with FIO2 as expected(a:96±1%, b:93±2%, c:86±3%, d:70±4%;P<0.01). All tests induced significant post-exercise reduction in Pdi,tw(a:23±4%, b:24±4%, c:24±5%, d:24±5%)however, the degree of this reduction was not dependent on FIO2. Neither mean ventilation sustained during exercise(a:124±18, b:117±14, c:121±15, d:123±9 l/min) nor end-exercise arterial lactate(a:10.7±2.6, b:9.5±3.9, c:9.5±3.6, d:11.9±3.8 mmol/l)differed among the four tests. In highly trained athletes exhibiting EIAH the degree of diaphragmatic fatigue at similar respiratory muscle load and lactate concentration is unaffected by manipulating FIO2 over an extreme range. We suggest that either: a)the diaphragm is not sensitive to oxygenation at these muscle loads, or b) hypoxemia is compensated by increasing diaphragmatic perfusion as oxygenation falls.

EFFECTS OF WHOLE BODY ELECTRO STIMULATION TRAINING AND TRADITIONAL STRENGTH TRAINING ON VARIOUS STRENGTH AND BLOOD PARAMETER IN JUVENILE ELITE WATER POLO PLAYERS

Kreuzer, S., Kleinöder, H., Mester, J.

Institute for Training Science and Sport Informatics, Germany

Introduction:

For many years local electromyostimulation (EMS) has been used in top sport and rehabilitation with various aims. These are the support of hypertrophy and the prevention of athrophy after injuries in particular. Up to now, EMS was limited to superficial muscles.

In this investigation a whole body electrostimulation (WB EMS) apparatus (Bodytransformer) was applied. This allows complex and deep stimulation of the whole horizontally striped muscles within one training unit.

This study intends to compare the effects of 4 week long WB EMS training with a traditional strength training (TST). Parameters were isometric maximal force (IMF) and power (P) of various trunk muscles. Moreover, kreatinkinase (CK) was analysed.

Methods:

27 juvenile top water polo players (age 16,07 +/- 1,18; weight 79,3 +/- 12,36) took part in the investigation. They were equally randomized in three groups. The training of each group was as follows: 1st group 2 times/week WB EMS, 2nd group 1 time/week WB EMS und 1 time/week TST, 3rd group 2 times/week TST. Each WB EMS training unit lasted 25 min: 2 min warm up (impulse time: 1 sec, pause interval: 1 sec, impulse frequency: 50 Hz, impulse width: 200 μs), 20 min training interval (4 sec, 4 sec, 85 Hz, 350 μs) and 3 min regeneration (1 sec, 1 sec, 50 Hz, 200 μs).

The TST consisted of 8 different strength exercises with stress on the trunk muscles.

Diagnostics consisted of a pre-test, a post-test and a re-test two weeks without training later. The pre-test comprised a medical check with an investigation of body composition (Tanita), electrocardiogram (Vicardio) and a blood count. IMF and P were measured with special force and distance sensors (mechaTronic) at Gym 80 strength machines. CK was measured in training unit 3, 5 and 7 taking blood samples shortly before training, 45 minutes and 24 hours after training.

Results:

The CK values of group 1 and 2 after the 3rd training unit are 25% resp. 70% higher than the standard values whereas group 3 shows no significant difference. The last measurement after training unit 7 shows a constant of CK in group 3 (average 214 U/l) whereas group 1 and 2 individually reveal a further increase of CK (average 921 U/l).

The strength tests also showed significant improvements for several muscle groups, i.e. isometrically for the abdominals and the chest muscle and dynamically for the abdominals. Within groups we found individual adaptations to WB EMS, i.e. back muscles pre-test to post-test increase of 7% and post-test to re-test increase of 17%.

Conclusion:

According to the CK values of the WB EMS groups the training intensity was very high in contrast to traditional strength training. Since it was one of the first approaches to use WB EMS with well-trained athletes the outcome is promising. There were several significant improvements in favour of the WB EMS group and many individual improvements. Further research in this area should help to work out guidelines for the use of this training form.

SHORT TERM EFFECTS OF SENSORIMOTOR TRAINING ON POSTURAL REFLEXES IN PARKINSON'S DISEASE

Turbanski, S., Haas, C., Schmidtbleicher, D.

Johann Wolfgang Goethe-University of Frankfurt/Main, Germany, Germany

It has been shown in numerous studies that sensorimotor training results in improved postural control. Furthermore it is well known that postural instability (PI) is a hallmark of Parkinson's disease (PD). Due to the fact that medication fails to improve postural control in PD (Bronte-Stewart et al. 2002) evaluation of training strategies should be dealt with priority in therapy (Bloem et al. 2001). Some studies have proven beneficial effects of physical activity in PD (Reuter et al. 1999, Ellis et al. 2005). Accordingly the aim of this study was to evaluate short term effects of sensorimotor training on postural reflexes in PD.

52 PD patients participated in this study divided equally into one experimental group (E) and one control group (C). We analyzed balance-correcting responses following a postural perturbation consisting of a standardized acceleration of support surface which was hanging on four springs. Each disturbance of postural stability was preceded by a random delay. The displacements of support surface were measured by an acceleration sensor attached to the platform. Moreover EMG measurements were recorded from the muscle Tibialis anterior. We evaluated pre-motor-time (PMT) which is the time between the perturbation stimulus and the onset of electromyographic (EMG) activity.

First three pre-tests were assessed in all subjects. Afterwards the treatment was applied to subjects of group E while control subjects had a rest. Finally all participants were retested in three post-tests. The sensorimotor training in group E was based on random whole-body vibration (amplitude: 3 mm, average frequency: 6 Hz +/- 1 Hz) using a SRT-medical machine. Participants performed 5 series lasting 60 seconds each.

Comparison of pre- and post tests showed more efficient balance-correcting responses in post-tests in group E ($p=0.02$) but not in group C ($p=0.26$). Analyses of group differences supported the assumption of treatment effects ($p=0.03$). But these effects could not be confirmed by our EMG-data. There was no significant pre-post difference in PMT, whether in group E ($p=0.50$) nor in group C ($p=0.09$). The main finding from this study is that a sensorimotor training based on random whole-body vibration improves balance-correcting responses in PD spontaneously.

One can speculate about modified neuromuscular coordination based on two different physiological aspects: on one hand corrective torque could be generated quicker. On the other hand we hypothesised a reduction of inadequate overproduction of corrective torque (Peterka and Loughlin 2004). Besides effects on rigidity and muscle stiffness in PD are to take into account (Haas et al. 2006).

ADIPOCYTOKINE RESPONSE TO ROWING AT INDIVIDUAL ANAEROBIC THRESHOLD

Mäestu, J., Jürimäe, J., Hoffmann, P., Purge, P., Jürimäe, T., Wonich, M., Pokan, R., von Duvillard, S.P.

Univesity of Tartu, Estonia

The published acute exercise (Ferguson et al., 2004) investigations with adiponectin suggest that submaximal exercise alone does not alter adiponectin concentration. However, similar to plasma leptin concentration, larger energy expenditure with high metabolic strain of the organism may be needed to alter plasma adipocytokine concentration. The purpose of this investigation was to study plasma leptin and adiponectin response to constant load rowing at individual anaerobic threshold. Eight college level male rowers (21.5±4.5 yrs, 184.9±5.0 cm, 78.5±8.4 kg, 11.8±1.2 %body fat, 5.01±0.43 L/min) took part in this investigation. The subjects were asked for: 1) incremental rowing exercise on rowing ergometer; and 2) for 30 minutes constant on-water single scull exercise on individual anaerobic threshold. During the incremental rowing ergometer exercise the individual anaerobic threshold was measured using the linear regression point analysis (Hoffmann et al., 1994). Two regression lines were calculated for heart rate (HR) and ventilation and the intersection points between both optimized regression lines were taken as the heart rate turn point (HRTP) and second ventilatory turn point (VTP2). HR at HRTP was used as the target HR for single scull rowing. If the differences between HRTP and VTP2 were greater than five beats lower HR was used. During constant rowing on single sculls the subjects were told to row a distance of 6.5 km (approximately 30 minutes) at the given target HR (range 5 beats/min). Blood samples for adiponectin, leptin, glucose and insulin were taken before exercise, immediately post exercise and 30 minutes post exercise.

Mean HR during constant rowing (167.7±6.9 beats/min) was not significantly different from the upper target HR but significantly higher than lower target HR. Adiponectin was significantly increased above the resting value 30 minutes post exercise (+14.7%; $p<0.05$), while not immediately post exercise (+11.6%; $p>0.05$). Similar to adiponectin, leptin was not changed after 30 minutes of rowing but was significantly decreased 30 minutes post exercise ($p<0.05$). Plasma insulin was significantly decreased post exercise and remained significantly lower 30 minutes post exercise. Glucose increased with exercise and returned to the pre-exercise level after 30 of recovery.

In conclusion, 30 minutes of rowing at individual anaerobic threshold level is above the threshold that is needed to detect significant decrease in the plasma leptin and adiponectin levels.

A QUANTITATIVE AND QUALITATIVE STUDY OF VOLLEYBALL DEVELOPMENT IN THE OLYMPIC GAMES

Salimi Avansar, A., Lames, M.

Instituts of sport science, Germany

A Quantitative and Qualitative Study of Volleyball Development in the Olympic Games

Alireza Salimi Avansar & Martin Lames

University of Augsburg, Institute of Sports Science, D-86135 Augsburg, Germany

1. Introduction

Because of the multidimensional development of sport sciences and also very intensive competence of the high international players and teams in world cups and Olympic games, sport researchers try to discover, from different aspects, what elements lead players and teams into success or failure and to explain scientifically and experimentally the results. In this regard, this research tries to study men and women's volleyball teams participating in the Olympic games 2004 Athens from the viewpoints of anthropometrics, physical fitness, technique and tactics, and consequently, to make a statistical comparison between the players' performance and the final results. This study also aims at comparing men and women's teams from different perspectives and at analyzing the results. Ultimately, the total results of this research are compared with those of the previous Olympic games (1992,1996,2000) to demonstrate the development of volleyball on the high level.

2. Methods

The data (age, height, weight and high jump) of all participating volleyball teams in the Olympic tournament 2004 Athens (12 men's teams and 12 women's teams including 144 men und 144 women) were collected. The exact points and time of each set and each game (38 men's games including 144 sets and 38 women's games including 141 sets) were taken from the international volleyball website (www.fivb.org).

For the first time, more than 60000 ball contacts (28123 ball contacts for men and 32056 ball contacts for women) were quantitatively and qualitatively analyzed to compare the performance of the participating teams and also to find a new norm to predict the logical limits of success or failure of each volleyball technique in high level games.

The results of the researches carried out upon the previous volleyball Olympic games (1992, 1996, 2000) were found in sport data banks (e.g. IAT, Bisp) and were compared with those of this research dealing with the Olympic games 2004 Athens.

3. Results

The results are presented in four parts: the first part is concerned with the anthropometric analysis and physical fitness of the participating teams and their relationship with the final standing. In the second part, the significance of the game results and the time of each set and each game is explained. The third part includes the comparison of the techniques and the final standing. At last, the volleyball development from the past Olympic games until now is illustrated.

SPORT SCIENCE SUPPORT IN ELITE SPORT - IS THERE A LESSON TO BE LEARNED FROM SUCCESSFUL SPORT SYSTEMS AS TO HOW TO GET THE KNOWLEDGE FROM THE LAB ONTO THE TRACK?

Böhlke, N.

Loughborough University, United Kingdom

The convergence in the design of elite sport systems is not a recent phenomenen. Whether it is the Australian or English Institute of Sport, or the Olympiatoppen in Oslo, all of these centres provide a similar spectrum of services which are considered to be crucial to success on the international sporting stage. And the delivery of sport science support is often considered to be one of the core elements in this portfolio.

Despite the similarities in the service portfolio of today's elite sport systems, medal tables reveal that some nations are still more "successful" than others. If services like sport science support are indeed crucial factors in the development of an athlete, this suggests that more successful sport systems might have found better ways to implement this support in the training practice. Hence, this study seeks to investigate the operational management processes which are applied by two successful elite sport systems for the delivery of these services. It is hoped to identify transferable good practice which other systems could learn from.

Data Collection

The Swedish Athletics Association and the cross-country section of the Norwegian Skiing Federation were chosen as the most suitable comparison partners for this study. A total of 45 people from these two federations and their partner organisations were interviewed. The interviewees were selected according to their position in the two systems and specifically included coaches, athletes and diagnostics staff. Over 65hrs of interviews were recorded and analysed with the help of the software solution NUDIST.

Results & Discussion

A striking similarity between both systems is that the integration of sport science support is not necessarily a result of an elaborate management approach but of a general laissez-faire climate in which every coach is allowed to decide in how far he or she wants to make use of the offered support.

Interestingly, cooperation between practitioners and theorists relied heavily upon the latter bringing with them a specific set of personal (soft) skills. In fact, this was considered to be of more importance than subject-specific knowledge. A member of the Swedish Olympic Committee indicated e.g. that he considers "interpreters" to be more important than "kings of specialists". This might suggest a careful (re-) consideration of the recruiting policy for diagnostic staff.

The questions concerning the transferability of the identified practices is a difficult one as they appear to be linked to the Scandinavian context. One of the Swedish interviewees indicated however that their success might not necessarily be due to the fact that the Swedish team is managed in a Swedish way. It may much more be that the "Swedish way" (team work, flat hierarchies, etc.) is simply more suitable for today's generation of athletes and coaches: "That is maybe also a part of our success that our approach is more modern to the kind of people living in the society."

CARDIOVASCULAR (CV) EFFECT OF RECOMBINANT HUMAN ERYTHROPOIETIN ADMINISTRATION IN TRAINED RATS WITH CV RISK FACTOR

Pellegrin, M., Meziri, F., Binda, D., Berthelot, A., Jacqueson, A., Laurant, P.

Unit Research EA3921 Cellular and Metabolic Optimisation, France

Doping drugs such as recombinant human erythropoietin (r-HuEPO) endangers the life of sportmen. Although the abuse of r-HuEPO to improve athletic performance is a major concern in endurance sports, its physiologic effects remains unclear. The aim of this study was to explore the effect of chronic administration of r-HuPEO on blood pressure (BP), mortality and endothelium- and Nitric Oxide (NO)-dependent vasodilatation in trained rats with or without endothelial NO pathway dysfunction. Wistar male rats (8-10 weeks old) were divided into 8 groups (n=10 per group): sedentary control; training group (6-week treadmill exercise; 5 days/week; 60 min/day); L-NAME group (NO synthase inhibitor, 10 mg/kg per day in drinking water); r-HuEPO group (100 UI/kg twice a week, subcutaneous injection); L-NAME+r-HuEPO group; L-NAME+training group; r-HuEPO+training group; and r-HuEPO+L-NAME+training group. BP was measured by an indirect method using a sphygmo-manometer. Acetylcholine (Ach) was used to assess endothelial function in isolated aortic segments. Chronic administration of L-NAME induced hypertension. Exercise prevented the rise in BP in the L-NAME rats. r-HuEPO did not modify BP in sedentary control and L-NAME rats. Exercise induced a slight hypertension in r-HuEPO rats but only after 5 weeks of treatment. Exercise did not prevent BP increase in r-HuEPO+L-NAME rats but on the contrary, BP was the highest in this group. We observed a 57% mortality rate in exercised r-HuEPO+L-NAME rats. Rats died during the exercise and the recovery period. We also observed a prominent reduction of the endurance capacity of the r-HuEPO+L-NAME rats. L-NAME+exercise induced cardiac hypertrophy. r-HuEPO+L-NAME treatment induced a greater cardiac hypertrophy than when given alone. This combined treatment probably produces a "compensatory" cardiac hypertrophy in response to the higher BP and the diminished endurance capacity. The endothelium- and NO-dependent relaxation to Ach was markedly altered in aorta from exercised r-HuEPO+L-NAME group. This finding suggests a profound endothelial dysfunction and the possible presence of CV risk factors in these rats. Chronic administration of r-HuEPO in exercised rats with endothelial dysfunction may exacerbate the endothelial failure. In conclusion, the combined effect of a more severe endothelial dysfunction and cardiac hypertrophy due to injection of r-HuEPO will amplify the CV risk in exercised rats with pre-existing CV risk factors.

SPORT AND GENDER: IS THERE A DIFFERENT INTERACTION ON HEART RATE AND VENTRICULAR REPOLARIZATION?

Zaccaria, D. 1, Bottinelli, R. 1, Stramba-Badiale, M. 3, Rossi, E. 2, Genovesi, S. 2

1 University of Pavia, 2 University of Milano-Bicocca, 3 IRCCS Istituto , Italy

A prolonged QT interval and the presence of a steeper QT/RR slope has been related to increased total mortality and sudden death. It has been observed that in females QTc is longer and QT/RR slope is steeper compared to males. The physical exercise is associated with a reduced mortality after myocardial infarction. The aim of the present study was to assess the effects of exercise training on QT

interval and on its relation with heart rate in men and women. The study was performed in 80 healthy subjects (40 males-40 females) who differed for the degree of physical activity. Four groups of 20 subjects each were studied: trained males(TM),control males(CM),trained females(TF),control females(CF).A 24h ECG Holter monitoring was recorded in each subject.The ECG signals were processed by Elatec Holter analysis software and a dedicated algorithm automatically computed the slope of the linear regression line QT/RR for the entire 24h.The program also provided for each hour the mean and the standard deviation of QT intervals corrected for heart rate according to the Bazett's formula(QTc).Recordings were analyzed separately for the 24h period,daytime and nighttime.Age didn't differ between trained and non-trained subjects. Mean weight,BMI and BSI were significantly greater in men than in women,but no differences were observed between trained and non-trained subjects in both genders.Mean 24h HR of trained subjects was significantly lower compared to the sedentary controls in both genders(62±5vs73±5 bpm TMvsCM and 71±7vs81±6 bpm TFvsCF,p<0.0001).Trained and non-trained women had a higher mean 24h HR than their male counterparts(CMvsCF-TMvsTF,p<0.01). The mean QTc was longer in females than in males in both trained and non-trained subjects(412±16vs399±17 msec and 424±22vs407±17 msec,respectively,p<0.05).The only exception was represented by the value of daytime QTc which showed no significant differences between TM and TF(402±18vs413±16 msec).Exercise training exerted different effects in men and women.While mean 24h QTc was similar in TM and CM, TF showed a shorter QTc than CF(412±16vs424±22 msec,p<0.05),both during the day and the night(413±16vs424±20 msec and 410±16vs424±22 msec,respectively,p<0.05).Gender differences in the relationship between QT and RR interval were observed in both trained and non-trained subjects(0.14±0.02v0.16±0.03,TMvsTF and 0.16±0.03 vs 0.20±0.04, CMvsCF,p<0.05).Exercise training significantly affected the relation between QT and RR interval by reducing the QT/RR slope in both genders(0.14±0.02vs0.16±0.02 TMvsCM and 0.16±0.03vs0.20±0.04 TFvsCF,p<0.05).In our study population the QT interval tended to be reduced in trained subjects, but the ventricular repolarization was significantly shorter only in trained females compared to their controls.Exercise training reduced QT rate dependence in both genders.Our data suggest that physical training might have a protective effect, especially in women, against the risk of arrhythmic events.

CARODIT INTIMA MEDIA THICKNESS IN OBESE CHILDREN AND ADOLESCENTS - A NON INVASIVE DIAGNOSTIC INDICATOR OF CARDIOVASCULAR HEALTH IN REHABILITATIVE INTERVENTION PROGRAMS

Boehm, B., Reiner, N., Strobl, T., Buck, M., Bauer, C.P., Oberhoffer, R., Michna, H.

Technical University Munich, Germany, Germany

Introduction: The intima media thickness (IMT) of the A. carotis communis is established as a valid surrogate marker for the progression of cardiovascular disease in adults. As a number of national studies show, obesity and cardiovascular diseases become a major health issue in children, too. This development is of particular concern since overweight in childhood and adolescence has been linked with increased rates of hypertension1, type II diabetes and early atherosclerotic lesions.2 In this context physical activity and sport intervention programs become of utmost importance. Objectives: Validation of the sonographic method and verification of its feasibility in obese children and adolescents. Additionally, to investigate, if this new parameter correlates with established invasive and physical fitness parameters. Methods: 42 obese children and adolescence (age 9-15yrs., mean height 163.13+-9.02cm, weight 83.4+- 26.43kg) were examined while taking part in a 6-weeks hospitalized rehabilitative intervention program. IMT was measured using GE Logiq Book XP, 10 Mhz linear probe, in B-mode, distal of the carotid artery bifurcation on a segment > 1cm length. Sigma Scan Pro 5.0 was used for IMT offline analysis. Body composition was measured using FUTREX 6100 AL. All subjects performed a standardized and valid physical fitness test. Blood samples were taken during routine examination analysing total cholesterol, high and low density lipoprotein (HDL, LDL) and triglyceride. Results: The IMT sonography is user-friendly (examination time 5 min/patient; offline analysis 8 min/picture). IMT mean for obese adolescents was 0.552 +- 0.044mm. The test-re-test variability was r=0.722, the intra observer variability was 3% (deviation mean approx. 0.017mm). The rehabilitative intervention program had a significant influence on weight, body mass index and body fat (p<0.05). IMT thickness tends to be reduced by the intervention. IMT values correlate with body fat (%), (p<0.05, r=0.503), so do BMI, body fat and blood pressure. A significant negative correlation exists between IMT values and high density lipoprotein (HDL). Regarding physical fitness the subjects had inferior performance on all tests requiring propulsion or lifting of body mass than standard values for non-obese demand. The sport intervention program had a significantly positive effect on the endurance performance (p<0.05). Conclusions: The sonography of the IMT served as a repeatable and reliable method for obese children and adolescents. In advantage to invasive diagnostics, the sonography can demonstrate the effect of the intervention program clearly on the level of the vascular system since it enables an insight of the blood vessel. Further emphasis lies on possible effects of physical activity on arterial wall thickness, in healthy and populations at high risk.

CLASSIFICATION FOR VISUALLY IMPAIRED ATHLETES - AN INTERIM REPORT

Janda, S., Jendrusch, G., Platen, P., Bolsinger, A., Bach, M., Kaulard, K., Lingelbach, B.

Ruhr-University Bochum; University Eye Hospital Freiburg; Institute of Optometry Aalen, Germany

In an ongoing study we analyzed results of visual function tests and ophthalmological findings in visually disabled athletes. These are contrasted with classification results of these athletes collected before/during international competitions (e.g. paralympic games).

Because classifications of visual impairments are mostly based on visual acuity (VA) so far, but the procedures constituted for the determination of VA do not correspond with the European Norm EN-ISO-8596, we took the International Open German Championships in Athletics in Berlin (2005) to compare the conventional measuring methods with those obtained by modern computerized and standardized methods to assess visual function.

PURPOSE: In the context of a long-term study of new methods for multifactorial visual performance diagnostics in the low-vision-field we intend to optimize, standardize and objectify the classification to a fairer one.

METHODS: Initially the existing classification data of 2035 athletes (73.4% male, 26.6% female) of 98 nations were evaluated. During the classification in Berlin, the Freiburg Visual Acuity and Contrast Test (FrACT), a standardized computer supported forced choice test, was carried out in order to measure VA, while conventional methods (S.O.S.H.-Low Vision Chart) were used for comparison. 19 athletes of the International Championships in Berlin participated in these inquiries (74% male, 26% female; average age: 21.7 ± 6.0 years).

RESULTS: Considering the classification data of 2035 athletes clinical pictures pattern like opticusatrophy, pigmentary retinopathy/macular degeneration, nystagmus and myopia were diagnosed most frequently. The starting classes B1 (blind athletes: 35.4%), B2 (visual im-

paired with less VA: 36.7%) and B3 (visual impaired with more VA: 27.3%) had almost the same quantity. 0.7% of the athletes were categorized as not eligible because of too good visual performance.
The first proving of the FrACT shows that there are high correlations to the results of the conventional measurements of VA (S.O.S.H.). This indicates that the new methods already contribute to the optimization/objectification of the classifying process because of the minimized influence of the classifier and the standardized computer supported realization.
CONCLUSION: The stocktaking shows that the differences in VA between the extreme poles in starting class B2 are obviously bigger than in B3. This unequal distribution of VA-steps requires – at least due to reasons of fairness – a discussion about a new categorization of the starting classes. Besides/in addition to visual acuity, contrast sensitivity, dynamic and peripheral vision is of great relevance in sports, which have stayed unconsidered yet.
The studies were supported by the Federal Institute of Sport Science (BISp), Bonn, Germany (VF08/04/66/2004, VF07/04/03/2005).

THE EFFECTS OF PLAYING RUGBY ON NECK FUNCTION

Lark, S.D., McCarthy, P.W.

University of Glamorgan, United Kingdom

The head/neck/face region is the most injured part of the body during rugby, particularly from impacts inflicted during the tackle (Wilson, 1999). However, not all head/neck injuries are disabling or result in acute neural damage, instead it may be the cumulative effects that are cause of latent cervical and balance problems.
The relationship between years of playing rugby and neck function were examined. Active cervical spine range of motion (ACROM) and proprioception were assessed in 14 controls (trained non-rugby playing sports men; 27.9 ± 7 years) and 46 male rugby players (26 rugby forwards, 25.8 ± 5 years; average 14.3 years played: 20 backs, 23.9 ± 5 years; average 13.8 years played). ACROM in flexion, extension, left and right lateral flexion, plus left and right rotation were measured using a cervical range of motion device (CROM: Youdas et al., 1991). The CROM was also used to determine ability of the subject to reposition their head back to a neutral position following head movement with the eyes closed (taken as an estimate of proprioception). Rugby backs and forwards were considered both as a group and separately.
Rugby forwards generally had the lowest ACROM, particularly neck extension (43° vs 55° backs, and 58° controls), in addition this trend was recorded for left (36° vs 40° vs 46°) and right lateral flexion (35° vs 41° vs 43°), left and right rotation (65° vs 71° vs 76° and 63° vs 67° vs 71° respectively). Moderate to large effect sizes (ES) were found for the differences between the rugby forwards and either rugby backs or controls (ES range 0.5 - 1.6). The decline in ACROM in the rugby players (forwards and backs) in relation to the number of years playing rugby was a moderately correlated (flexion $p = 0.01$; left lateral flexion $p = 0.03$; extension $p = 0.05$; left rotation $p = 0.08$). In addition, repositioning was significantly worse in all rugby players after neck extension compared to controls (6° vs 3° in controls; $p < 0.05$).
There appeared to be a decrease in ACROM whose severity related to the number of years playing rugby. The group whose ACROM was affected most was the rugby forwards, who showed similarity to whiplash patients or healthy elderly individuals (Youdas et al, 1991; Trott et al, 1996). In addition to the impaired ACROM, the increased repositioning error in rugby players suggests a compromised proprioceptive ability. These combined results imply that participation in rugby can have an effect on the neck equivalent to chronic disability or ageing. Furthermore, these changes may increase the likelihood of future injury and exacerbate any age-related neck degeneration.

THE EXPRESSION OF VEGF IN YOUNG AND ELDERLY WOMEN AND MEN

Kadi, F., Ponsot, E., Ekström, V., Lexell, J.

Department of Health Sciences, Sweden

Introduction
Vascular endothelial growth factor (VEGF) is a glycoprotein mitogen acting on endothelial cells and playing an important role in vasculogenesis and angiogenesis. VEGF is considered as a major factor responsible for basal skeletal muscle capillarisation. The effects of aging on VEGF protein expression are poorly understood. Two studies from the same group showed that VEGF expression in vastus lateralis muscle is lower in old men and women compared to young men and women (Ryan et al. 2006; Croley et al. 2005). However, the elderly population participating in these two studies was characterised by a low physical fitness level. The aim of our project was to investigate the question of whether VEGF expression is altered in healthy active elderly.
Methods
Seven healthy active elderly women and men (age range, 70-83 years) were compared to six healthy young women and men (age range, 20-32 years). All individuals participated regularly in recreational sports such as aerobics, jogging, cycling, and ball games, and were considered to have a comparable physical activity pattern. Muscle biopsies were obtained from the tibialis anterior muscle of the dominant leg. After tissue homogenisation and determination of protein concentration, the VEGF protein expression was assessed using western blot analysis using a monoclonal antibody against VEGF. Densitometric analysis was performed with a computerised image processing system (scion software). The protein level of VEGF in all samples was expressed relative to the protein level of a muscle sample that served as control.
Results and conclusion
Analysis of VEGF protein expression in tibialis anterior muscle showed no significant differences between young and elderly. The difference between the present findings and those from the two earlier studies from the same group (Ryan et al. 2006; Croley et al. 2005) likely results from differences in the populations studied and also from the fact that our populations of young and elderly were considered to

have a comparable physical activity pattern. Thus, aging per se is probably not a primary factor involved in the regulation of VEGF protein expression.

CHANGES IN SERUM CYTOKINES AFTER REPEATED BOUTS OF DOWNHILL RUNNING

Smith, L., McKune, A., Semple, S., Eisenburg, B., Steele, H., Anderson, R.

Tshwane University of Technology, South Africa

Introduction: An initial bout of damaging exercise has been shown to induce muscle/connective tissue damage, and is associated with increases in indirect markers of muscle trauma. During a subsequent bout, there appears to be significantly less damage, and this is associated with lower levels of indirect markers of damage. Circulating cytokines are molecules associated with tissue trauma and healing. Whether there are alterations after an initial bout of aerobically biased eccentrics, and whether these levels are altered after a subsequent bout, is not clear. Therefore, the primary purpose of this study was to investigate any significant differences in serum cytokines after an initial bout of downhill running (RUN1) compared to a subsequent bout (RUN2).

Methods: Six healthy, active but untrained males volunteered for the study. All were required to run down a -13.5% treadmill grade for 60 min., at a pace that elicited 75% of their pre-determined VO2peak, on a level grade (RUN1); the exercise was repeated 14 d later (RUN2). Blood was drawn before the runs, immediately after, and then every hour for 12 h (14 samples) as well as every 24 h for 6d. Serum was frozen at -80°, until analyses. Samples were analyzed using a multi-plex bead assay (Bio-Rad, CA, USA). A repeated measures ANOVA was used to analyze results (2 x 14, to assess the 12 h period; 2 x 6, to asses 24 h intervals) with $p < .05$, and appropriate post hoc tests.

Results: Most changes (x + se, pg.ml-1) were seen in the initial 12 h period. IL-6 was significantly lower after RUN2 (6 + 1) compared to RUN1 (12.3 + 1). IL-10 was significantly higher after RUN2 (1.6 + .1) compared to RUN1 (.82 + .2). Regarding the chemokines: macrophage chemotactic protein (MCP)-1 was significantly lower after RUN 2 (93+ 1.9) versus RUN1 (103 + 1.9). Surprisingly, macrophage inflammatory factor (MIF)-1β was significantly higher after RUN2 (50 + 1) compared to RUN1 (42 + 1). When comparing the 24 h periods, IL-8 was significantly lower after RUN2 (5.6 + .2) compared to RUN1 (6.1 + .1).

Discussion: Similar to Hirose et al (2004), alterations in circulating cytokines were considerably less than what has been reported after strenuous endurance exercise (Nieman, 2001). Concerning the differences between the two runs, the overall cytokine profile appeared to reflect a reduced systemic inflammatory response after RUN2, with lower levels of pro-inflammatory MCP-1 and IL-8, lower levels of pro/anti-inflammatory IL-6, and higher levels of anti-inflammatory IL-10.

CHRONIC NAHCO3 INGESTION DURING INTERVAL-TRAINING RESULTS IN GREATER IMPROVEMENTS IN MITOCHONDRIAL RESPIRATION AND ENDURANCE PERFORMANCE

Bishop, D., Thomas, C., Moore-Morris, T., Mercier, J.

University of Western Australia, Australia

We have previously shown that NaHCO3 supplementation during interval training results in greater improvements in endurance performance in humans (1). It was hypothesised that this may have been due to a reduced metabolic acidosis during training and greater improvements in muscle oxidative capacity. Previous authors have identified the acute, detrimental effect of a large drop in pH on mitochondrial phosphorylation (2,3). Therefore, a smaller drop in pH (following NaHCO3 ingestion) during interval training may result in a reduced impact on mitochondrial function and promote improved mitochondrial adaptations with training. However, further research is required to investigate the effects of NaHCO3 ingestion during training on chronic changes to muscle mitochondria function. 24 male Wistar rats performed an incremental test to exhaustion on a treadmill (10 m/min + 3 m/min). They were then matched on peak speed and randomly assigned to one of 3 groups (Baseline, Placebo, Bicarb). 48 h later they performed a time to fatigue (ttf) test at the peak speed achieved during the incremental test; this was repeated post-training in the two training groups (Placebo & Bicarb). Placebo ingested NaCl, while Bicarb ingested NaHCO3 (0.05 mg/kg), administered by esophageal catheter, 30 min prior to each training session. Training consisted of 6 (1st wk) - 12 (5th wk), high-intensity, 2-min intervals (with 1-min rest) performed 3x/wk for 5 wk. Mitochondrial respiration was determined on both the soleus (SOL) and EDL, with both pyruvate (PYR) and palmitoyl-carnitine (PC) as substrates. Muscle fibre composition was also determined. Compared to baseline, there was a significant increase in SOL-PYR state 3 respiration with training (14.9 ± 3.3 v 19.4 ± 6.4 v 25 ± 5.8 nmol O2/min/mg dw), with a significantly greater increase in Bicarb. There were no significant changes in the EDL or when PC was used as a substrate. Following training, there was also a significant increase in ttf (6.5 ± 2.5 v 53.5 ± 30.4 v 81.2 ± 24.7 min) with a significantly greater increase in Bicarb. There were no significant changes in fibre composition with training. Consistent with our previous findings, the group ingesting NaHCO3 before each training session had significantly greater improvements in endurance performance, despite performing identical training. The significantly greater increase in state 3 respiration in the soleus muscle of the Bicarb group suggests that an improved endurance performance may be related to greater improvements in muscle oxidative capacity. While it has previously been reported that acidosis acutely impairs oxidative phosphorylation, via a direct effect on the mitochondrial function itself (3), our results suggest that metabolic acidosis during training may also impair chronic mitochondrial adaptations to training.

STEWART'S SIMPLIFIED ECUATION TO ASSESS THE ACID-BASE STATUS

Peinado, A.B., Díaz, V., Calderón, F.J., Benito, P.J., Martín, C.

Politecnical University of Madrid, Spain

INTRODUCTION: The physical-chemistry conception of the acid-bases status during exercise is fundamental at the time of understanding the factors that affect to [H+] (1). The independent variables that determine the acid-base balance were included by Stewart in the coefficients of an equation of fourth degree (1, 2). The objective of this study was to simplify the mentioned equation and to verify its reliability.

MATERIAL AND METHODS

20 men performance a constant load test of 30 minutes in a treadmill to an intensity corresponding to the mean of the two ventilatory thresholds, previously determined with an incremental test. Capillary blood samples at rest, and at 10th, 20th and 30th were obtained (total of samples = 96). The acid-bases parameters were analyzed with a gasometer and lactate by enzymatic method. [H+] was calculated using the equation of Stewart: A[H+]4+B[H+]3+C[H+]2+D[H+]+E=0 (STW)(1); and using our proposal, a simplification of previous one, easier to solve: A[H+]2+B[H+]+C=0 (SE). Program GNU Octave was used to solve the equation of fourth degree.

A one way ANOVA was used to compare the values of [H+] and pH measured, calculated with STW and calculated with SE. An analysis post-hoc Sheffé was used to find the differences. In order to verify the reliability of SE the coefficient of determination was obtained between the different equations and the measured values. The significant level was set at $p<0.001$.

RESULTS

The difference of the mean between STW and SE was 0.02nmol/L for [H+] and lower for pH, which was not statistically significant. Nevertheless, the difference of mean between STW and SE with the measured values was greater than 8nmol/L for [H+]. These differences were highly significant as for [H+] as for the calculation of pH ($p<0.001$). With the linear regression analysis between STW and SE $r=0.99$ was obtained. Nevertheless, $r<0.60$ was obtained between the measured equations and values.

DISCUSSION

The obtained results show that the proposal SE can be used, since the mathematical complexity is reduced. Nevertheless, the results obtained with the previous equations and the values measured with the gasometer were significantly different. Kowalchuk and Scheuermann obtained differences lower than 3nmol/L for [H+] and $r=0.81$ when comparing values measured and considered with STW (2, 3), which is in discord with our results. The differences can be due to the differences between the type of blood samples, capillary blood samples in our case and arterialized venous blood in the case of the previous authors, as well as to incorrect values in the equilibrium constants and errors when measuring the independents variables (2).

SALIVA PROTEIN PATTERN, A NEW LABORATORY INVESTIGATION TOOL FOR ATHLETES

De Palo, E.F., Antonelli, G., Gatti, R., Spinella, P., Chappin, S., Ragazzi, E.

University of Padua, Italy

Introduction. The saliva concentrations of total proteins (sTP) have been investigated as a marker of nutritional status [1] and could be linked to protein hormones [2]. The assessment of the usefulness of saliva to estimate the effect of physical exercise on salivary compounds would be a new investigation approach. Aim. To examine the ability of capillary electrophoresis (CE) pattern as a laboratory tool to study sedentary and athletes before and after a physical exercise. Subjects & Methods. 12 athletes (19±1 y, 69±4 kg, 180±3 cm, BMI 21.5±1.7 kg/m2) were studied, before and after physical exercise (45 min at 60% VO2max). A sedentary control group (n=10, 42±13 y, 61±6 kg, 169±2 cm, BMI 21.2±1.7 kg/m2) was also studied. Saliva was collected by salivette devices, at rest and immediately after the physical exercise test. CE was performed with an uncoated fused-silica capillary (length 47 cm, 50µm i.d.), separation at 5 kV using 150 mM boric acid pH 10.3, detection at 254 nm (typically used for the protein profile assessment). sTP was measured by a colorimetric method. The CE pattern analysis was carried out by a multivariate approach, based on Cluster Analysis and Principal Component Analysis (PCA). Biplot presentation of the PCA data was obtained to assess any correlation among the various peaks obtained in CE profiles. Results. The sTP levels were: athletes 326±156 and 629±345 mg/L ($p<0.001$), pre and post-exercise respectively; sedentary 425±204 mg/L. The multivariate unsupervised analysis of data, carried out by means of Cluster Analysis, showed that the sTP CE absorbance profile, obtained from controls and athletes, before and after exercise, can be separated only in part. By PCA multivariate technique an agglomerate of values, describing both sedentary controls and athletes before exercise, and a second distinct, although spread, group of scores pertaining to the athletes after exercise, was isolated. The biplot PCA values relative to CE peaks showed a strict correlation in the behaviour of four CE peaks (minutes: 17, 20, 22 and 24), suggesting that these peaks could be considered as the most informative for a possible differentiation key among the subjects. Discussion. This is the first study to investigate the saliva CE protein pattern of athletes before and after exercise. Walsh et al. [3] recently demonstrated that sTP and hydration are correlated, and our findings confirm the exercise effect on sTP. Moreover, the salivary CE profiles demonstrated that physical exercise affects some salivary compounds also by the variation of their abundance. The multivariate analysis, here used, provided a promising statistical support to the interpretation of the results, suggesting the more relevant CE peaks for further investigation.

THE ROLE OF PHYSICAL ACTIVITY IN INTEGRATED CHILD'S DEVELOPMENT AND STUDY PERFORMANCE

Zurc, J.

University of Primorska, Science and Research Centre of Koper, Slovenia

The purpose of our study was to analyse the role of physical activity in child's emotional, social and cognitive development. We found out that there is put a great emphasis on the connection between physical activity and cognitive development (Thun-Hohenstein et al., 1991; Williams, & Ericsson, 2005; Gardner, 1997). It is followed by a studies about the connection between emotional development and physical activity (Fagot, & Obrien, 1994; Graziano et al., 1998; Planinšec et al., 2004). However, the most disregarded are the studies about the connection between physical activity and social development (Bandura, 1989; Pellegrini et al., 2002; Parke, 2004).

The integrated development is reflected mostly through study performance (Ismail, 1976; Duda, 1985; Pišot 2003). Therefore we carried out the research on the representative sample of 2023 ten year old Slovenian pupils (48.2% girls, 51,8% boys), average age 10.5. We investigated the connection between physical activity and study performance. The data on the frequency of child's physical activity was obtained with a questionnaire which is the most used method in studying child's behaviour in the area of physical activity (Cavill et al., 2001). The data was processed with SPSS.

The results showed that the frequency of physical activity during their free time is statistically connected with study performance. The best study performance was attained by girls and boys, who were active in free time at least twice a week. With decrease of frequency of physical activity during the free time the study performance also decreases. The results of analysis of children with the best studying results (A-students) showed that most of them (45%) fall into the category of those who are physically active every day or twice to three times a week. The percentage of these falls accordingly with decreased free time motor activity and reaches the lowest point in the category of physically inactive in free time (23.9%). Among physically inactive are those children with average learning performance (C-students) (34.1%) whose percentage decreases rapidly with increased frequency and reaches the lowest value at those who are active twice to three times a week (16.5%) (p=0.000).

On the basis of our findings we concluded that physical activity has a great influence not only on physical and motor development but also on other areas of development. Bandura A (1989) Annals of Child Development

LONGER-TERM EFFECTS OF A PLAYGROUND MARKINGS INTERVENTION ON SCHOOL CHILDREN'S PLAYTIME PHYSICAL ACTIVITY

Ridgers, N., Stratton, G., Fairclough, S., Richardson, D.

Liverpool John Moores University, United Kingdom

Playtime provides a daily opportunity for children to engage in moderate-to-vigorous physical activity (MVPA). Environmental interventions such as playground markings may increase playtime MVPA in primary school children. Previous studies have investigated the short-term effects of playground markings on MVPA (Stratton & Mullan, 2005); however, the longer-term effects are not widely reported. The aim of this study was to explore the 6-month effects of a playground markings intervention on boys' and girls' playtime physical activity levels.

Two hundred and twenty-two children from 19 primary schools (15 experimental, n = 170; 4 control, n = 52) participated in the study. Physical activity during playtime was quantified using heart rate telemetry prior to, 6 weeks and 6 months following the playgrounds being painted with multicolour playground markings. Control schools received no markings through the study. The children's heart rate (HR) was recorded every 5 s. The HR threshold of greater than 50% heart rate reserve (HRR) represented MVPA. A 2 x 2 x 3 (sex x group x time) repeated measures ANOVA was used to analyse changes in children's MVPA. The alpha level was set at $p < 0.05$.

Boys (37.9 ± 13.7%) engaged in significantly more MVPA during playtime than girls (27.3 ± 12.2%; $p < 0.001$). The control group (39.9%) was significantly more active than the experimental group (26.9%) at baseline ($p < 0.01$). The time x group interaction was significant ($p < 0.01$). Follow-up tests revealed that MVPA significantly increased by 6.7% in the experimental group between baseline and 6 weeks post test ($p < 0.01$), whilst the control group's MVPA significantly decreased by 9.7% ($p < 0.01$). Experimental boys and girls' MVPA increased 8.2% and 4.3% between baseline and six-weeks follow-up respectively. Between six weeks and six months, the experimental boys and girls' activity decreased by 0.6% and 3.9% respectively, but these decreases were not significant.

These results indicate that painting primary school playgrounds is a suitable environmental intervention for stimulating and increasing children's voluntary MVPA during school playtime, though greater increases were observed and maintained for boys than girls. Observations of school playtime indicated that boys played on the sports markings, whist girls used the skills based markings. The results suggest that additional strategies may need to be implemented during playtime to increase girls' physical activity, whilst painting playgrounds is a suitable stimulus for increasing and sustaining boys' activity levels during playtime. In conclusion, playground markings appear to be a suitable school based intervention that can increase children's participation in MVPA during primary school playtime over the short-term, and sustain the increase in boys' physical activity over 6 months.

Stratton, G. & Mullan, E. Prev Med,41, 828-833, 2005.

BURNOUT LEVELS AND THEIR DETERMINANTS IN A SAMPLE OF ITALIAN PE TEACHERS

Carraro, A.

University of Padua and SSIS of Veneto, Italy

Factors that influence the professional condition of teachers could be grouped into three areas: personality factors, occupational hazards and specific work environment conditions. When job-related demands and stressor factors become excessive, there can be lots of different, possible reactions. Burnout (BO) has been identified as one type of chronic response to the cumulative, long-term negative impact of work stressors. Based on Maslach's research, some symptoms of the syndrome are commonly accepted: emotional exhaustion, depersonalization and low personal accomplishment. Although teachers' burnout has been the focus of many studies, only a few have dealt with PE teachers.

The target population was a not selected series of 150 Italian PE teachers, (56% female, 44% male; mean age 44.4, SD 5.82; mean years of service 18.03, SD 7.74). We used a specific questionnaire together with the MBI (Maslach Burnout Inventory). The questionnaire got information about personal background: demographic, educational and occupational data, working conditions, personal physical fitness perception, attitudes towards one's own body and BO level perception. Questionnaires were directly delivered to PE teachers in their school and collected after 3-5 days. Descriptive statistics were used to define profiles and BO levels. In addition, analysis of variance was performed entering scores of MBI subscales as dependent variables, and the social statistic information, professional information and body attitude variables as independent variables. A chi-square test was performed on demographic data.

The three main perceived job-related stressor factors were: working in badly administered structures (21%), being under paid (18%) and having unsatisfied relations with colleagues (16%).

The MBI subscales scores revealed a medium level of emotional exhaustion (M 17.70, SD 7.20), a high level in the low personal accomplishment (M 31.03, SD 8.04 and high level in depersonalization (M 6.17, SD 5.41).

In the account of the central role of body and the importance of the lived body in the profession of PE teachers, we studied body-related and personal body fitness perceptions in the sample, comparing these data with the MBI subscales. At the moment they answered, 11% of the teachers practiced regularly physical activity, 20% often, 31.1% sometimes, 6.7% seldom, and 7.3% never practiced. Data analysis showed how teachers regularly practicing, had lower BO levels in all MBI subscales: in the emotional exhaustion scale (F 6.95, df 3, $p < 0.001$), in personal accomplishment (F 29.51, df 3, $p < .001$), and also in depersonalisation (F 40.98, df 3, $p < 0.001$).

Comparing our results to those concerning other curriculum teachers, we found that PE teachers felt less fulfilled in their job, showing lower scorings in low personal accomplishment (31.03 vs. 35.71), and also in emotional exhaustion (17,68 vs. 19,84), they also showed a higher rating in depersonalisation (6.16 vs. 3.80).

COMPARATIVE ANALYSIS OF RECEIVING AND PASSING THE BALL IN THE EUROPEAN FOOTBALL CHAMPIONSHIPS SWEDEN 1992 AND BELGIUM–NETHERLANDS 2000

Mavrek, S., Jerkovic, S., Jerkovic, M.

Karl-Franz-University Graz - Austria, University of Zagreb - Croatia, Croatia

The aim of this research was to compare the effects of successful or unsuccessful receiving and passing the ball in the results of the matches of the European Football Championships 1992 and 2000.

The sample consisted of totally eight matches (final match, semi-final matches, quarter-final matches and one randomly selected match from the group) in each Championship. The group of predictor variables included successful and unsuccessful passing the ball (SPB and UPB), successful and unsuccessful receiving the ball by leg (SRL and URL) and successful and unsuccessful receiving the ball by trunk (SRT and URT). Criterion variables were: the result of match (RM), the number of scored goals (SG) and the number of received goals (RG). Differences between two groups (variables from Championships 1992 and 2000) were examined by discriminant analysis.

Results

Correlation between predictor variables in European Football Championship Sweden 1992 showed high positive correlation (.97) between variables SPB and SRL, high correlation (.64) between variables UPB and SRT and relative high correlation (.50) between variables UPB and URL (at $p<.05$). Distinctive negative correlation between predictor variable URL and criterion variable RM was confirmed by Backward method of regression analysis (URLBeta=-.60).

Multiple regression analysis showed ($R=.751$, $F=1.949$, $p=.17$) that the group of predictor variables in European Football Championship Belgium-Netherlands 2000 has not statistically significant influence on variable RM because $p>.05$. However, distinctive negative correlation between predictor variable UPB and criterion variable RM (UPBBeta=-.60) was confirmed by simple regression analysis between these two variables ($R=-.59$, $F=7.82$, $p=.014$). Variable UPB has statistically significant influence on variable RM because $p=.014$ ($p<.05$).

Discriminant analysis showed that there are differences between two groups of variables because Chi-square is 25.900, $p=.0021$. Group centroids have the following values: G1=1.285 (Euro 2000) and G2=-1.285 (Euro 1992). Therefore, group G1 is better than group G2. Within-groups correlations between discriminating variables and discriminant function showed that variable URL (.768) differs these two Championships the most, while variables SRL (.212), SRT (.262) and SPB (.222) also differ two Championships, but not so much.

Conclusions

Comparing the frequencies of variables of these two Championships, there is a bigger number of SPB, UPB, SRL and URL in 2000. Therefore, tempo of the game in 8 years is increased. If we look the frequencies of variables SPB and SRL in 4 finalists of both Championships, we can notice that France was champion with the highest frequencies while Danemark became champion with the lowest frequencies. That means that these two representations have had two different styles of the game. Overall conclusion is that better result in the match (win or draw) is achieved by reduction of mistakes in receiving and passing the ball.

THE LIMITS OF SCIENCE: A JUSTIFICATION FOR THE ART OF COACHING

Freeman, W.H.

Campbell University, United States

Often we speak of coaching as a "scientific" process, implying that it is so well understood that any well-trained coach would likely produce the same training plan as any other coach. But is coaching today really primarily a science–or is it still in large part an "art", with the coach blending scientific knowledge, practical experience and more than a bit of personal alchemy to produce an effective training plan? This paper discusses two questions: (1) Do we really understand the effects of training on the human body so completely, including the

most effective mechanisms of change; and (2) is coaching success dominantly based on an advanced knowledge of sport science? It is clear that (1) there is still much to learn about the complex interrelationships of training and performance factors as they act upon the biological ecosystem we call the "athlete"–both in our knowledge of mass outcomes and in the variables within any individual that may differ from group data, and (2) the most successful coaches often are not the most highly trained sport scientists. Just as the elite medical researcher rarely performs the most intricate surgery, the advanced sport scientist rarely coaches the talented athletes who come to dominate their sports. As academics and researchers we need to recognize that as the competition of a lifetime approaches, it is that mysterious "art" that often makes the final difference in fitting together the pieces of the next great champion's puzzle.

ACUTE PASSIVE STRETCHING ALTERS MUSCULAR STIFFNESS BUT NOT THE ELECTROMECHANICAL COUPLING IN HUMAN CALF MUSCLES

Cè, E. 1, Alfieri, P. 2, Paracchino, E. 2, Roione, G.C. 2, Veicsteinas, A. 1, Esposito, F. 1

1 Institute of Physical Exercise, Health and Sport; 2 Faculty of Sport Science, University of Milan, Italy

Maximum force and power output are significantly impaired by passive muscle stretching. Structural changes of the stretched muscles and a reduction of neuromuscular activation have been suggested to be responsible for such a decrease in maximum force. Thus, the study was aimed to verify whether stretching-induced changes in muscle activity were related to alterations in the electromechanical coupling and/or in muscle stiffness. To do this, 17 male active subjects (22 ± 1 yrs, body mass 75 ± 2 kg, stature 179 ± 2 cm; mean ± SE) underwent 3 tetanic electrical stimulation (50 Hz) at maximal intensity (maximal M wave +10%) before and after a bout of passive stretching of calf muscles. During contractions, surface EMG and mechanomyogram (MMG) were simultaneously recorded from the belly of the medial gastrocnemius muscle, together with the force (F) signal. Delays between the onset of EMG and MMG (delta t EMG-MMG), EMG and F (delta t EMG-F) and MMG and F (delta t MMG-F), as well as peak F were then calculated. After passive stretching, peak F decreased by 32.6±5 % ($p<0.05$). Delta t EMG-F and delta t MMG-F significantly increased by 16.7±4 % and 13.9±4 %, respectively. No differences were found in delta t EMG-MMG. From these results it appears that acute passive muscle stretching induced a depression in maximum stimulated force, suggesting changes in muscle contraction behaviour. These changes did not affect the electromechanical coupling at the muscle level, as indicated by a similar delta t EMG-MMG after stretching. However, lengthening of the delta t EMG-F and delta t MMG-F may suggest stretching-induced reduction in muscle stiffness.

LONGITUDINAL STUDY 'DOPING FREE SPORT': STEROID PROFILES IN URINE

Schweizer, C., Sottas, P.-E., Saugy, M., Kamber, M.

Laboratoire Suisse d'Analyse du Dopage, Switzerland

Introduction

The measurement and interpretation of an athlete's urinary steroid profile is important in the fight against doping in sport. Changes of this profile may be due to biological variations but also due to the use of doping. The aim of this study was to illustrate that top level performance could be reached without doping and to evaluate the biological variation of the steroid profile over time. In a joint project, the Federal Office of Sports, the Swiss Anti-Doping Commission and the Swiss Laboratory for Doping Analysis performed a longitudinal study with 20 top-level athletes (19-32 years) from five different endurance sports (athletics, triathlon, cycling, cross-country skiing and orienteering).

Study design and methods

During the study, all athletes had to submit to two kinds of urine samples: one at pre-announced dates during medical check-ups within and off season (5 to 8 times) and one at unannounced out of competition doping controls (7 to 12 times). All urines were analysed for prohibited substances according to the doping list of the World Anti-Doping Agency. In addition, the steroid profiles were evaluated as well: among others the concentrations of testosterone (T), epitestosterone (E), androsterone (A), etiocholanolone (Etio) as well as different ratios (T/E, A/T, A/Etio) were measured. An elevated T/E ratio may be an indicator for the use of a prohibited substance. In these cases, some complementary investigations are required to find if the elevated ratio is due to doping.

Results

There was no difference in the steroid profiles between announced and unannounced controls. In men, the inter-individual variation of the T/E ratio was between 14 and 38%: The lower were the concentrations of T and E, the higher the variations. In women, the variations were generally higher (up to 66%) due to the lower steroid concentrations. there was no indication for doping use in any of the samples analysed.

Discussion

To our knowledge this is the first time that such a homogenous group of athletes (top level endurance athletes) was followed up so closely over a period of two competition and two training seasons. The data will serve as a basis to evaluate steroid profiles of other athletes for possible doping use. However, due to inter-individual variations of steroid profiles it is advisable to collect individual reference values from longitudinal studies for top level athletes.

THE EFFECT OF AN 80-MINUTE INTERMITTENT RUNNING PROTOCOL ON HAMSTRINGS STRENGTH: IMPLICATIONS FOR THE INCREASED SUSCEPTIBILITY TO HAMSTRINGS INJURY

Andrews, W., Hori, N., Dawson, B., Newton, R.

Edith Cowan University, Australia

Epidemiological research has shown a possible relationship with fatigue and hamstrings injury (Woods et al., 2005). There has also been evidence of increased susceptibility to hamstrings injury due to reduced hamstrings torque production and an imbalance between the hamstrings and quadriceps muscle groups (Orchard et al., 1997). However there is no research which has investigated the effects of a long-duration running protocol on hamstrings and quadriceps torque relationship. PURPOSE: To examine the effects of an 80-minute intermittent running protocol (IRP) on concentric hamstrings (Hc), concentric quadriceps (Qc) and eccentric hamstrings (He) muscle torque. The conventional (HcQc) and functional (HeQc) hamstrings: quadriceps torque ratios were also examined. METHODS: The dominant and non dominant kicking legs of twenty two semi-professional Australian Rules Football players were examined before (baseline) and immediately following (post) an 80-minute IRP on a Woodway® non-motorised treadmill. Each subject completed maximal Hc, Qc and He muscle contractions on a Biodex isokinetic dynamometer at an angular velocity of 60°.sec-1 at baseline and post the 80-minute IRP. The IRP was divided into 4 x 20-minute quarters consisting of five MS efforts, sixteen fast runs (65% of MS), thirty two jogs (35% of MS) and thirty two walks (20% of MS) per quarter. RESULTS: There was a decrease in He torque in the dominant (pre, 212.64±55.15Nm; post, 190.77±54.28Nm, $p<0.01$) and non dominant (pre, 206.47±62.36Nm; post, 190.18±58.43Nm, $p<0.01$) legs. There was no decrease ($p>0.05$) in Hc and Qc torque in either leg following the IRP. The HeQc ratio decreased in the dominant (pre, 0.89±0.25; post, 0.82±0.25, $p<0.01$) and non dominant (pre, 0.93±0.26; post, 0.87±0.25, $p<0.05$) legs, however there was no decrease ($p>0.05$) in the HcQc ratio for either leg following the IRP. DISCUSSION: Maximal He torque is reduced following an 80-minute IRP on a non-motorised treadmill. There appears to be no detrimental effect on maximal Hc and Qc torque production. There is a reduction in the functional HeQc torque ratio however there is no effect on the conventional HcQc torque ratio. CONCLUSION: The duration of the intermittent running protocol used in this study is similar to many team game sports. The intermittent running protocol was enough to reduce eccentric torque production, which may provide an insight into hamstrings muscle function and increased risk of injury following games of longer duration.

THE RELATIONSHIP BETWEEN HEART RATE RECOVERY AND POWER OUTPUT DURING REPEATED BOUTS OF SPRINT EXERCISE IN FEMALES

Papaspyrou, A., Bogdanis, G.C., Evangelidis, P., Theos, A., Maridaki, M.

University of Athens, Greece

Introduction

Heart rate (HR) recovery after high intensity exercise depends on athlete's training level (Darr et al., 1988) and may influence the ability to perform in repeated bouts of high intensity. The purpose of the present study was to examine whether recovery of power output during repeated sprints on a cycle ergometer are related with heart rate recovery parameters in females.

Methods

Seventeen female games players (age: 21.0±0.9 years, mass: 75.1±3.7 kg, lean leg volume- LLV: 7.4 ± 0.3 L) performed 4-5 maximal 6s sprints on a Monark cycle ergometer against different loads, with full recovery. Instantaneous power was obtained by taking into account the changes in kinetic energy of the flywheel and optimal force (Fopt) was calculated (Arsac et al., 1996). On another occasion, participants performed a graded test on the treadmill until exhaustion (11.9±1.3 min), where maximal oxygen uptake (VO2max) was determined. On a third occasion participants performed seven 6 s sprints separated by 24 s of passive recovery, against a resistance equal to 50% of Fopt. Peak (PPO) and mean power output (MPO) were recorded for each sprint and average MPO for the seven sprints per LLV (AMPO/LLV) was calculated. HR was recorded during and for 5 min into recovery and the time constant (HRτ) and amplitude (A) of HR recovery was calculated.

Results

VO2max was 42.1 ± 1.2 ml/kg/min and peak HR at the end of the sprint test was 172 ± 2 b/min. PPO and MPO in the first sprint was 821 ± 26 W and 649 ± 22 W, respectively. PPO and MPO expressed per LLV were 111.8 ± 3.3 W/L and 88.1±2.5W/L. The percent drop in PPO and MPO during the seven sprints was 17.3 ± 1.8 % and 19.2 ± 1.6 %. HRτ was 88 ± 6 s while A was 90 ± 2 b/min. AMPO/LLV was 77.9±1.7 W/L and was positively correlated to HRτ ($r=0.59$, $p<0.01$). The percent drop in PPO and MPO was not correlated with VO2max or with HRτ.

Discussion

The relationship between AMPO/LLV and HRτ it may indicate that HR recovery is related to the anaerobic capacity.The lack of a relationship between drop in power output and VO2max and HRτ would suggest that these parameters do not significantly influence the process of recovery during repeated sprint exercise.

EFFECTS OF LUNG VOLUMES ON BREATH-HOLD DIVING DEPTH

Ferretti, G.

CMU, Université de Genève, Switzerland, and Université de Brescia, Italy, Switzerland

The speed that a human can attain is the ratio of the metabolic power to the energy cost of the movement (C), so that the distance covered is the ratio of the available metabolic energy (E) to C. In breath-hold diving, this means that the maximal diving depth (d) is directly proportional to the E stored by the diver and inversely proportional to the C of diving. In water, C is the ratio of the drag of water (D) to the mechanical efficiency of diving (h), so that d= h E/D. A reduction of C was pursued either by reducing D or by increasing h. The former was achieved by improving the hydrodynamics of diving, the latter by improving the diving technique. Concerning E, it is the sum

of the energy provided by aerobic (EO2), anaerobic lactic (ELa) and anaerobic alactic (EPC) metabolisms. ELa and EPC can be set invariant, as they are imposed by maximal blood lactate concentration (Lab, say 15 mM) and by muscle phosphocreatine concentration (PC, 20 mM). In turn, EO2 = ELO2 + EBO2 + EtO2, where suffixes L, B and t designate the O2 stores in lungs, blood and tissues, respectively. EBO2 depends on haemoglobin concentration ([Hb]), EtO2 on myoglobin concentration, that are practically invariant. So EO2 = ELO2 + K, where K is the energy provided by other sources than lung O2 stores. Since the energy equivalent of O2 is a constant depending on the respiratory quotient, the last equation implies that EO2, and thus d, are linear functions of lung O2 volume at the dive's start. We thus expect extreme divers to have very large total lung capacity (TLC) values. This is so for Korean diving women, whose TLC is low (< 5 L). The TLC of Enzo Maiorca, who first dived to 100 m under controlled conditions, was 7.8 L, at the uppermost limit of normal population. Bob Croft, however, who set a world record to 73 m in 1968, had a TLC of 9.1 L. TLC values above 9 L in elite breath-hold divers are a common finding nowadays. At least 15 values above 9 L, and a couple above 10 L, can be reckoned in the literature. Several divers also practise oropharyngeal breathing before diving, which increases the TLC by further 1.5 – 2.0 L. This data support the hypothesis put forward above. In a man with a body mass of 70 kg, a muscle mass of 20 kg, a TLC of 7 L, a blood volume of 5 L, a [Hb] of 150 g/L, a Lab of 15 mM and a PC of 20 mM, who dives close to TLC, the E at the dive's start, in O2 equivalents, would be 6.76 L, of which 1.20 L provided by ELO2. In an extreme diver with the same characteristics as that man, except that his TLC is 10 L instead of 7 L, E would be 7.27 L, of which 1.71 L provided by ELO2. This difference may appear small, yet calculation of the energy balance of deep free dives shows that the C of diving is very low, so that the rate of energy expenditure is similar to that of a 50 W exercise on a bike. If this is so, a 0.5 L increase in ELO2 would imply a 43 m increase in depth. Having large lung volumes is indeed an advantage in deep breath-hold diving.

THE INFLUENCE OF A CARBOHYDRATE-ELECTROLYTE SOLUTION ON TREADMILL RUNNING PERFORMANCE

Gant, N., Williams, C., Backhouse, S.H.

Loughborough University, United Kingdom

The ingestion of carbohydrate immediately before and during exercise lasting less than 1 hour may enhance performance. These benefits may occur independently of the status of carbohydrate stores, which are unlikely to become depleted over this relatively short duration. One possibility is that carbohydrate favourably influences the central nervous system and enhances voluntary workrate. This study examines the influence of a carbohydrate-electrolyte solution (CES) on running performance and subjective experiences using a novel treadmill running performance test.

Eight well trained male runners performed a 45 min treadmill running protocol on 5 separate occasions. Participants ingested a volume of fluid equivalent to 7 ml∙kg-1 body mass (BM) 15 min before exercise and a further 2.5 ml∙kg BM-1 every 10 min during exercise. After 3 familiarisation trials during which the reliability of the protocol was assessed, flavoured water was substituted for either a 6% CES or a taste matched placebo (PLA) in a double blind fashion. The treadmill running protocol consisted of 15 min running at a speed equivalent to 70% VO2 max followed by a 30 min performance test. Throughout the performance test an ultrasonic radar modulator altered the speed of the treadmill belt automatically according to changes in participants' actual running velocity. Time remaining was the only indicator of performance available to participants during the test and treadmill belt velocity was recorded continuously.

A suitable period of familiarisation with the experimental protocol is reflected in the lack of statistical bias between the final 2 familiarisation trials. Total distance covered during the performance test in these trials was 7.56 ± 0.94 km and 7.51 ± 0.98 km respectively. The intraclass correlation coefficient between trials was 0.99 and the coefficient of variation was 2.5%. When manipulating the test solution no statistical differences were detected between trials in the total distance covered during the performance test (CES 7.34 ± 0.62 km vs. PLA 7.26 ± 0.53 km). However, the distance covered during the last 5 min of exercise was significantly greater during the CES trial (CES 1.22 ± 0.11 km vs. PLA 1.17 ± 0.12 km; $P<0.05$) and there was a trend toward a greater variability in treadmill speed over this period. Subjective rating of perceived exertion was similar between trials, but felt arousal was significantly higher during the last 10 min of exercise.

The method used to self-select running speed during this treadmill performance protocol results in an acceptable level of agreement in the distance covered between trials. These results suggest that the ingestion of a CES solution providing approximately 1 g∙kg BM∙h-1 of carbohydrate enhances running performance toward the later stages of a 45 min run. This faster and more variable running pace coincides with a higher level of perceived activation which is subjective indicator of the readiness to perform exercise.

IMPACT OF DAILY WHOLE BODY VIBRATION TRAINING (WVT) ON MUSCLE BLOOD FLOW AND METABOLISM DURING 14 DAYS OF BED REST

Liphardt, A.M., Adams, F., Gottschalk, S., Baecker, N., Frings, P., Heer, M., Luft, F.C., Jordan, J., Boschmann, M.

DLR-Institute of Aerospace Medicine, Germany

Prolonged microgravity (µG) causes loss of bone mass and reduction in skeletal muscle mass and performance. Bed rest in 6°-head-down-tilt (HDT) is a well-established model to simulate some of the physiological effects astronauts experience in µG. Similar to µG, immobilization in 6°-HDT bed rest leads to a lack of mechanical loading in the lower extremities. Although the negative effects on the muscular-skeletal system are known, training methods during space flight still need optimization. Daily WVT might prevent these processes. Because muscle performance and metabolism are strongly associated, we studied the effect of WVT on muscle blood flow and metabolism during 14 days of HDT by micro dialysis.

Eight healthy male, non-obese subjects performed 14-days of bed rest in 6°-HDT in the clinical research facility at DLR-Institute of Aerospace Medicine. The study was carried out as a cross-over-design, consisting of two phases, each lasting 23 days. Each subject received WVT in one phase and a control intervention in the other phase. Study phases were divided into three periods: a 4-day adaptation period, a 14-day intervention period in 6°- HDT bed rest and a 5-day recovery period. During the intervention period, all activities including eating, showering and weighing were carried out in the 6°-HDT position. Study phases were identical with respect to environmental conditions, study protocol and diet. The WVT consisted of 5 x 1 minute whole body vibration twice daily on the Galileo 900 vibration plate (20 Hz / 2-4 mm). At the day before entry into HDT (day -1) and day 13 of HDT, a microdialysis probe was inserted into the right quadriceps femoris muscle (vastus lateralis) and perfused with Ringer's solution (+50 mM EtOH) and increasing doses of isoproterenol (ISO, 0, 0.01, 0.1, 1 and 10 µM). Changes in muscle blood flow were monitored by the ethanol dilution technique.

At day -1, ethanol ratio decreased dose-dependently from 0.11±0.01 to 0.06±0.02 whereas dialysate glucose remained unchanged during perfusion with ISO. At the same time, dialysate lactate increased from 1.12±0.08 to 2.66±0.15 mM and dialysate pyruvate from 0.014±0.003 to 0.100±0.008 mM. Dialysate glycerol did not change significantly. At day 13 of HDT, no significant differences for both baseline and ISO induced changes in ethanol ratio and dialysate metabolite concentrations were observed. If subjects received WVT during HDT, baseline ethanol ratio increased to 0.18±0.03 ($p<0.01$, vs. HDT). However, baseline dialysate metabolite concentrations and

relative changes in ethanol ratio and dialysate metabolite concentrations during perfusion with ISO remained unaffected by additional WVT.

After 13 days of HDT, baseline and ISO induced changes in muscle blood flow and metabolism remain almost unchanged. However, additional WVT reduces significantly baseline perfusion. But, this reduced tissue perfusion is not limiting for both resting and ISO stimulated muscle metabolism.

THE SYSTOLIC TIME IS SHORTENED MORE THAN CARDIAC CYCLE ABOVE CATECHOLAMINE THRESHOLD DURING GRADED EXERCISE

Tanaka, H., Matsuda, T., Kumahara, H., Kiyonaga, A., Shindo, M.

Laboratory of Exercise Physiology, Japan

Introduction

The heart sound is a convenient and noninvasive technique for assessing cardiac performance. This may provide the valuable information regarding exercise stress. Obara et al. (2005) reported that the amplitude of the first heart sound (S1) during exercise accelerates above the lactate threshold. The systolic time, which can be determined by the appearance time of S1 and that of the second heart sound, may vary with the change in a volume of venous return, cardiac contractility and total peripheral resistance. Most of the parameters, which influence the systolic time, are affected by the sympathetic nerve activities. The purpose of this study was to investigate whether the systolic time during exercise could be applied for an alternative index of the catecholamine threshold.

Methods

Nine males, aged 25+/-3 years and 23.6+/-3.7 kg/m2 of body mass index, underwent a submaximal graded cycle ergometer test. The work rate started at 15 watts and then increased at 15 watts every 2 minutes until the heart rate reached 85% of its maximum expected for the age. The heart sound was monitored beat-by-beat throughout the exercise session. Blood from the antecubital vein was sampled and the plasma epinephrine was determined every 2 minutes during the graded exercise test. The plasma epinephrine concentrations were plotted against the work rates. The epinephrine threshold (ET) was determined as the initial break point for plasma epinephrine. The systolic time intervals were calculated for 6 consecutive beats. The correlation coefficients and regression line below and above the ET was individually calculated between the systolic time and the cardiac cycle.

Results

The average of ET was 86.6+/-19.6 watts. The systolic time shortened above the ET in all subjects, thus resulting in the existence of a break point of the systolic time against cardiac cycle. The slope of regression line in the systolic time against the cardiac cycle was found to be steeper above the ET in all cases. The value of slope of regression equation above ET was doubled on average (0.19+/-0.04 in below ET vs. 0.42+/-0.05 in above ET, $p<0.001$).

Discussion/Conclusion

These results suggested that the systolic time starts to shorten sharply above the epinephrine threshold, since the augmentative effects of the sympathetic nerve activity may accelerate the cardiac contractility. Based on the above findings, the break point of systolic time could provide us with valuable information regarding exercise stress.

ELECTROMYOGRAPHIC ANALYSIS OF BICEPS BRACHII AND VASTUS LATERALIS MUSCLE DURING AN AEROBIC AND AN ANAEROBIC CYCLING TEST IN SPRINTERS AND LONG-DISTANCE RUNNERS

Tavares, P., Parada, J., Anjos, I., Ribeiro, G., Rosado, M.F., Santos, A., Fontes Ribeiro, C.A.

Faculty of Sport Science and Physical Education, Portugal

In day life and sports we move the arms rhythmically during walking or cycling. However, in cycling laboratory tests the arms neuronal activity is usually neglected, since the majority of the studies focus the leg, in special the Vastus lateralis muscle. Is our goal to do a comparative study between the arm (Biceps brachii) and leg (Vastus lateralis) neuroactivity in two cycling maximal tests.

Male volunteers participated in this study: sprint athletes (SA), endurance athletes (EA) and age and sex-matched sedentary controls (SC). All the subjects performed an aerobic maximal graded exercise test in cycle ergometer (Monark 824E), consisting in a constant pedal frequency (60 rpm) starting with 50 W workload and increasing 25 W every 2 minutes until fatigue. The Wingate test (as a maximal anaerobic test) consists in pedalling for 30 seconds at maximal power.

During the tests the surface-EMG parameters (RMS and MPF-mean power frequency) were evaluated (MegaWin® ME3000 device) in the Biceps brachii and Vastus lateralis of each subject. In order to compare individual results the RMS-EMG values were normalized by dividing the obtained values by the crural and bicipital perimeters of each subject. Results were analysed according to power and time.

Different EMG profiles were found depending on the analysed muscle and exercise type. Concerning the Biceps brachii muscle we observed different behaviours in MPF and RMS depending on the exercise performed. Thus, in the aerobic test there was a higher MPF values for SC and the lowest to EA, decreasing in both groups along the test. The SA presented a constant MPF in the first part of the test followed by a sudden fall in the last part. The RMS showed higher values for EA and a progressive increase during the test in all subjects. The SA and SC groups had lower EMG amplitude. In EA the RMS profile was similar but reverse (increasing) to the observed MPF. In all the cases, the EMG parameters indicated fatigue. The anaerobic test (for all groups) showed a constant value of MPF, but significant lower when compared to the aerobic test. The RMS values decreased during the anaerobic test, but presented absolute values about ten times higher than in the aerobic test.

The Vastus lateralis muscle also showed differences depending on the performed test. Thus, in the graded aerobic test the SA presented a decrease in MPF values that were constant for EA and SC. The corresponding RMS values increased during the test, being the SA the group that present the lowest values. A positive correlation with power was found. In the anaerobic test the MPF values decrease for EA and remain constant for the other subjects. However, RMS remains constant for all the studied groups. The differences found concerning EMG parameters may be related with the proportion of fiber types recruited.

This work was supported by a PAFID programme from the Portuguese Sport Institute and by FCT (Fundação para a Ciência e Tecnologia), Portugal.

EFFECTS OF ALTITUDE TRAINING ON VASCULOGENIC/ANGIOGENIC GROWTH FACTORS

de Marées, M., Wahl, P., Knuth, S., Buitrago, S., Suhr, F., Tandi, S., Achtzehn, S., Mester, J.

German Sport University Cologne, Germany

Effects of altitude training on vasculogenic/angiogenic growth factors

Markus de Marées, P. Wahl, S. Knuth, S. Buitrago, F. Suhr, S. Tandi, S. Achtzehn, J. Mester

Institute of Training Science and Sport Informatics, German Sport University Cologne, Germany

Introduction

In competitive sports high altitude training is used to increase EPO concentrations and erythrocytes in order to improve O2-transport capacity in blood. Hypoxia and EPO, however, seem to be a major stimulus for angiogenesis/vasculogenesis as well1. Like EPO, vascular growths factors (VEGF), are also controlled by HIF-1α and may be induced by hypoxia2.

The aim of this study hence was to realise a protocol with a large homogenous group of highly-trained athletes where the control group trains at sea level and the experimental group under natural hypoxic conditions. The effects of hypoxia and sea level training on angiogenic/vasculogenic growth factors were measured.

Methods

Thirty-two highly-trained junior swimmers (18 subjects in experimental group, 14 subjects in control group) participated in the study. The athletes of the altitude group stayed for three weeks in a training camp at an altitude of 2300 m. During the baseline two incremental tests on a cycle ergometer under sea level conditions and under artificial hypoxic conditions with 2 blood samples (before and after, respectively) were carried out. The same protocol was carried out in both groups. In first and second week after the training period the athletes realized two post-investigation tests. Before and after the training phase swimming competitions were carried out.

Results

Significant changes of EPO, VEGF and IGF-1 were measured for the high altitude group although a highly individual component could be proven. As expected, VEGF and EPO both regulated by HIF-1α increased only in high altitude group. The breakdown of IGF-1 in the high altitude group indicated a more exhaustive training compared to sea level. Endostatin showed a significant increase at the first day of hypoxic exposure. During the hypoxic intervention endostatin then returned to nearly base-line levels. Whether that is a general trend for adaptation or can stronger reactions for the mentioned values caused by highly physically activity be displayed (data not shown yet)?

The results in general showed a clear influence of hypoxic conditions also with respect to performance parameters such as anaerobic threshold compared to the control group.

THE INFLUENCE OF RAMP RATE ON THE VO2-WORK RATE RELATIONSHIP IN ROWING

Draper, S., Townsend, M., Potter, C., Samuel, K.

University of Gloucestershire, United Kingdom

The relationship between the rate of oxygen uptake (VO2) and work-rate (W-R) is a concept that is central to exercise physiology. Whilst this relationship was traditionally viewed as linear, recent findings have demonstrated non-linearity in both cycling (Zoladz et al., 1995) and running (Jones et al. 1999). This non-linearity is however often masked by the use of fast incremental protocols that do not allow the slow component of VO2 to fully develop. Hansen et al. (1988) demonstrated in cycling that when a fast ramp rate was used the slope of the VO2 – W-R relationship was unchanged across exercise intensities. However, when a slower ramp rate was used this slope increased at higher W-Rs. Such a response to incremental exercise has never been investigated in rowing exercise. The purpose of the present study was to investigate the influence of ramp-rate on the VO2 – W-R relationship in rowing.

Ten physically active male subjects (mean ± SD); age 21 ± 1 years, height 1.79 ± .04 m and mass 82.2 ± 11.2 kg volunteered to take part in the study. Each preformed two incremental tests to exhaustion on a rowing ergometer (Concept II model C, Nottingham UK). One test was a fast incrementing (25 W·min-1) and the other slow (10 W·min-1); each was performed on separate days and the order of theses tests was counterbalanced. Power and VO2 were measured throughout each test on a stroke-by-stroke and breath-by breath (K42b, Cosmed , Italy) basis respectively. Ventilatory threshold (VT) and peak VO2 (VO2peak) were calculated for each test and data were split both at the half time for each test and at VT to analyse the change in slope.

Neither VO2 at VT nor VO2peak was affected by ramp rate ($P = 0.899$ and 0.718 respectively) but power at VT was significantly lower in the slow ramp test ($P = 0.029$). The slow ramp test demonstrated an increased slope when data were split at VT and any visual VO2 plateau was removed ($P = 0.041$). The fast ramp test showed a decreased slope when data were split by both time ($P = 0.036$) and at VT ($P = 0.026$).

The results supported previous research in cycling as an increased slope was identified above VT in a slow incremental test showing that the VO2 – W-R relationship is not linear in rowing. The mechanisms responsible for the decreased slope above VT in the fast test are unclear and warrant further investigation. For the assessment of rowers, the ramp rate does not affect VO2peak but does alter the W-R at VT.

ANGIOTENSIN I CONVERTING ENZYME GENE POLYMORPHISM AND PHYSICAL TRAINABILITY IN ELDERLY: AN ELECTROCARDIOLOGICAL APPROACH

Tobina, T., Mori, Y., Akagi, Y., Doi, Y., Ishii, K., Chiba, H., Shindo, M., Kiyonaga, A., Tanaka, H.

Fukuoka University, Japan

Introduction

It is established that inter individual differences exists in exercise effects and a specific genetic factor was behind that. The well known genotype influence human physical performance and trainability is angiotensin I converting enzyme (ACE) gene insertion/deletion (I/D) polymorphism. ACE is a key enzyme to produce angiotensin II (Ang II) and it is known that individual with the D allele has higher ACE activity in serum and tissue. The Ang II stimulates cell growth, resulting greater exercise induced left ventricular hypertrophy (LVH) in D allele. Some studies confirmed the phenomenon, but it is unclear whether D allele contributes improvement of cardiac function to exercise training. It is most likely that morphological cardiac changes accompany electrophysiological adaptation. In electrocardiological approach, Schuit et al reported that QT interval corrected by heart rate (QTc), which prolongation is prognostic factor for arrhythmia and sudden death, is decreased by exercise training. Furthermore, some studies suggested that there is association between ACE gene I/D polymorphism and QTc prolongation. In the present study, we investigated the association between ACE gene I/D polymorphism and physical performance and cardiac adaptation in elderly.

Methond

One hundred thirty five elderly (51 men and 84 women) participated in this study. Genomic DNA was obtained from peripheral blood and ACE gene I/D polymorphism were decided by PCR method. All subjects performed incremental exercise test on bench stepping and lactate threshold (LT) was determined for aerobic capacity and training intensity. The participants were instructed to do bench step exercise for 140min/week for 12weeks. A 12-lead resting electrocardiogram (ECG) was recorded. QT interval corrected by Bazzet formula.

Results

The distribution of ACE genotype in I/I, I/D and DD was 44 (32.6%), 73 (54.1%) and 18 (13.3%), respectively. Characteristics and training time were similar among the genotypes. The baseline of aerobic capacity was higher in I/I than that in I/D, and QTc was longer in I/D than that in I/I only the women but not in the men. Training responses were adjusted by age, training time and the baseline. The aerobic capacity was improved in all genotypes. The increase in aerobic capacity in I/D was greater compared with that of I/I in women (0.98±0.79 vs 0.43±0.81 mets: Mean±SD). QTc was not decreased by exercise training in men and women. That is tendency to decrease in QTc only D/D women (426±19 vs 418±15 msec). Furthermore, training response of QTc was significantly different in D/D vs I/I and I/D vs I/I (D/D: -7.8±12.3, I/D: -2.7±17.3 and I/I: 9.8±17.3 msec, respectively)in women. Conclusion: The D allele of ACE gene I/D polymorphism may contribute cardiac function improvement to exercise in women.

EFFECTS OF PROLONGED BED REST ON THE CARDIOPULMONARY RESPONSE TO POSTURAL CHANGES IN HUMANS

Tam, E. 1+2, Fagoni, N. 3, Azabji-Kenfack, M. 1, Cautero, M. 2, Lador, F. 1, Moia, C. 1, Capelli, C. 2, Ferretti, G. 1+3

1 CMU, Genève, CH, 2 Uni Udine, IT, 3 Uni Brescia, IT, Switzerland

In order to gain a better understanding of the cardio-pulmonary impairment induced by prolonged bed rest, we measured steady-state oxygen uptake (V'O2) and carbon dioxide output (V'CO2), by Grønlund's algorithm on a breath-by-breath basis, cardiac output (Q'), by open circuit acetylene washout, heart rate (HR), by electrocardiography, and mean arterial pressure (MAP), by fingertip plethysmography, on 18 male subjects (33.1 years ± 0.9; 71.1 kg ± 1.1; 1.75 m ± 0.01) before (BB) and after (AB) 90 days of head down tilt bed rest, in the following conditions : upright and supine posture, both at rest and at the 50 W exercise. The stroke volume (SV) was calculated as the ratio of Q' to HR. The total peripheral resistance (TPR) was calculated as the ratio of MAP to Q'. V'O2 was lower ($p<0.01$) supine than upright (0.43 l/min vs 0.52 l/min at rest; 1.06 l/min vs 1.27 l/min at 50W) in BB. In AB, V'O2 was 0.81 l/min at rest and 1.61 l/min at 50W upright, whereas supine it was 0.74 l/min at rest and 1.54 l/min at 50W. All the values in AB were significantly higher than the corresponding values in BB. V'CO2 followed the same patterns as V'O2, so that the gas exchange ratio was the same in all conditions. In BB, Q' was the same supine and upright. In AB, Q' was significantly higher supine than upright at rest (6.11 l/min vs 5.40 l/min). All Q' values observed in AB were significantly higher than the corresponding values in BB (rest: 5.40 vs 4.50 upright; 6.11 vs 5.05 supine. 50 W exercise 8.26 vs 6.99 upright and 9.18 vs 7.38 supine). SV was higher supine than upright (71.2 ml vs 51.2 ml BB, 78.6 vs 55.4 ml AB at rest; 76.9 ml vs 67.2 ml BB, 87.5 ml 70.8 ml AB at 50W). HR was lower supine (70.3 bpm at rest, 95.2 at 50W) than upright (87.8 bpm at rest, 104.7 at 50 W) in BB, and was (77.3 bpm at rest, 103.9 at 50W) and (97.7 bpm at rest, 116.8 at 50 W) in AB. SV was the same in AB as in BB, whereas HR was higher in AB than in BB. MAP was lower supine than upright in AB (94.3 mmHg vs 105.4 mmHg at rest; 101.6 mmHg vs 115.4 mmHg at 50W). In supine posture, MAP was lower in AB than in BB, both at rest and at exercise. TPR was lower supine than upright in AB (17.8 mmHg*min/l vs 21.6 mmHg*min/l at rest; 12.8 mmHg*min/l vs 16 mmHg*min/l at 50W). In supine posture, TPR was lower in AB than in BB, both at rest and at exercise. These results suggest that the cardio-pulmonary system adjusts to reduced blood volume and increased venous compliance essentially by increasing HR, perhaps modulated by increase in sympathetic output tone. The HR increase is larger than the drop in SV, so that Q' is increased in AB. This is coherent with the higher V'O2 levels in AB than in BB at the same power. The V'O2 increase could be mainly due to an impairment of the motor control system after 90 days of bed rest.

SEX DIFFERENCES IN HAMSTRING/QUADRICEPS RATIO AFTER AN ISOKINETIC ENDURANCE TRIAL

De Ste Croix, M., Deighan, M.

University of Gloucestershire, United Kingdom

It is well known that the Hamstring/Quadriceps (H/Q) ratio is important for knee stability, especially at high limb velocities (Gerodimos et al. 2003). Studies have suggested that females fatigue less than males during muscular endurance tasks (Hicks et al. 2001) but there appear to be no studies that have examined sex differences in the H/Q ratio after an isokinetic fatigue task.

Twenty five subjects, consisting of 14 males (age 23.9 ± 4.5 y; mass 78.6 ± 6.9 kg; stature 1.82 ± 0.07 m) and 11 females (age 29.1 ± 6.5 y; mass 62.4 ± 8.2 kg; 1.66 ± 0.05 m), agreed to participate in the study. Gravity corrected isokinetic concentric knee extension and flexion

peak torque for the dominant limb were assessed using a calibrated Cybex 6000. After a standardised warm up subjects performed 3 maximal efforts at 1.04 and 3.14 rad.s-1, followed immediately by a 50 repetition fatigue task at 1.56 rad.s-1. Immediately after the fatigue task the subjects repeated the strength assessment at the 2 velocities. The H/Q ratio was expressed as a percentage. A sex (2) by velocity (2) by test occasion (2) Repeated Measures ANOVA was undertaken to examine sex and velocity specific differences in the H/Q ratio pre and post fatigue. Mean (± SD) values pre and post fatigue task for males were: 54% (± 11) and 62% (± 15) at 1.04 rad.s-1 and 62% (± 11) and 70% (± 13) at 3.14 rad.s-1. Females' values were 46% (± 6) and 51% (± 9) at 1.04 rad.s-1 and 53% (± 8) and 58% (± 11) at 3.14 rad.s-1. There were no interaction effects for all variables examined. However, a significant test occasion effect ($P < 0.05$) was observed with a higher ratio evident after the fatigue task for both velocities. A significant sex effect ($P < 0.05$) was also observed for both velocities with males demonstrating a higher ratio than females. A significantly higher ratio ($P < 0.05$) was evident at 3.14 compared to 1.04 rad.s-1 at both velocities. These data suggest that when the knee muscles are fatigued the H/Q ratio provides increased stability of the knee, irrespective of movement velocity. In all cases this was due to greater levels of fatigue in the quadriceps compared to the hamstrings. Males' greater ratio than females could be attributed to stronger hamstring muscles in relation to their quadriceps. To conclude, as the knee muscles fatigue there is an increase in the H/Q ratio which could reduce any potential injury risk.

WINGATE TEST: DETERMINATION OF OPTIMAL LOAD IN OLDER WOMEN

Fernández Peña, E., Ditroilo, M., Benelli, P., Centonze, D., De Lillo, F., Giacomini, F., Grassi, E., Trisolino, G., Stocchi, V.

Istituto di Ricerca sull'Attività Motoria, Università degli Studi di Urbino , Italy

The Wingate Anaerobic Test (WAnT) was introduced in the 1970s and ever since has been widely used for measuring the anaerobic power output for primarily knee extension. Athletes involved in different sports have been assessed with the WAnT (1). Modifications and adaptations of the original protocol, especially the appropriate resistance that would lead to the highest possible peak power output (PPO), have been suggested when particular populations, such as sedentary individuals and children, had to be evaluated. However, to the best of our knowledge, very few studies focused on the WAnT protocol adjustments for elderly, despite the fact that anaerobic power output is related to the ability of successfully perform daily tasks (3). Accordingly, the aim of the present study was twofold: i) identify the best ergometer resistance for older healthy women in a 6 second WAnT for achieving the maximal PPO; ii) present some normative data related to WAnT for older women.

Fourteen healthy women (age 66.14 ± 3.8 years; weight 66.21 ± 7.8 kg) volunteered and gave their written informed consent for participating in the study. They underwent a medical examination and were familiarized with a mechanically braked cycle ergometer (Monark 894E) before inclusion. The pedals were equipped with toe clips and straps. Each participant was requested to perform, in random order, three 6-second WAnTs against a resistance equivalent to 7.5%, 5% and 3.8% of body weight (BW). Since it has been shown that the PPO is typically gained in the first 5 seconds for a normal WAnT (1,2), a 6-second test was chosen. After a 5-minute warming up, they pedaled as fast as possible against the unloaded flywheel, and the resistance was applied when they reached about 100 rpm (measured by an automatic counter).

The PPO (mean±SD) for 3.8% and 5%BW was 3.97±0.65 W/kg and 4.23±0.64 W/kg respectively, which means a 6.64% higher with 5%BW. Results for PPO at 7.5%BW are not presented because most of the subjects weren't able to complete the test with such a high resistance, or performed it at a pedaling rate that was too low (<50 rpm). A paired t-test analysis showed statistical significance between the 3.8 and 5% conditions ($p<0.01$).

Nowadays the original 7.5%BW load is considered too small for testing healthy adults, and 10% and 9%BW loads are recommended respectively for adult athletes and nonathletes (1). Marsh et al. (2) used a 8.5%BW load with healthy and physically active older men in a 30-second WAnT, yielding a PPO of 10.7 W/kg. The results presented showed that older healthy women reached a higher PPO with a resistance of 5%BW when compared to a 3.8% and 7.5% during a 6-second WAT. These findings are in agreement with Slade et al. (3), who found a 3,83 W/kg PPO with a 6,7%BW in a similar population.

AN INTEGRATIVE APPROACH IN STUDYING HUMAN CARDIOVASCULAR RESPONSE TO ACUTE NORMOBARIC HYPOXIA

Nesterov, S.V.

University of Turku, Finland

Physiological responses to acute hypoxia – deficiency in the amount of oxygen delivered to the body tissues of the organism – are complex and involve a wide range of mechanisms, occurring at all levels in the body to achieve enhanced survival in hypoxic environment: from integrated systems' response to relatively self-sustained peripheral responses on molecular level. The purpose of the work was, encompassing in the one study cerebral circulation, central circulation and the control of circulation by autonomic nervous system, find out the integrative response of the cardiovascular system to severe acute hypoxia.

The study was performed on 45 practically healthy right-handed men aged 18-34 years. The hypoxic exposure consisted of 15 minutes of breathing hypoxic gas mixture (8% oxygen in nitrogen). Impedance plethysmography methods were used: rheoencephalography – to estimate cerebral blood flow, integral rheography – to estimate the stroke volume and cardiac output. Pneumotachography was used to assess the respiratory frequency, pulse oximetry – hemoglobin oxygen saturation. Autonomic nervous system influence on the heart rate was assessed with continuous wavelet transform-based analysis of heart rate variability (HRV). A part of the study was solely dedicated to evaluating the influence of respiratory frequencies (RF) on HRV. (It showed that estimation of HRV without simultaneous estimation of RF conveys a possibility of misinterpretation of results for the decreasing RF nonlinearly increases HRV not mentioning the fact that RF less than 9 per minute automatically transfers a "parasympathetic" peak into a "sympathetic" region.)

Hypoxic exposure led to the predominant reduction of HRV. It was found out that the known hypoxic reaction "sympathetic increase – parasympathetic decrease" is the most frequent but not the only possible: "both increase" (after initial drop) was a reaction, although rare, in persons with high hypoxic tolerance and "both decrease" was a sign of the bad tolerance leading to collaptoid reaction. Stroke volume always decreased under the exposure; however, cardiac output could decrease, increase or stay almost unchanged. No particu-

larly surprising results were obtained for the cerebral blood flow: it increased; however, in the left hemisphere there was a significant ($p < 0.0001$) prevalence of internal carotid artery supply over that coming from the vertebrobasilar system; in the right, this prevalence was not significant ($p = 0.09$).

Although the study showed some individuality of reactions, in general, acute hypoxia can be seen as a strong influence leading to isolation of functional systems and attracting them, through losing their homeokinetic properties, to final stability.

ANTHROPOMETRIC PROFILE OF ELITE SYNCHRONIZED SWIMMERS AGED 13-15Y

Bante, S., Bogdanis, G.C., Papaspyrou, A., Maridaki, M.

University of Athens, Greece, Greece

Introduction

Synchronized swimming is classified into a special category of sports that are collectively termed "artistic sports". In this category of sports not only the technical skills, but also the harmony in movement as well as the physical structure are very important and may influence the judge's evaluation. The purpose of the present study was to determine the anthropometric profile of synchronized swimmers aged 13-15 years, and the relationship of selected anthropometric characteristics to performance scores.

Methods

The sample consisted of 128 synchronized swimmers aged 13-15 years. These swimmers were members of 17 national teams that took part in the 15th Comen Cup 2005. Measurements included body weight, height, selected body lengths, diameters, perimeters and skinfolds, and were performed by an experienced anthropometrist using standard procedures. From these data, the Heath-Carter somatotype was determined and the percentage of body fat and lean body weight were estimated using the equations of Durnin and Rahaman. Synchronized swimmers were then divided into two subgroups, the medalists (3 top teams, n=35) and the non-medalists (n=93) and t-tests were used to compare the two subgroups. The relationship between anthropometric variables and performance scores were determined using Pearson's Correlation Coefficient.

Results

Medalist synchronized swimmers had similar height, body weight, arm length and leg length with the non medallists. However, medalists had a lower percentage of body fat (18.0 ± 0.5 vs. 19.7 ± 0.4 %, $P<0.01$) and a higher lean arm cross sectional area (43.5 ± 0.8 vs. 39.0 ± 0.6 cm2, $P<0.05$) compared to the non medalists. Low but significant correlations were found between performance scores of all swimmers and thigh length ($r=0.39$, $P<0.01$), leg length ($r=0.36$, $P<0.01$), arm length ($r=0.24$, $P<0.01$) and arm lean cross sectional area ($r=0.3$, $P<0.05$). The values for the somatotype components were 3.2 ± 0.1 - 3.2 ± 0.4 - 4.0 ± 0.1 with the ectomorphic component being predominant.

Discussion

The results of this study show that the medalist synchronized swimmers had similar body structure (height, lengths, weight) but different body composition (body fat, lean arm cross sectional area) compared with the non-medalists. However, physical characteristics of young synchronized swimmers do not seem to be related to performance in agreement with previous reports referring to senior synchronized swimmers (Poole et al. 1980, Yamamura et al. 1999).

SOLEUS TENDON TAP REFLEX ADAPTATIONS TO LOWER LIMB SUSPENSION IN HUMANS

Seynnes, O.R., Pensini, M., de Boer, M., Maganaris, C.N., Narici, M.V.

Manchester Metropolitan University, United Kingdom

Simulated and actual microgravity conditions induce a loss of muscle mass and strength (1) and, as recently reported, a reduction in tendon stiffness (2). Concomitantly, studies looking at the neuromuscular adaptations to unloading have typically reported increases in the Hoffmann (H) reflex in both humans and animals (3,4), reflecting an increase in synaptic efficiency. In accordance with these spinal adaptations, one would expect the tendon tap (T) reflex to increase in microgravity. However, since muscle spindles act in series with the tendon, an increase in tendon compliance following disuse might induce changes in stretch reflex opposite to those observed above.

In the present study, neuromuscular adaptations to 23 days of unilateral lower limb suspension (ULLS) were assessed in the soleus (SOL) and gastrocnemius lateralis (GL) muscles of 6 healthy men (aged 18 to 20 yr). Measurements were performed at baseline, at the end, and after 7 days of recovery from ULLS. Spinal reflex activity (maximal H reflex and T reflex) and maximal muscle compound action potential (M) were recorded on the SOL muscle. In order to differentiate the influences of changes in synaptic efficiency and tendon material properties, the T reflex was recorded at 4 increasing intensities of tendon tap percussion (T1, T2, T3, and T4). The highest intensity was defined as that necessary to evoke a maximal response (T4) in all subjects at baseline, while the lowest intensity corresponded to the liminal level necessary to evoke a T reflex (T1). Consistently with previous literature, maximal voluntary contraction and electromyography activity of the GL decreased by 9% ($p=0.03$) and 26% ($p=0.03$), respectively. These changes were accompanied by a gain in synaptic efficiency represented by an increased H/M ratio (+27%, $p=0.04$) and a similar trend for T4/M (+11%, $p=0.20$). However, the slope of the recruitment curves of T/M versus percussion intensity increased by 49% ($p=0.04$), indicating that at the intensities eliciting T1 and T2, the sensitivity of this response was reduced. Indeed, when the influence of spinal adaptations was by-passed by normalising the T to H, the normalised T reflex was depressed at all intensities of hammer strike. Seven days after resuming normal ambulation, H reflex decreased to its initial value. Instead, the T reflex was depressed in all subjects but one.

Taken together, these results highlight an antagonism between the influence of adaptations at the spinal and tendinous levels upon the T reflex. Most of all, they show for the first time that, during prolonged disuse, the effect of an increased tendon compliance on the T reflex is masked by an acute increase in synaptic efficiency.

THERE IS NO AN ELECTROMYOGRAPHIC THRESHOLD DURING INCREMENTAL EXERCISE IN ELDERLY SUBJECTS

Ferri, A., Adamo, S., Longaretti, M., Lanfranconi, F., Marzorati, M., Colombini, A., Grassi, B.

University of Milano-Bicocca, Italy

Introduction. During incremental cycling exercise in young (Y) people, the metabolic and ventilatory changes associated with the aerobic-anaerobic transition phase seem to be associated with muscular changes reflected by non-linear increases in surface electromyographic activity (EMG)1. The EMG threshold could be explained by an increased contribution of fast twitch motor units to maintain the required energy supply for contraction. Because of atrophy of type II fibres with age, it was hypothesised that there would not be an EMG threshold in elderly (E). It was further hypothesised that EMG and ventilatory thresholds would occur at the same time in young (Y).

Methods. 12 Y (28.2±3.2yr; mean±SD) and 12 E (78.2±3.8yr) males carried out an incremental exercise to voluntary exhaustion on a cycle ergometer. Pulmonary ventilation (VE), gas exchange (O2 uptake, VO2, and CO2 output, VCO2) and vastus lateralis (VL) EMG were recorded continuously during the test. Root mean square (RMS) and median power frequency (MDF) of the EMG signal were calculated and ventilatory threshold (VT) was determined by conventional methods2. Values obtained at exhaustion were considered "peak" values.

Results. At exhaustion, peak power (107.9±22.9 W) and VO2peak (18.8±4.4 mL kg-1 min-1) in E were about 50% lower ($p<0.001$) than in Y (243.3±42.9 W and 37.0±5.2 mL kg-1 min-1, respectively). The VT occurred at 70.6±8.3% and 62.3±13.2% of the VO2peak, and at 65.5±11.6% and 55.8±17.2% of the maximal power in E and Y, respectively. In Y, RMS values showed a non-linear increase, reflecting a breaking point, at 62.4% of the peak power, whereas in E, a significant positive linear regression ($R2=0.98$) was found. MDF values increased positively in Y from the first point to 90% of the peak power, where MDF started to decrease; in E a positive linear correlation was found throughout the incremental test. When RMS was correlated to VO2, a non-linear increase was found in Y with a break point corresponding to 78.2% of the VO2peak, whereas in E, no break point was found.

Discussion. These results suggest that elderly people show a different pattern of fibre recruitment with respect to young during incremental exercise, probably because of the preferential atrophy of fast-twitch fibres, that occurs with ageing. The presence of an EMG threshold during incremental exercise in Y is consistent with previous research, and may be due to the progressive recruitment of type II fibres. Whereas in E there was a linear relationship between RMS and VO2, in Y increases in RMS exceeded increases in VO2 after 78% of the VO2peak, indicating that RMS is not always a reliable estimate of energy expenditure during an incremental cycling exercise.

SWIMMING TRAINING, LEFT VENTRICULAR DIMENSIONS AND FUNCTION AND MAXIMAL OXIGEN UPTAKE IN YOUNG BOYS

Madeira, R., Trabulo, M., Alves, F., Gomes Pereira, J.

University Lusófona of Humanities and Technologies; Faculty of Human Kinetics, Technical University of Lisbon; British Hospital, Portugal

The purpose of this study was to determine the effect of swimming training on left ventricular (LV) cardiac morphology and function in young boys and analyse the relationship between LV dimensions/function at rest and maximal oxygen uptake (VO2max) in young swimmers. Antropometric and body composition measures, resting M–mode and Doppler echocardiography and a treadmill protocol for determination of VO2max were performed by twenty four boys separated into two groups: swimmers (SA) and control group (CG).

Two dimensionally guided M mode recordings were obtained parasternally in accordance with the recommendations of the American Society of Echocardiography; measurements of the left ventricular (LV) wall thickness and internal diameter were obtained by positioning the trackball cursor on the screen. VO2max was determined using the modified Balke treadmill protocol. The athletes were encouraged to reach maximal effort. VO2max was defined as peakVO2. All the studies were performed by the same investigator. Echocardiographic data and VO2max was expressed in absolute units and then scaled allometrically for individual differences in anthropometrical data - body mass (BM), height (H), body surface area (BSA), body fat percentage (%BF) and fat free mass (FFM). Mean values for SA were compared with those for CG using *t* tests for unpaired data. Pearson product–moment correlation coefficient was calculated to evaluate the relationships between LV dimensions and functions and VO2max. Results of all statistical testes were considered significant if $p< 0.05$. SA and CG were of similar age but different in their anthropometric and body composition characteristics. The SA group was significantly heavier, had greater BSA, owing to significantly reduced %BF ($p<0.01$) and showed greater FFM, was slightly, but not significantly, taller and had greater BMI, when compared to CG. Fifty percent of SA exhibited end–diastolic LV internal chamber dimension above normal (> 54 mm). Cardiac dimensions in both groups were within normal ranges. Absolute end–diastolic LV internal chamber dimension (LVIDd) and end–systolic LV internal chamber dimension (LVIDs) were significantly greater in SA than CG. The differences between the groups persisted after allometric scaling. CG displayed significantly greater mean values for relative end–diastolic wall thickness ($p < 0.01$) but both groups showed LV eccentric enlargement ($RWTd < 0.44$). LVM was greater in SA than in CG, after scaled by BSA-1.5. Absolute and relative LV systolic functions were significantly greater ($p < 0.01$) in SA, namely LV end–systolic volume, SV and Q as well as LV diastolic function (LV end–diastolic volume). Heart size was highly correlated with VO2max in swimmers and end–diastolic LV internal chamber dimension was the main determinant factor. Swimming training induced a typical "athlete's heart" with dominance of volume and diameter (eccentric LV hypertrophy) and mild changes in LV mass.

RELATIONSHIP BETWEEN DECAY TIME OF HEART RATE AND TIDAL VOLUME AFTER EXERCISE BY OCULOCARDIAC REFLEX

Tajima, T., Tadano, C., Yona, M., Muro, M.

Toho university school of medicine, Japan

Purpose :

Many investigators have reported that heart rate (HR) recovery after exercise is regulated by central command (CC) and arterial baroreceptor reflex. It has been suggested that the decay time of HR response is related to the exciting strength of vagal activity via CC. The HR decrease is a consequence of the oculocardiac reflex (OCR) that produces bradycardia and cardiac arrhythmias such as nodal rhythm throughout a trigeminovagal reflex.

We evaluated the change of the vagal activity after exercise when the eyeballs were pressured immediately after exercise.
Method :
Five healthy males (mean age: 30.8±8.2 yrs) took part in the incremental exercise test using a cycle ergometer. The subjects were in a supine position on the cycle ergometer and after resting for 5 minutes they proceeded with the exercise for 3 minutes. Immediately after exercise HR responses of the recovery were measured for 5 minutes with OCR and without OCR in both eyeball pressure for 10 sec at about 80mmHg. The respiratory responses, inspired (iVt) and expired tidal volumes (eVt), were measured simultaneously by breath- by-breath method. The recovery HR was calculated from R-R interval at corresponding phase of respiration. The time constant of HR recovery (T30) and the decay rate of HR recovery (DR5) was calculated form the decay time of HR response for 30 sec and for 5 sec, respectively. These indexes were defined as an index of parasympathetic activity immediately after exercise.
Results :
The T30 was compared with OCR and without OCR by pressure of the eyeballs (EP). The DR5 after exercise in EP (0.0209 HR/sec) increased more than CON (0.0073 HR/sec). However, T30 in CON (60.25sec) declined faster than in EP (67.21sec). Thereby, the relationship between DR5 in EP and T30 in CON was negative in correlation (r=0.798). However, the relationship between iVT and HR response also showed a negative correlation during EP.
Discussion/Conclusion :
Although HR recovery for 5 seconds was short, the effects of exciting vagal activity by pressuring eyeballs was reinforced. Vagal activity was excited immediately after the exercise stopped, but as time passed, OCR induced a negative feedback and then slowed down the recovery in the time between 5 seconds and approximately 2 minutes.
In conclusion, the slope of the decay time of HR for 5 seconds was affected immediately by OCR. Furthermore we suggest that OCR may repress vagal activity temporarily because it might affect iVT and take a role in respiratory drive.

DRINKING WATER AD LIBITUM DOES NOT PREVENT MASS LOSS. DOES IT PREVENT DEHYDRATION?

Golja, P. 1, Blatnik, J. 1, Mekjavic, I.B. 2
1 Nova Gorica Polytechnic, 2 Jozef Stefan Institute, 39 Jamova St., SI-1000 Ljubljana., Slovenia

Background
Guidelines for maintaining proper hydration recommend fluid intake at a level which matches sweat and urine losses (Casa, 2000; Coyle, 2004). Such guidelines are not easy to follow, as the sensation of thirst during exercise results in a water consumption lower than the concomitant sweat loss (Pitts, 1944), but the voluntary over-consumption of water may lead to hyponatraemia (Noakes, 1985). Also, in competitive long duration sports it is not practical to drink at high rates; the athletes may voluntarily risk dehydration in order to save time. No such conflict is present during non-competitive activities. The aim of the study was to assess whether and to what level dehydration occurs during moderate non-competitive activity in temperate environment with ad libitum water availability.
Methods
Sixteen subjects were weighted and then rested supine for 1 hour in a 24°C environment. Upon rest, venous blood samples were taken in supine position, and urine samples were obtained. The subjects then walked outdoors for 12.5 km at an average walking speed of 5.5 km/h. During the walk, eight subjects drank water ad libitum (NH) and the other eight were restricted from drinking (DH). Following the walk, the subjects were again weighted, rested supine for 1 hour, and blood and urine samples were obtained. The concentration of haemoglobin (Hb; g/L) and sodium in the blood (Na+; mmol/L), the hematocrit (Hct) and urine specific gravity (USG) were determined.
Results
The mean (SD) subjects' age was 24 (4) years and pre-walk body mass 70 (11) kg. The ambient data during the walk were: Ta = 20 (4)°C, Pb = 977 (1) hPa, and RH = 61 (12) %. Body mass decreased for 0.8 (0.4) % in the NH group, and for 2.5 (1.0) % in the DH group. USG increased in both groups ($P<0.01$), but in the NH group remained below the cut-off value for dehydration of 1.020 (Casa, 2000). Despite mass loss, plasma Na+ concentration remained within normal limits (135-145 mmol/L) in both groups. Plasma volume, as calculated from changes in Hb and Hct (Harrison, 1985), increased ($P<0.01$) by 5 (5) % in both groups, probably due to the fluid shifts between extravascular and intravascular fluid compartments.
Conclusions
In subjects exercising in temperate environment, water intake ad libitum was lower than the sweat loss. However, the resulting mass loss was less than 1 %, and was thus lower than the "tolerable" body water loss of 2 % (Coyle, 2004). Despite a reduction in body mass, plasma Na+ concentration remained normal, likely due to the intercompartmental fluid shifts. These results suggest that in temperate environments the sensation of thirst during exercise is sufficient to maintain the hydration within the "tolerable" (optimal) limits.

SELECTION PROCESS OF YOUNG SOCCER PLAYERS ACCORDING TO THEIR PLAYING POSITION

Gil, S., Gil, J., Irazusta, A., Ruiz, F., Irazusta, J.
Faculty of Physical Activity and Sports Sciences, University of the Basque Country, Spain. , Spain

Introduction
Specific characteristics have been described for the different positional roles in soccer players (1,2). The aim of the present study was to establish the relevance of the characteristics in the selection process of players for each position. Thus, we compared the characteristics between the selected and not selected soccer players within each positional role.
Material and methods

We assessed 241 soccer players from the Getxo Arenas Club, Spain (56 forwards, 79 midfielders, 77 defenders and 19 goalkeepers). Their mean age was 17.31±2.64, the height 175.78±8.56cm and weight 69.2±9.68kg.
The height and weight, skin fatfolds four diameters and perimeters were measured. The body composition and the somatotype were calculated.
The endurance (using the Astrand Test), velocity (30 m flat sprint), agility (30 m + 10 cones) and leg power (squat jump, counter-movement jump and drop jump) were also measured.
A Student-t test was performed to analyze the differences between the selected (S) and the non-selected (NS) players within each playing position. Also, logistic regression was used to study the importance of the variables in the selection process.
Results
• FORWARDS: The selected players ran faster in the agility (S: 4.77±0.27s vs NS: 4.98±0.28) test. They also performed better in the flat sprint test (S: 3.61±0.29s vs NS: 3.76±0.35) and the jump test (S: 42.08±5.15cm vs NS: 40.42±3.38). The logistic regression showed that best predictor to be selected in the group of forwards was the agility test, followed by the drop jump test.
• MIDFIELDERS: Selected players were taller (S:174.86±6.98cm vs NS:170.45±7.67). They also had higher relative maximal oxygen consumption (S:60.09±7.93 ml•kg-1•min-1 vs NS:53.20±12.47) and performed better in the agility test (S:4.77±0.28s vs NS:5.01±0.32). In fact, the latter was the most important variable, followed by the height.
• DEFENDERS: The predictor variables were the amount of fat in the extremities (S:32.89±8.39mm vs NS:39.47±16.14) and, after that, the C.M.J. jump.
• GOALKEEPERS: Although none of the differences among goalkeepers were statistically significant, the selected players tended to perform slightly better in all the tests.
Conclusion
In the selection process the most relevant characteristics are consistent with the different workloads for each positional role. Thus, the selected forwards had the better agility and power. Agility was also the best predictor for the selection of midfielders, together with height and the endurance capacity. In the defender group, having a leaner body and the power of the lower legs were the important features. However, it is possible that a different set of tests would be more appropriately used for goalkeepers.

THE INFLUENCE OF EXERCISE EXPERIENCE ON HIPPOCAMPAL STRUCTURE AND PSYCHOLOGICAL WELL-BEING IN HEALTHY YOUNG PEOPLE

Sensui, H., Fujimoto, T., Gondo, Y., Ono, Y., Ogawa, S., Kinomura, S., Tashiro, M., Itoh, M., Takekura, H., Nagatomi, R., Nagamatsu, T.

Meiji Yasuda Life Foundation of Health and Welfare, Japan

Maintaining mental health throughout life is one of the most important public health goals, and it is increasingly clear from psychological research that exercise can be of benefit. The hippocampus is one of the regions that have recently received considerable attention in mood disorders research, and the highly plastic and stress-sensitive hippocampal region is thought to play a central role in depressive illness. The primary mechanisms underlying the relationship between exercise and psychological effects are still poorly understood, however, animal studies demonstrated that exercise-induced hippocampal cell proliferation may be associated with mental health promotion and sustention. To elucidate the effect of exercise on hippocampal structure in human, hippocampal gray volumes were compared between the students who actively been engaged in physical exercise (athlete group) and those who did not exercise for a long time (sedentary group). Method: For the present study, young male university students and graduate students were recruited. All subjects were highly educated, right-handed healthy males, who had never smoked. Regularly exercising subjects were included in the athlete group (n= 22) and those who had scarcely participated in regular exercise were classified in the sedentary group (n= 26). Optimized voxel based morphometry (VBM) was performed to compare hippocampal structures between the two groups after acquisition of T1-weighted MR images. VO2max measurement and psychological survey were also performed. Result: Optimized VBM revealed that the athlete group had greater gray volume in bilateral hippocampal tails than the sedentary group. Likewise, the athlete group had significantly higher psychological well-being (self-efficacy, development of identity and self-acceptance) and VO2max than the sedentary group. There were no differences in age, height and weight between the two groups. Conclusion: This study suggested that exer cise experience influenced hippocampal structure even in healthy young students. Similar to previous research, exercising students had better psychological well-being than those who did not. Since smaller hippocampus could be a risk factor for developing psychiatric disorders, exercise-induced hippocampal soundness might contribute to the psychological benefit of exercise.

METHODOLOGICAL ASPECTS OF ANAEROBIC PERFORMANCE ASSESSMENT

Santos, A.M., Lopez, R., Fontes Ribeiro, C.A.

Faculty of Sport Science and Physical Education, University of Coimbra, Portugal

There are intrinsic problems with determining peak power (PP) from the Wingate test (WAnT), particularly with regard to optimal braking force, which was originally set to optimise mean power. The force velocity test (FVT) may overcome this problem since several sprints are completed against different braking forces. By plotting the highest power achieved for each of these bouts against the respective braking force, the resulting parabola enables optimal peak power (PPopt) to be calculated accurately for each subject. Therefore, the aim of this study was to characterise the anaerobic performance obtained through FVT and WAnT with different loads. We also intended to verify how the peak power (PP) and mean power (MP), obtained by the WAnT, change with increments of 0.010 Kg.Kg-1 of Body Mass (BM) in the applied loads.
Written informed consent to participate was received from 14 student's girls aged 20.3  1.4 years old. Anthropometric measures were: body mass 56.1  8.9 kg , stature 160.9  4.7 cm, sitting height 83.3  1.9 cm; skinfolds sum (triceps, suprailiac, abdominal, anterior mid-thigh and medial calf) 88.9  20.4 mm. All subjects performed the FVT in order to determine their PPopt, , their own optimal load (OL) and their optimal RPM (ORPM). After the FVT, each subject randomly performed six WAnTs with five different loads (0.065, 0.075, 0.085, 0.095 and 0.105 kg.kg-1 of BM, and one more with their OL obtained by the FVT); the rest period between tests was, at least, 48 hours. Post-exercise blood lactate levels were obtained 5 minutes after the WAnT.

PP-values obtained in the WAnT with the five different loads were: 474.6  62.5, 502.1  66.3, 523.1  68.2, 538.1  67.4 and 527.5  81.9 W, whereas the MP-values were: 374.9  42.6, 392.3  48.5, 405.5  47.6, 413.5  50.4 and 407.8  62.5 W. The PP-values in the WAnT with the OL were significantly higher than those obtained with the standard load (536.86 ± 74.62 W vs 502.07 ± 66.31 W). The same occurred with MP-values: 412.10 ± 54.58 W vs 392.25 ± 48.48 W.

The results suggest that the performance of the WAnT with the OL, individually determined with the F-V test, allows the achievement of the maximum values of PP and MP, which is not in accordance with the existent literature. We also verified, by the performance of WAnT with five different loads, that the determination of the PP through the WAnT protocol is sensitive to variations of 0.010 Kg.Kg-1 of BM, either with low or heavy loads. The determination of the MP through the same protocol is also sensitive to variations of 0.010 Kg.Kg-1 of BM when low loads are applied, namely 0.065 Kg.Kg-1 or 0.075 Kg.Kg-1. Thus, data suggest that in order to assess in a more precise way the anaerobic performance in the WAnT, it is necessary to determine previously the OL of each subject, instead of the application of a standard and pre-defined load.

AGE-RELATED CHANGES IN THE CEREBRAL BLOOD FLOW FROM 12 TO 18 YEARS OF AGE IN FEMALES

Sadamoto, T., Sato, K., Ohmori, F., Okajima, M., Iwadate, M., Kagaya, A.

Japan Women's College of Physical Education, Japan

<Purpose> To understand physical capabilities of children and the potential impact that sport activity can have on children, it is important to describe the developmental state of their bodies and various aspects of functions. There are few studies focusing on the development in cerebral blood flow. Especially, it has not yet known how changes occur in the cerebral distribution of cardiac output as a child grows. To challenge this question, we studied age-related changes in the cerebral distribution of cardiac output in healthy females between 12 and 18 years of age. <Methods> A hundred and thirty-one girls took part in the experiments. Duplex ultrasonography (Logiq5 and Vivid7, GE-Yokogawa Medical Systems, Tokyo) was used to assess vessel diameter and mean flow velocity in the left common carotid artery (CCA) and the left middle cerebral artery (MCA) while the subject was quietly sitting. The blood flow in CCA (BFCCA) was calculated as the product of π × (diameter/2)2 × (mean flow velocity) × 60 (ml/min), and used as an index of the cerebral blood flow in this study. Arterial blood pressure was measured non-invasively by photoelectric plethysmography with a Finometer (Finapres Medical Systems BV, Arnhem). Heart rate, stroke volume (SV) and thus cardiac output (CO) were determined from the blood pressure waveform using Modelflow software program implemented in the Finometer. The cerebral distribution of CO (%) was calculated as BFCCA/CO × 100. <Results & Conclusion> The BFCCA began to increase from 14 years and reached the peak at 15 years. The increase in BFCCA was accompanied by both increases in vessel diameter and mean flow velocity in CCA. There was 18-20 % of increase in BFCCA for 3 years from 12 to 15 years. Similarly, the decline in VMCA, which probably reflects the vascular growth in MCA, occurred from 13 to 15 years. After 15 years both BFCCA and VMCA reached the plateau. The increase in CO began between the ages of 12 and 13 years and was nearly complete by 15 years. The increase in CO was due to a significant increase in SV. For 3 years from 12 to 15 years CO increased by 60-65 %. This marked increase in CO, three times larger than the increase in BFCCA, produced a gradual decrease in the cerebral distribution of CO. The highest value of distribution was 11 % observed at 12 years, followed by a gradual decline to 6.5-7.0 % at 14-15 years of age. The cerebral distribution of CO over the age of 15 years was almost identical to that observed in adult females. From these findings, it was suggested that the development in cerebral blood flow is accomplished by the age of 15 years in females.

PULMONARY O2 UPTAKE KINETICS AND MUSCLE DEOXYGENATION IN CHILDREN AT THE ONSET OF MODERATE INTENSITY CYCLING EXERCISE

Welford, D., Barker, A.R., Welsman, J.R., Armstrong, N.

University of Exeter, United Kingdom

The purpose of this study was to examine the relationship between pulmonary oxygen uptake kinetics and muscle deoxygenation measured by near infrared spectroscopy (NIRS). This relationship has previously been examined in adults (Delorey et al. 2003; Grassi et al. 2003) but no such study has been carried out with children.Twelve children (6 boys, 6 girls) visited the laboratory for a determination of peak VO2 and then completed at least 4 step change transitions from unloaded pedalling to a constant work rate corresponding to 80% of their previously determined ventilatory threshold. Each participant's breath by breath responses were interpolated to 1s intervals, time aligned and then averaged. A single exponential that included a time delay was used to analyse the averaged response following phase 1 (15s). Muscle deoxygenation was also measured during the constant work rate tests using a NIRS device (Hamamatsu NIRO 300) that utilizes continuous wave spectroscopy to determine changes in deoxyhaemoglobin (Hb). Data were collected at 1s time intervals and then individual tests were time aligned and averaged and a single exponential that included a time delay was used to analyse the averaged response from the start of the test.

The delay in muscle deoxygenation at the onset of exercise was 5.7 ± 2.9 seconds. There was no significant difference between the time course of adaptation of Hb and O2 , as shown by the time constant for O2 (22.8 ± 4.5 seconds) and the MRT (time delay + time constant) for Hb (23.0 ± 6.6 seconds).

NIRS measures of muscle deoxygenation reflect the balance between local muscle oxygen delivery and muscle oxygen utilisation. The delay in muscle deoxygenation at the onset of exercise was similar to that shown in other studies. In conclusion, the significant relationship between the kinetics of pulmonary O2 and muscle deoxygenation during the initial transition to moderate exercise may reflect an appropriate matching of muscle blood flow and muscle O2 consumption. Further studies are necessary to examine the relationship between pulmonary oxygen uptake kinetics and muscle deoxygenation at different intensities of exercise.

THE INFLUENCE OF BODY TEMPERATURE ON A 10 KILOMETER RUNNING PERFORMANCE

Che Muhamed, A.M., Hamzah, S.

University of Malaya, Malaysia

Introduction: Self-paced and externally regulated exercise performance in the heat has been shown to decline as body core temperature rises to around 400C (Tucker et al., 2004). The underlying mechanism responsible for this has been associated with a reduced central nervous system function, reduced cerebral blood flow (Nybo and Nielsen, 2001), impaired substrate availability or utilization and increased accumulation of blood lactate (Febbraio, 2001). To date this hypothesis has not been directly tested in a real outdoor environment. Accordingly, the aim of the study was to investigate the ability of well trained male middle distance runners to perform under heat stress environment during a 10-kilometer (km) road race.

Method.

Nine well trained male runners volunteered for the study. They were divided into three different groups which were tested on three different environmental conditions, a very hot-dry (VHD;350C, 53%rh, n=3) to hot-humid (HH; 300C, 73%rh, n=3) and warm-humid (WH; 260C, 88%rh, n=3). In each trial, a subject ran a total distance of 10 km, with the speed eliciting an exercise intensity of 70% max was prescribed within the first 5 km. For the following 5 km, subject were instructed to maintain a highest possible self paced speed. Rectal (Tre) and Mean skin temperature ( ) were recorded via VitalSense Telemetric Temperature System (The Mini Mitter Company Inc, Oregon) and recorded at every 1km distance.

Result.

Runners in the VHD group recorded a highest mean (±SD) Tre at the end of the first 5km at 39.9 (±0.1) as compared with 38.9 (±0.3) in the HH and 38.0 (±0.1) in the WH condition. Similarly was higher in the VHD group as compared with the HH and WH group (39.0±0.8 vs. 35.2±0.8 and 32.8±0.3, respectively). In the self paced section of the trial, a largest reduction in running speed during the last 5km as compared to the first 5km was recorded in the VHD group followed with the HH group. Mean speed reduced by 1.3km (±0.6) and 0.3km (±2.3) in the VHD and HH, respectively. Contrary, runners in the WH group who experienced less heat stress during the first 5km run were able to increase their running speed with a mean of 2.3 km (±0.6).

Conclusion.

It was evident that runners in the VHD group with a mean Tre of 39.9 (±0.1) at 5km suffered from a largest drop in running speed within the next 5km. This observation clearly demonstrates the difficulty in maintaining or increasing physical performance as Tre closely reach 400C as described in earlier studies (Tucker et al., 2004; Nybo and Nielsen, 2001).

THE RELATION BETWEEN HIPPOCAMPAL STRUCTURE AND PSYCHOLOGICAL WELL-BEING IN EXERCISING AND NON-EXERCISING STUDENTS

Fujimoto, T., Sensui, H., Takekura, H., Gondo, Y., Ono, Y., Ogawa, S., Kikuchi, J., Kinomura, S.,Tashiro, M., Itoh, M., Nagamatsu, T., Nagatomi, R.

Tohoku University, Japan

Maintaining mental health throughout life is one of the most important public health goals, and it is increasingly clear from psychological research that exercise can be of benefit. The hippocampus is one of the regions that have recently received considerable attention in mood disorders research, and the highly plastic and stress-sensitive hippocampal region is thought to play a central role in depressive illness. The primary mechanisms underlying the relationship between exercise and psychological effects are still poorly understood, however, animal studies demonstrated that exercise-induced hippocampal cell proliferation may be associated with mental health promotion and sustention. To elucidate the relation between hippocampal structure and psychological well-being, correlation analysis between hippocampal gray volumes and psychological well-being were conducted in the students who actively been engaged in physical exercise (athlete group) and those who did not exercise for a long time (sedentary group). Method: For the present study, young male university students and graduate students were recruited. All subjects were highly educated, right-handed healthy males, who did not smoke. Regularly exercising subjects were included in the athlete group (n= 22) and those who had scarcely participated in regular exercise were classified in the sedentary group (n= 26). The correlation analysis between the gray volumes in the regions where the gray volume differences were detected between the two groups using optimized voxel based morphometry (VBM) and psychological states measured by psychological scales measuring development of identity, self-efficacy, self-acceptance and subjective happiness were performed. Result: Optimized VBM revealed that the athlete group had greater gray volume in bilateral hippocampal tails than the sedentary group. There were no significant correlation between psychological states and the gray volume of right and left hippocampal tails in each group. However, there were tendency of positive correlations of self acceptance (R= 0.36, P= 0.064) and subjective happiness (R= 0.34, P= 0.080) with the gray volume of left hippocampal tail in the sedentary group. Conclusion: The gray volume in the left hippocampal tail might be associated with psychological well-being. We are going to increase the number of subjects in future study.

EFFECTS OF FLUID SHIFT ON EMG PARAMETERS

von Walden, F., Elman, T., Pozzo, M., Tesch, P.

Karolinska Institutet, Sweden

Lack of weight bearing (e.g. spaceflight, bed rest) provokes muscle atrophy and compromised muscle force [1]. Acutely exercise-induced changes in muscle fatigue can be assessed through myoelectrical manifestations, i.e. by analyzing electromyographic (EMG) spectral content (mean power frequency, MNF) [2]. Hence, the EMG technique should be a useful tool for monitoring in-flight muscle function including muscle fatigue phenomenon. Unfortunately, there is a cephalic fluid shift occurring in microgravity such that calf girth and volume are reduced. Similarly, the transition from vertical to supine position brings about alterations in bio impedance of the leg [3]. Thus

altered electrical properties of muscle may affect EMG parameters. The aim of this study was to investigate whether cephalic fluid shifts presents a methodological limitation to employing EMG techniques in assessing exercise-induced muscle fatigue.

Ten men performed unilateral, isometric plantar flexions at 20 and 60% of maximum isometric contraction (MVC) for up to two min. Measurements were performed in the supine position, preceded by 1 hr rest in the supine or vertical position. Bi-polar surface EMG was detected from the soleus and gastrocnemius muscles and mean frequency (MNF) and amplitude (ARV) were analyzed. A three-way ANOVA (factors Position, Force and Muscle) on MNF slope disclosed dependence from force ($P < 0.05$) and muscle ($P < 0.05$) but was not different for position. The rate of decrease in MNF (0.035 ± 0.16 and 0.033 ± 0.12 Hz/s for supine and vertical, respectively) at 20% MVC was smaller for SOL than for any of the gastrocnemius heads. There was no difference across muscles at 60% MVC. The initial value of MNF differed across muscles ($P < 0.05$) but not across positions. ARV initial value showed dependence on muscle ($P < 0.05$) and force level ($P < 0.05$) but not on position, with larger values at 60% MVC for all muscles ($P < 0.05$). A three way ANOVA on ARV slope showed significance for muscle ($P < 0.05$), with SOL showing larger ARV increase over time than the other two muscles ($P < 0.05$).

This study investigated the effect of a cephalic fluid shift on EMG parameters. Our results indicate that alterations in body fluid distribution do not affect myoelectrical manifestations of muscle fatigue. This would suggest that fluid shift is not a methodological limitation of EMG techniques as a tool for assessing exercise-induced muscle fatigue in microgravity conditions.

DIMINISHED INCREASES OF URINARY DOPAMIN LEVELS ON SWIMTRAINING - A QUESTION OF WATER IMMERSION?

Krakowski-Roosen, H., Stoia-Djeska, C., Skipka, W.

German Cancer Research Center, Germany

Introduction: Physical activity is associated with muscular work and increases in neuromuscular functioning, as derived from alterations in electromyographic recordings or in plasma concentrations of neurotransmitters. Activity of the motorcortex could be read from electroencephalogram-recordings or functional magnetresonancetomography, but methodical limitations cause the lack of data during sports. Dopamin (D) as the most important neurotransmitter in the motorcortex was found to be increased during and after several kinds of physical exercise and is a good indicator for motorcortical activity.

The aim of the present study was to get some insight view on extensive intervall swimtraining.

Method: Experienced, male (n=14) and female (n=12) swimmers of two different performance levels (PL) passed 90 min of extensive interval training at the same individual level of 75%. Urinary samples were taken immediately before (BL) and after the training session, furthermore 90 and 180 min afterwards. Glomerular filtration rate (GFR) was calculated by creatinine clearance. In a second experiment plasma dopamin was measured in 15 male volunteers before and after a 25 minutes lasting period of thermoneutral immersion (34.3±0.4°C).

Results: Urinary D changed significantly with time ($p=0.044$; MANOVA) with no differences for gender or PL. D level is weakly but highly significant correlated to GFR ($r=0.355$; $p<0.000$) and so data is corrected for GFR: There remain no differences for time, gender or PL at all. Immersion itself lead to a slightly but not significantly decreased plasma level of D.

Discusssion: „Dry" physical exercise has already shown markedly increasing dopamin levels mentioned as a sign for motorcortical activity, 90 minutes of swim training failed to do so. Methodical limitations for the urinary data may be corrected by GFR, but GFR itself seems to be influenced by the activity level (Stoia et al. 2006). As land based exercise differs from exercise in the water particularly through the lack of postural work, the diminished urinary dopamin levels are mentioned to reflect a lower motorcortical activity in the water although a resting control experiment failed to prove this thesis. Further experiments are necessary to clear up the part of antigravitational work and posture on the overall motorcortical activity.

A COMPARISON OF CONTINUOUS AND DISCONTINUOUS PROTOCOLS FOR THE DETERMINATION OF MAXIMAL OXYGEN UPTAKE

Barber, R., Wood, D., Draper, S., James, D.V.

University of Gloucestershire, United Kingdom

Previous research suggests that the highest oxygen uptake (VO2peak) derived from a traditional discontinuous test (DCT) and continuous test (CT) is similar, although the incidence of a VO2-plateau is higher for a DCT. However, it has been suggested that a VO2-plateau in a traditional DCT could be an artefact of the test protocol (Noakes, 1997). The present study compared VO2peak and the incidence of a VO2-plateau for a DCT with a comparable CT.

In a counterbalanced order, 10 participants completed a DCT, in which speed remained constant whilst gradient increased in 2.5% increments, and a CT in which speed remained constant whilst gradient increased as a continuous linear function of time. Breath-by-breath VO2 data were interpolated to 1 s values and smoothed using 15 s moving averages and 60 s sequential averages.

The highest of the smoothed values for both sampling periods were taken as VO2peak and compared between the CT and DCT. Peak VO2 derived between 1 min 45 s & 2 min 45 s for the DCT was compared with the VO2peak derived for 60 s sequential averages for the CT. Peak VO2 was higher for the CT than for the DCT when VO2 was determined between 1 min 45 s & 2 min 45 s for the DCT (4066 ± 711 vs. 3871 ± 619 ml.min-1; $p= 0.008$), but not for 15 s (4231 ± 710 vs. 4258 ± 654 ml.min-1; $p= 0.717$) or 60 s (4066 ± 711 vs. 4157 ± 634 ml.min-1; $p= 0.242$) averages.

For the identification of a plateau for the CT three approaches were used: a modelling approach; a 95% confidence-interval approach; and an absolute criterion (<150 ml.min-1) approach. A plateau was identified in 100% of participants for the modelling and absolute criterion approach, and in 90% of participants for the confidence-interval approach. For the identification of a plateau for the DCT two approaches were used: a participant sample-specific approach, and an absolute criterion approach. The sample-specific approach identified a plateau in 100%, 100% and 90% of participants for 60 s averages, when VO2 was determined between 1 min 45 s & 2 min

45 s, and 15 s averages respectively. The absolute criterion identified a plateau in 60%, 80%, and 70% of participants for 60 s averages, 15 s averages, and when VO2 was determined between 1 min 45 s and 2 min 45 s respectively.

The findings from the present study suggest that the highest VO2 and a high incidence of a VO2-plateau can be identified in both CTs and DCTs with appropriate protocols, but, due to the substantial practical advantages, a CT should be the test of choice for the routine assessment of VO2max.

RELATIONSHIP BETWEEN EXPIRATORY GAS RESPONSE AND LOAD INTENSITY DURING CONSTANT-LOAD EXERCISE

Kimura, M., Saito, H., Németh, H., Watanabe, T., Ito, S.

Kokushikan University, Japan

INTRODUCTION

The purpose of this study was to examine the relationship between load intensity and expiratory gas parameters during constant-load exercise. According to previous studies, VO2 response reaches steady state during constant-load exercise in the moderate intensity domain. Additionally, VO2-load (W) relationships have already been extensively investigated for moderate intensity constant-load exercise; it is known that this relationship has linear characteristics within this domain. With recent advances in mechanical measurements, it is possible to measure many expiratory gas response parameters. For our study, we measured many parameters and performed 3 analysis methods.

METHODS

Subjects were 5 healthy males and 2 females.

Exercise protocol was set with a bicycle ergometer (REhcor500P, Groningen, The Netherlands). The subjects had to check the monitor and maintain a pedaling rate of 60rpm during exercise. Following a 7-minute warm-up (2W) and a 3-minute increase to reach the constant-load, exercise load (2W, 22W, 42W, 62W, 82W and 102W) was maintained for 20 minutes. Expiratory gas parameter were measured using an expiratory gas analyzer (AE300S, and AT for WINDOWS, Minato Medical Science, Japan) which outputs data on a breath by breath basis. Expiratory gas parameters (VO2, VCO2, HR, VE, RR, R, TVe, ETO2, ETCO2) were measured continuously throughout the exercise period.

Data analysis software (KyPlot 4.0, Kyens Laboratory, Japan) was used to create the calculation average, moving average, and fitting data.

RESULTS

(1) Our results showed that VO2-load relationship was linear during constant-load exercise.

(2) Gender difference was not observed in the VO2-load relationship.

(3) Relationship between exercise load and expiratory gas parameters (VCO2, HR, VE, RR, TVe) had linear characteristics for analysis.

(4) The coefficients of the formula for expiratory gas parameter relationships depend on analysis method.

DISCUSSION

We conclude that load intensity has a strong relationship with expiratory gas response parameters in moderate intensity constant-load exercise. Although these results are consistent with previous studies, linear characteristic formulas vary depending on the analysis method utilized.

PHYSIOLOGICAL, BIOCHEMICAL AND FUNCTIONAL CHANGES INDUCED BY TOP-LEVEL OFF-ROAD COMPETITIVE MOTOCROSS HEATS

Ascensão, A., Azevedo, V., Oliveira, E., Ferreira, R., Marques, F., Magalhães, J.

Faculty of Sport Sciences, University of Porto, Portugal

Physical conditioning of motocross riders has been considered an important component in this specific and complex sport performance. However, to our knowledge few studies regarding the impact of motocross heats on functional and physiology variables of riders have been addressed so far. In this regard, the present study was designed to analyze physiological, biochemical and functional changes induced by top-level off-road competitive motocross heats.

To achieve this purpose, fifteen (15) elite motocross riders (28,3 ± 7,9 yrs; 71,1 ± 7 kg; 169 ± 4cm; 53,5 ± 3,7 ml.kg-1.min-1; 14,9 ± 3,3 % fat) performed one treadmill running test to exhaustion in order to determine maximal heart rate (HRmax), maximal oxygen consumption (VO2max) and ventilatory threshold (Lan vent). Thereafter, three 30 min competitive off-road motocross heats were performed to measure biochemical (blood lactate and urine catecholamine concentrations) and/or functional (forearm power and fatigue tests) alterations induced by race. Exercise intensity through HR monitoring, estimated VO2max, rating of perceived exertion (RPE) and forearm pain were also accomplished.

During the 30 min heats, the riders spent: (i) 26 minutes (87%) of time above 90% of HRmax; (ii) 27 minutes (89%) between 95-100% of VO2max and; (iii) 25-28 minutes with an HR higher than that corresponding to Lan vent. Significant impairments were observed on maximal forearm isometric handgrip force as well as on Wingate variables after the race. Blood lactate concentrations significantly rose from rest vs. 10 min, 20 min and final time of analysis ($p>0.05$). However, significant decreases were observed between 10 min vs. 20 min and final of the race. A significant increase in the urine levels of catecholamines was observed after the race.

In conclusion, the present data suggested that competitive motocross heats are performed at high exercise intensity. Motocross specific effort induces significant functional and physiological alterations that may reflect a decrement on physical performance.

CHANGE OF FORCE DEVELOPMENT BY ANTAGONIST CONDITIONING CONTRACTION AT SEVERAL INTENSITY AND DURATION

Kamimura, T., Takenaka, T.

Kokushikan University, Japan

INTRODUCTION

Muscle force potentiation by preceding contraction of the antagonist muscle has been reported. Effect of antagonist conditioning contraction was thought to be neuromuscular influence by 1b inhibition of golgi tendon organ (GTO) and change of elastic energy. In most prior

studies maximum voluntary antagonist contraction was used as conditioning contraction, and duration of conditioning contraction was fixed but different in each study. In this study, the muscle contraction force and maximum rate of force development (dF/dt) after antagonist conditioning contraction at several intensities and durations were examined.

METHODS

Elbow and shoulder joint were kept at 90 degrees, and isometric elbow extension and flexion were performed. After a warm-up, measurements at maximum extension were done three times each subject. 100% muscle extension was determined by measuring the maximum extension 3 times and calculating the average. Intensity of antagonist conditioning contraction was set at 25, 50, 75, and 100%. Duration of antagonist conditioning contraction was set at 1, 2, 5, and 10 seconds. Simple maximum elbow flexion was measured three times, and the mean value was considered to be 100%. Total 16 patterns (combinations of 4 intensities and 4 durations) were used as antagonist conditioning contractions at random sequence. Electromyography (EMG) signals were measured at biceps brachii and triceps brachii, and root mean square (RMS) amplitudes were calculated. Force, dF/dt, and RMS amplitude of total 16 patterns were evaluated. The statistical analysis was done using two-way ANOVA and correlation analysis of Pearson.

RESULTS

The elbow flexion force was not significantly affected by antagonist conditioning contraction. However, dF/dt increased significantly either with decrease of duration or increase of intensity. As for RMS amplitude of biceps brachii and triceps brachii during elbow flexion no statistically significant difference was obtained.

CONCLUSION

Potentiation of muscle force output was not obtained. However, dF/dt depended on intensity and duration of antagonist conditioning contraction. The role of stored elastic energy and activity of GTO might be important factors in the effects of antagonist conditioning contraction.

INTERMITTENTLY INCREASING THE WORKLOAD TO 50 %MVC DURING REPETITIVE WORK IN COLD: MORE BENEFICIAL IN INDUCING EMG GAPS THAN 30 %MVC?

Oksa, J., Paasovaara, S., Ollila, T.

Fiinish Institute of Occupational Health, Oulu, Finland

In our previous repetitive work study at 4°C we observed that increasing every fourth minute the workload from 10 %MVC to 30 %MVC (breaking the monotonous work cycle) the amount of EMG gaps increased by 44 % and 37 % ($p<0.05$ in relation to work at 10 %MVC level) in the forearm flexors and extensors, respectively (Oksa et al. 2006). The aim of this study was to evaluate if using 50 %MVC intermittent work level would further enhance the occurrence of EMG gaps during repetitive work at 4 °C. Eight healthy and volunteer females performed six 20 minute repetitive work bouts (120 minute exposure) at 4 °C twice and at 21 °C (reference) once. The work consisted of wrist flexion - extension work at 10 %MVC (21 °C and 4 °C), contraction every third second. During the second exposure to 4 °C every fourth minute a double contraction was performed at 50 %MVC level (4 °C/50). During the exposures EMG activity of the wrist flexors and extensors was measured. The amount and duration of EMG gaps were analyzed from the data. The results showed that the amount of EMG gaps in the forearm flexors was 9.9 /min, 10.6 /min and 11.9 /min at 4 °C, 4 °C/50 and 21 °C, respectively. The percentage difference between 4 °C conditions was 7 % and 12 % and 20 % between 21 °C and 4 °C conditions. The amount of EMG gaps in forearm extensors were 10.6 /min, 10.6 /min and 12.6 /min, at 4 °C, 4 °C/50 and 21 °C, respectively. The percentage difference between 21 °C and 4 °C was 19 %. The duration of the gaps varied between 0.2 - 0.4 seconds and there were no differences between conditions. The results indicate that in both 4 °C conditions there are less EMG gaps in relation to 21 °C and that using 50 %MVC instead of 30 %MVC for breaking the monotonous work cycle at 4 °C does not induce more beneficial effects in terms of EMG gap occurrence.

CAN OLDER FEMALES BENEFITS FROM SPECIFIC RESPIRATORY MUSCLE TRAINING?

Watsford, M., Murphy, A.

University of Technology, Sydney, Australia

Sarcopenia affects central and peripheral physiological function, compromising activities of daily living and quality of life. Traditional strength training and cardiovascular training have been demonstrated as viable modalities to overcome the deleterious effects of sarcopenia, however, a seemingly endless search for new training modalities suggests that specific respiratory muscle (RM) training may assist physical performance for the older population. Controlled RM training is a proven method of improving RM strength and endurance in healthy and non-healthy humans and RM training may reduce the competition for blood flow between the central and peripheral body segments, thus improving exercise efficiency. Therefore, the current study examined whether the training modalities of walking and threshold RM training could improve physical function in older females.

Fifty-two healthy females (mean age 64.4 yr, range 60-69 yr) were randomly allocated to one of four groups for an eight week training program. The groups were: RM training (RMT), walking training (EX), both RMT and EX (RMTEX) and non-exercising control group (CON). Pre-testing consisted of assessment of pulmonary function, RM strength (maximal inspiratory and expiratory pressure) and RM endurance (RME). Physical assessment included an incremental treadmill test to an RPE of "hard" (TRPE15) which included measures of cardiovascular and respiratory function, along with subjective ratings of perceived exertion (RPE) for breathing and peripheral fatigue.

The RMTEX and RMT groups improved RM strength and RME to a greater extent than the EX and CON groups. Furthermore, the improvements in RM strength and endurance were significantly negatively correlated with pre-test scores for these variables. The RMTEX and EX groups displayed within group improvements in walking performance in the form of reduced submaximal HR, reduced RPE and a greater TRPE15. Further to these expected changes, the RMT group displayed several within-group changes including an improved TRPE15 (12%), decreased submaximal percentage of maximum voluntary ventilation (mean -18%), decreased submaximal HR (mean -5%) and decreased submaximal breathing RPE (mean -6%).

RM training improves RM strength and endurance in older females. Further, RM training may augment the physiological response to exercise in older females. Correlation analysis showed that the mechanisms associated with the improved exercise performance were related to improved RM strength and endurance. It appears that the combination of RM training and submaximal exercise has implications for functional performance and perceived exertion during walking tasks in older adults. Further, the improvements in submaximal exercise function indicate that RM training may aid activities of daily living, as such activities are carried out at low-moderate intensities, however, further specific assessment is required.

THE EFFECT OF PROLONGED FASTING ON FUEL SELECTION DURING SUBMAXIMAL EXERCISE OF DIFFERENT INTENSITIES

Stannard, S., Thompson, M.

Massey University, New Zealand

Introduction

It is well known that fasting increases the contribution of lipid as a substrate to support exercise. Most studies, however, compare only an overnight fast with the acutely fed or postprandial state and have not investigated the interaction between fasting duration and exercise intensity. This study was conducted to compare the effects of a 12-hr (overnight) and 72-hr period of water only fasting on fuel selection and blood-borne metabolic markers during exercise of three different submaximal intensities.

Methods

Six endurance trained men (four cyclists and two runners), VO2max 65.8 ± 10.6 ml.kg-1.min-1, 13.6 ± 3.5% body fat, underwent a three stage (6 min per stage) incremental submaximal exercise test on two separate occasions: A) after a 12 hr overnight water-only fast; and B) after a 72 hr water-only fast. Expired respiratory gases were collected into Douglas bags during the final two minutes of each workload for calculation of respiratory exchange ratio (RER). Venous blood samples were collected from the forearm during the final minute of each workload and were immediately analysed for plasma glucose and lactate concentrations.

Results

VO2 averaged 39, 54 and 69% VO2max in the 12-hour fasted, and 40, 55 and 68% VO2max in the 72-hour fasted state in stages 1, 2, and 3 respectively (no significant difference, p = 0.953). RER values indicate a significant interaction between fasting period and exercise intensity (p = 0.031) such that the large difference in RER at the lower intensities had diminished at the higher workload. Plasma glucose concentration was significantly lower during exercise in the 72-hr fasted state (p = 0.007), whilst plasma lactate concentration was significantly higher (p = 0.001). There was a proportionally greater increase in plasma lactate with increasing exercise intensity (p = 0.001) in the 72-hour fasted state than occurred in the 12-hour fasted state. There was no effect of fasting on the intensity-induced increase in circulating glucose concentration (p = 0.377).

Conclusion

The results of this study show that prolonged fasting alters the relationship between exercise intensity and fuel selection. In particular the data show an increased reliance upon fat metabolism during submaximal exercise after prolonged fasting compared with an overnight fast, but this difference diminishes as exercise intensity increases. The concomitant accelerated production in lactate with increases in exercise intensity during prolonged fasting most likely indicates that the larger motor units being recruited still rely on glycolysis, whereas the smaller oxidative motor units have shifted to preferential lipid oxidation.

EFFECTS OF SWITCHING PEDAL RATE MODEL ON THE NET MECHANICAL EFFICIENCY AND VO2 SLOW COMPONENT DURING CYCLING EXERCISE

Migita, T., Hirakoba, K.

Kurume University, Japan

Introduction Switching pedal rate at the halfway point during constant-metabolic demand cycling exercise (rpm switching model) could induce the alteration of muscle fibers recruitment pattern synchronized with switching from lower pedal rate to higher one and vice versa, which in turn lead to affect the net mechanical efficiency (η) at later phase of exercise, because the η correlates with type of muscle fibers recruited in exercise. Therefore, we examined the effects of rpm switching model on the η and VO2 slow component (VO2SC) and compared with those of previously employed exercise model for maintaining a given pedal rate throughout exercise at the same metabolic demand (control model). Methods Seven healthy male volunteers [mean ± SD: age 24 ± 2 yr, body mass 64.8 ± 7.5 kg] completed four 6 min constant-metabolic demand cycling exercises, which consisted of two trials (60 rpm and 110 rpm) in control model and two trials (60→110 rpm : 60→110swi and 110→60 rpm : 110→60swi) in rpm switching model. Pulmonary gas exchange parameters were measured during all exercise tests. Non-linear regression technique was used to fit the data of VO2 and the amplitude of VO2SC was quantified. Total mechanical power output (Ptot) was calculated as sum of external power output delivered to cycle ergometer plus internal power output estimated as 0.153×frequency^3, where frequency is in Hz (Minetti et al., 2001). Total energy turnover (Etot) was sum of aerobic and anaerobic energy turnovers, which were calculated using VO2 or blood lactate accumulation, respectively. The η was defined as the ratio of Ptot to Etot. Results and Discussion Although Ptot in 4 trials was remained at a constant and same level throughout the exercise tests, the estimated η at early phase (from 2 to 3 min) of 4 trials decreased at later phase (from 5 to 6 min), probably owing to the appearance of VO2SC. The extent of reduction of η between early and later phases was the smallest in 60→110swi (23.6 ± 1.2 % for early phase, 22.2 ± 1.8 % for later phase) and the greatest in 110→60swi (25.3 ± 2.1 % for early phase, 21.0 ± 1.8 % for later phase). However, the amplitudes of the VO2SC were not significantly different among four exercises (350 ~ 479 ml/min). Consequently, the difference of reduced η in two trials of rpm switching model could not be accounted for by the difference of VO2SC. It seems likely that the difference of η between two trials in rpm switching model would be caused by alternation of muscle fibers recruitment patterns depended on muscle developed tension and contraction frequency. THE VO2 OVERSHOOT IN ENDURANCE-TRAINED ATHLETES: THE INFLUENCE OF MODE OF EXERCISE

Kilding, A.E., Jones, A.M.

Auckland University of Technology, New Zealand

The VO2 overshoot in endurance-trained athletes: the influence of mode of exercise

Kilding A.E1 and Jones, A.M2

1Division of Sport and Recreation, Auckland University of Technology, Auckland, NZ; and 2School of Sport and Health Sciences, University of Exeter, St. Luke's Campus, Exeter, UK

Introduction: For many years, the dynamic response of oxygen uptake (VO2) following the onset of moderate-intensity exercise (i.e. below the gas-exchange threshold, GET) in healthy humans has been suggested to follow an exponential time-course with time to reach a VO2

steady-state being largely dependant on aerobic fitness. However, recent observations by Koppo et al. (2004) and Kilding et al. (2005), in trained cyclists and runners respectively, highlighted that the exponential response of VO2 at phase II appears to be distorted by an apparent transient 'overshoot' in some athletes. To further explore this observation, the purpose of the present study was to determine whether the overshoot of VO2 above the eventual steady state is dependent on mode of exercise in trained athletes. Method: Ten endurance athletes (5 cyclists and 5 runners) participated in the study. Following maximal exercise tests to determine the gas-exchange threshold (GET) and VO2peak for both cycling and treadmill running, each subject performed repeated (n=6) six min square-wave transitions from low-to-moderate (80% mode specific GET) exercise in both modes of exercise. After data interpolation and ensemble averaging, kinetic parameters were estimated using a mono-exponential model with time delay. The magnitude of the VO2 overshoot (if observed) was measured as the peak amplitude of the VO2 above the steady state (mean VO2 during last 30s). Results: During cycling, 100% of the cyclists and 60% of the runners demonstrated an overshoot. During running, 60% of runners and 0% of cyclists demonstrated an overshoot. In both modes, the overshoot occurred between ~50 and ~150 s after exercise onset. The magnitude of the overshoot above the eventual steady-state VO2 was 209 ± 75 ml.min-1 during cycling and 156 ± 63 ml.min-1 during running. Conclusion: In conclusion, the occurrence of a VO2 overshoot following the onset of moderate-intensity exercise is more prevalent during cycling than during running, regardless of the athletes' preferred exercise discipline. These data challenge the notion that the required (steady-state) VO2 is constant following the onset of moderate-intensity exercise, and that VO2 projects towards this steady-state with a mono-exponential time course in Phase II of the response. Further work to determine the origins (metabolic or mechanical) of these observations in both modes of exercise is required.

THE EARLY SPECIALIZATION EFFECT OF DIFFERENT SPORTS, SWIMMING VS FOOTBALL, IN PRE-PUBERTAL CHILDREN

Fernandes, R., Pereira, F.D.

Escola Superior de Desporto de Rio Maior, Portugal

Introduction

Regular physical activity has proved to be beneficial for health promotion. Do different sports promote a metabolic specialization in pre-pubertal children? To answer this question we assessed a group of young athletes to test their physical performance (VO2max) and the short-term power output (Wingate Test- WAnT arm and leg evaluations). The WAnT allows a practical assessment for both legs and arms performance (2). Assuming the specificity of the anaerobic capacity for the main requested muscle groups (3), probably, football players would perform better with their legs and the swimmers with their arms.

Methods

A group of young athletes (n=22) with a two-year of training practice was divided in two sub-groups (n=11): swimmers (age: 11,27 y ± 0,47; W: 37,82 kg ± 4,14; BMI: 17,22 kg/m2 ± 1,59) and football players (age: 11,5 y ± 0,52; W: 41,00 kg ± 5,71; BMI: 18,09 kg/m2 ± 1,59). Modified Balke maximal protocol using ergo-spirometry procedures (Cosmed® b2) was selected to determine VO2max and the Ventilatory Anaerobic Threshold (VAT) as estimates for the aerobic capacity. The anaerobic capacity for both arms and legs was quantified using the WAnT, performed in a cycle-ergometer (Monark® 849). Three relative parameters were assessed: Peak Power, Average Power and Power Drop. Heart rate was measured in all the tests with the Polar S610. The two groups were compared and the experimental variables correlated (SPSS, ver.12.0).

Results

The results were similar for both groups on the WAnT and VO2max tests. There were no significant differences observed for the experimental parameters between the groups. No correlations were found when relating the prolonged with the short-term power outputs between running and cycling. Nor differences were found within each group between arms and legs cycling.

Discussion / Conclusions

No correlations were found between the anaerobic capacity (WAnT) for arms and legs within each sport. The results for both tests are in agreement with the literature and slight higher for the VO2max test.

It seems that, during the pre-pubertal development period, different sports have no significant specific metabolic effect on athletes, confirming the hypothesis of "lack of specialization" (4, 5 and 6).

EFFECT OF THE USE OF THE FIRE FIGHTING EQUIPMENT ON DIFFERENT FATIGUE FACTORS AND STRENGTH POST MAXIMAL EFFORT

Aguado, R., Ruesta, M., Izquierdo, M., Ibáñez, J., Gorostiaga, E.

Centro de Estudios, Investigación y Medicina del Deporte. , Spain

Six male professional firemen were recruited and gave informed written consent to take part in the study, which was approved by the ethics committee.

Selection criteria included male gender; age between 35-42 yr; high level of habitual aerobic activity, defined as at least two 30-min sessions of continuous aerobic-type per week; high aerobic fitness, defined as maximal oxygen uptake (VO2max) running above 55 ml.Kg.min-1; no current participation in competition at national or international level; and no illness or medications known to impair exercise or alter endocrine function. Subjects were asked not to change their dietary habits or training programs during the study. On

entry of the study, subjects underwent a full medical history and physical examination". The mean (SD) age, height, mass, and VO2max the male subjects were 40.2 years (1.5), 175.8 cm (1.8), 73.2 kg (1.8), and 57.3 ml.Kg.min-1 (1.4), respectively.

Subjects exercised on a treadmill a protocol with 5,4 km.h-1 constant velocity and incremental % inclination grade, based in Balke-Ware protocol (Froelicher, VF 1987) compound for a first discontinuous part with three stages of 3 minutes of exercise at constant workload (30% - 45% - 60% VO2max respectively), and 2 minutes of resting between trials. Second part was defined by an incremental continuous protocol, increasing 2% grade inclination every 1 minute until fatigue. Protocol was completed in two occasions at same time, separated at least one week, one time with fire fighting equipment and one time with sportswear

Previous the protocol, subjects exercised various strength tests: maximal isometric leg extension forces (MIL), height vertical jump (CMJ) and power-load concentric actions with loads 30% of body mass half-squat (HS30). These tests were reply during each resting trial, and after the fatigue, always at the same time after the stop exercise: CMJ after 15 seconds, HS30 after 30 seconds and MIL 60 second only after fatigue. During recovery after fatigue, MIL was repeated after 3, 5, 10, 15 and 30 minutes to determinate the strength recovery.

During the test was analyzed the VO2, RER, blood lactate concentration (bLA), blood ammonia concentration (bAM), blood uric acid concentration (bU), rectal temperature (RT), skin temperature in the head (HT), skin temperature in the leg (LT), heart rate (HR) and rating of perceived exertion (RPE).

Test completed with fire fighting equipment in comparison with the normal sportswear had an average of bLA 26% higher, bAM 28% higher, RT 1% higher, HT 1% higher, LT 11% higher, VO2 27% higher, RER 10% higher, HR 18% higher, rate of loss of mass 237% higher and RPE 131% higher. These result produced an effect in the strength observed in MIL 2% lower, CMJ 31% lower, HS30 13% lower, total time test 16% lower.

Fire fighting equipment reduce the performance during an endurance test and the fatigue produced decrease more the legs strength, possibly due to a higher increase in the central temperature and higher dehydration.

THE EFFECT OF 15-DAY CYCLING TOUR ON ANABOLIC AND CATABOLIC HORMONES IN UNTRAINED WOMEN AND MEN

Wu, C.-L., Chui, Y.C., Chang, C.K., Ku, S.H., Hong, W., Chang, Y.W.

National Taiwan College of Physical Education, Taiwan

Single bout of intensive endurance training has been suggested to affect catabolic and anabolic hormones in trained subjects. This study was aimed to investigate the effect of long haul cycling tour on anabolic and catabolic hormones responses in untrained subjects. Fourteen healthy, young, untrained subjects (7 male and 7 female) aged 18-35 years old were recruited from a cycling group of Cycling Taiwan 1000 km 2005. The tour covered approximately 1100 km in 15 days. Overnight fasting blood samples were collected in the morning on the day 1, day 3, day 7, day 11, and day 15 before daily departure during the tour. Plasma testosterone (T), cortisol (C), insulin-like-growth factor-1 (IGF-1) and growth hormone (GH) were measured to examine the anabolic and catabolic hormones changes during the tour. Testosterone concentrations were significant higher in male subjects than female subjects ($p<0.001$). Testosterone concentrations changes (%) were increased more significantly by the end of the tour in male subjects compared to that of female subjects ($p<0.05$). Cortisol concentrations rose in day 3 and dropped significantly on day 15 in both genders ($p<0.05$). Testosterone-to-cortisol ratio (T/C) were elevated gradually and peaked at the end of the cycling tour in both genders ($p<0.05$). Plasma GH concentrations were decreased sharply in the early stage of the tour in both genders. IGF-1 concentrations were significantly dropped on day 3 compared to day 1 but gradually recovered till the end in both genders. We concluded that anabolic hormones increased steadily during the long haul cycling tour. However, the catabolic hormone was elevated in the beginning but decreased on the following the days.

MODULATED RENAL FUNCTION DURING EXTENSIVE INTERVAL TRAINING IN SWIMMING

Stoia-Djeska, C., Skipka, W., Krakowski-Roosen, H.

University of Medicine and Pharmacy Carol Davila, Bucharest, Romania

Introduction: Strenuous physical activity is combined with a reduction in renal function. The immersion situation is generally leading to an improved diuresis, but knowledge about the counterbalancing effects of swimming with its sympathicotonic stimulation due to work and the hormonal responses on immersion is scarce. The aim of this study was to investigate the influence of swimming exercise on the behavior of urine excretion and the glomerular filtration rate (GFR) in high trained and low trained subjects.

Methods: We investigated 14 men and 12 women of different performance capacity who made an extensive interval training in front crawl lasting about 90 min. The total distance ranged from 3500m to 4200m. Distance, intensity and interval had been fixed individually, respecting the personal performance capacity of subjects; so the subjects had been divided into well trained and low trained swimmers. Before swimming, immediately after it, as well as 1.5 and 3 hours after cessation of training both urinary and blood samples were taken to determine urine flow and GFR by measurement of creatinine clearance. We calculated the training velocity (TV) as an indicator of the intensity of the effort in this exercise. We also calculated the Pearson correlation index (r) between the difference of GFR values in the two moments before and immediately after swimming (ΔGFR = GFR2-GFR1) and TV.

Results: During swimming training we have registered a significant increase in urine excretion from 0.61±0.31 to 1.31±0.43ml/min and this range was kept in the following 3 hours. GFR also increased significantly from 119±54 to 135±55ml/min with further augmentation to 144±57ml/min 1.5 hours after swimming. A significant positive correlation was found between ΔGFR and TV ($r=0.522$, $p=0.006$, ΔGFR=333TV-378) in the entire group; and also in the group of men ($r=0.577$, $p=0.031$).

Discussions and conclusions: Our study emphasized that in swimming training renal function is differentiated from the behavior during exercise on land; we have found that in swimming the renal function is increased and the increasing of GFR during our swimming training - leading to the effect that GFR-related dopamine excretion in our experiments was not increased significantly (Krakowski-Roosen et al 2006) - could be correlated with training velocity. These aspects are more evident for men than for women and they are not related to the performance capacity of the subjects.

THE BLOOD PRESSURE RESPONSE TO EXERCISE IS NOT RELATED TO MINIMUM MICROVASCULAR RESISTANCE IN 9-10 YEAR OLD CHILDREN

Middlebrooke, A., Farr, C., Armstrong, N., Mawson, D., Shore, A.

University of Exeter, United Kingdom

An exaggerated blood pressure response to exercise has been shown to be a strong predictor of future hypertension (1) and cardiovascular mortality (2) in adults and is associated with cardiovascular risk in children (3). In adults, an exaggerated blood pressure response to exercise has been shown to reflect impaired vascular function (4). The aim of this study was to investigate whether the blood pressure response to maximal exercise is associated with minimum microvascular resistance in 9-10 year old children.

100 children, 53 boys and 47 girls (age: 9.9±0.4years, body mass index: 17.3±2.6kg.m2) were recruited. Systolic and diastolic blood pressure were measured using a manual mercury sphygmomanometer and stethoscope at the site of the brachial artery at rest (supine), pre-exercise (seated on ergometer) and immediately after a continuous incremental exercise test to exhaustion on a cycle ergometer. Delta blood pressure was calculated as post-maximal minus pre-exercise blood pressure. Maximum microvascular hyperaemia was assessed by the maximum skin hyperaemic response to local heating (42°C) and minimum microvascular resistance was calculated as resting mean arterial pressure / maximum microvascular hyperaemia.

There was no significant sex difference in maximum microvascular hyperaemia although minimum microvascular resistance approached significance (boys: 39.7±7.4 v girls: 43.6±11.9mmHg.V, p=0.052). There was no significant sex difference in resting systolic blood pressure, systolic or diastolic blood pressure pre-exercise, post-maximal exercise or in delta systolic or diastolic blood pressure. However, resting diastolic blood pressure was significantly higher in girls (boys: 61±6 v girls: 64±6mmHg, p=0.02). Sex specific correlation analysis revealed that neither maximum microvascular hyperaemia nor minimum microvascular resistance was significantly correlated with systolic or diastolic blood pressure at rest, pre-exercise, post-maximal exercise or delta systolic or diastolic blood pressure in boys. In girls, resting systolic blood pressure was significantly correlated with maximum microvascular hyperaemia (r= -0.31, p=0.037) and minimum microvascular resistance (r=0.34, p=0.022). There was no significant correlation between either maximum microvascular hyperaemia or minimum microvascular resistance and resting diastolic blood pressure, systolic or diastolic blood pressure pre-exercise or post-maximal exercise or delta systolic and diastolic blood pressure.

These data collectively demonstrate that in 9-10 year old children the systolic and diastolic blood pressure response to exercise does not reflect minimum microvascular resistance.

WHICH DIFFERENCES ARE TO BE EXPECTED IN LABORATORY RUNNING TESTS BETWEEN SOCCER PLAYERS AND SPRINTERS?

Rakovac, M., Vucetic, V., Soric, M., Heimer, S.

University of Zagreb, Faculty of Kinesiology, Croatia

Training principles and aerobic requirements of sprinters and soccer players - forwards differ substantially. Nonetheless, due to characteristics of the football game, forwards must have a high ability to perform short sprints and are often exposed to demands characteristic for a sprint race. The aim of the study was to determine if there were significant differences in functional capacity parameters between forwards and sprinters.

Sample consisted of 15 Croatian top-level soccer forwards (mean age ± SD 23.67 ± 3.81 years) and 10 sprinters (100m and 200m) (mean age ± SD 20.53 ± 3.01 years). Groups did not significantly differ in weight (forwards 79.57 ± 7.72 kg; sprinters 76.11 ± 4.31 kg) and height (forwards 179.92 ± 6.11 cm; sprinters 184.86 ± 5.12 cm). In spirometry testing no significant differences in forced vital capacity (FVC) and forced expiratory volume in the first second (FEV1) were found between the groups (FVC - forwards 6.53 ± 0.95 L; sprinters 6.16 ± 0.65 L; FEV1 - forwards 5.31 ± 0.56 L; sprinters 5.25 ± 0.55 L). Both groups performed an incremental treadmill test to exhaustion. Following variables were observed: heart rate at ventilatory threshold (VT), speed at VT, maximum speed attained, absolute and relative maximal oxygen uptake (VO2max), absolute and relative oxygen uptake at VT, percentage of VO2max at VT (%VO2VT); maximum heart rate, maximum ventilation, respiratory frequency and tidal volume at maximum speed, ventilatory equivalent for oxygen at maximum.

T-test was used to determine differences in observed variables between the groups.

Statistically significant differences between the groups were found in three variables. Forwards reached a higher maximum speed than sprinters (19.13 ± 1.68 km/h vs 17.15 ± 1.38 km/h, respectively; t = 3.09, p = 0.01), had a higher speed at ventilatory threshold (13.53 ± 1.03 km/h vs 12.40 ± 0.99 km/h, respectively; t = 2.74, p = 0.01) and a lower heart rate at ventilatory threshold than sprinters (170.07 ± 10.15 bpm vs 177.80 ± 6.49 bpm, respectively; t = -2.13, p = 0.04). No statistically significant differences in aerobic capacities were found - VO2max (absolute - forwards 4.52 ± 0.42 L/min; sprinters 4.36 ± 0.27 L/min; relative - forwards 56.92 ± 3.02 ml/kg/min; sprinters 56.22 ± 3.39 ml/kg/min); %VO2VT (forwards 85.69 ± 3.64 %; sprinters 83.77 ± 4.84 %).

Despite the markedly different aerobic demands of respective sports and training principles, athletes showed no statistically significant differences in aerobic capacities. Results confirm findings of previous studies (Ruzic, 2005), which pointed to the needful caution in interpreting functional testing results in athletes of different energetic groups of sports. Namely, even not having preferable aerobic capacities, some athletes develop compensatory mechanisms that enable top-level performance.

TRACK AND FIELD WORLD RECORDS AND BEST PERFORMANCES IN DECATHLON RECORD HOLDERS

Mauri, C., Serena, E., Cereda, F., Manfredini, G., Peroni-Ranchet, F., Mognoni, P.

Università Statale di Milano, Italy

Track and field world records and best performances in decathlon record holders

A typical application of the logistic equation is a common model of population growth, which states that: 1) the rate of reproduction of a population is proportional to the existing population, all else being equal, 2) the rate of reproduction is proportional to the amount of

available resources,, all else being equal. Thus the second term models the competition for available resources, which tends to limit the population growth (Wikipedia.org). Recently logistic equations were used to predict upper asymptote (UA), maximal rate of growth and corresponding calendar year (Centered Year = CY) of 6 male and 2 female world-record running in races in the range of 0.8 and 42.195 km (1). The analysis started in 1920. The UA or predicted speed of "Peak" World Records of males were by 0.6-3.3% higher. These limits refer to 5 and 10 km races. CYs occurred from the late 1940s to the mid-1960s and were considered reasonable from several points of view. The determination coefficients (R^2) were satisfactorily high (0.947-0.984).We extended the logistic approach to World Records in all Decathlon events to compare them to results obtained in the same events by Decathlon World records holders (DEC). Records of javelin throw were excluded from the analysis because the aerodynamics characteristics of the tool were changed. Furthermore, we tried to differentiate the anthropometry of world record holders (WRH) and DECs.

The R^2s of WRHs were high for all events (range 0.956-0.986) except long jump (=0.852). The CYs were unreliable for 100 m race and high jump (1705 and 1915, respectively). The UA of shot put was slightly less than actual record. On the other hand, the UAs were unlikely high for high jump (+9.4%), pole vaulting (+14.7%), discus throw(+18.8%). In summary there was a clear discrepancy between the good fitting of experimental data by using logistic equations and the meaning of the numerical coefficients.

In DEC the performances in each events were not monotonically increasing and consequentely the R^2 were low (range 0.617-0.894). Furthermore, data of shot put were fitted by a power function being not consistent with any logistic function. The CYs were unreliable for 110 hm, 400 m , long jump and 100 m, being all before 1920. In 2006 the DEC predicted records were less than 10% worst than WRH predicted records for 110 hm (-6.8%) 100 m (-7.5%), 400 m (-9.3%) The larger differences were found for 1500 m (-22.9%), shot put (-32.0%) and discus throw (-40.2%). There was a tendency towards an increasing difference between WRH and DEC in high jump and pole vaulting. The ANOVA of height and body mass showed that DECs were too tall and heavy to compete in 1500 m race. The DEC body mass was significantly lower than in discus throwers or shot putters.

RELATION BETWEEN STATURE AND CONTACT OR FLIGHT TIME IN RUNNING

Peroni-Ranchet, F., Cereda, F., Serena, E., Griner, R., Casolo, F., Mognoni, P.

Istituto Padre L. Monti, Saronno (Mi), Italy, Italy

According to a well known study, the variation coefficients (=VC) of stride times (or stride length) were 5.9-6.0% in the range of running speeds between 3.15-4.12 m/s. Such data refer to 21 subjects ranging from 1.69 to 1.83 m. The correlation coefficient between stride time and stature (H) was not significantly different from zero (1). We measured contact time (Tc) and flight time (Tf) during treadmill running at different speeds up to the maximal one maintained for at least 5 s. Rest pauses were inserted between 0.28 m/s incremental steps to avoid fatigue. The 21 subjects' height was 1.77±0.15 (1.52-1.98) m. Maximal attained speed was 7.5±0.7 (6.1-8.9) m/s At 4.17 and 6.11 m/s step lengths (Ls) were 1.450 m±6.9% (= ±VC) and 1.834 m ±8.1%, respectively. Ls was significantly related to H (R^2=0.42-0.37). The forward movement of the centre of gravity (=CG) during contact (Lc) was related to H (R^2=0.56-0.57) while the movement during flight was completely independent (R^2=0.00-0.00). In 90% of the subjects Lc plateaued over 5 m/s and was strictly related to H (R^2=0.79). At the fastest speed the unexplained difference of Ls from linear regression ranked from +0.19 to – 0.20 m. It is unknown if these differences are due to anthropometric characteristics not taken into account like body mass, muscle fibre distribution and length or mass of leg,thigh, shank, foot. Nevertheless, in cycling the dependence of freely chosen cadence on muscle fiber type is an open question (2). The vertical velocity (Vv) at the beginning of Tc can be computed from Tf (Vv=9.81*0.5*Tf). Assuming a half time of Tc as pushing time and a linear increase of vertical velocity up to the take-off, the vertical displacement of the CG and vertical work may be obtained. Assuming a decrease of forward speed in the first half of Tc indipendent of average speed (3), the changes of kinetic energy in forward direction may be obtained. The computed vertical and horizontal powers are a good approximation of values obtained by force-platforms and imaging analysis. A positive relationship between horizontal power and H was found but the p value was only 0.025.

ESTIMATION OF ANAEROBIC RUNNING CAPACITY FROM A SINGLE RAMP TEST

Sentija, D., Vucetic, V., Milanovic, D.

Faculty of Kinesiology, University of Zagreb, Croatia

Background:

Ramp-pattern treadmill tests with gas exchange measurements are widely used for determination of maximal oxygen uptake (VO2max) and the speed at the first (aerobic) and second (anaerobic, AnT) ventilatory threshold. If the test is performed to volitional exhaustion (all-out), then the maximal running speed (Vmax) achieved in the test should be influenced, in part, by the anaerobic capacity of the subject. We hypotesize that the anaerobic capacity for running could be estimated from the distance run above AnT (AWCd), to the point of exhaustion. Recent studies reported that parameters of the 'critical power' model (CP and AWC, as measures of the anaerobic threshold and anaerobic work capacity) can be estimated from ramp-pattern tests on a cycle ergometer (Morton et al, 1997; Pouilly et al, 2005).

Purpose:

The purpose of this study is to evaluate the validity of AWCd from a single treadmill test as an estimate of anaerobic capacity, by examining the relationship between AWCd and the performance in a field test commonly used to assess anaerobic capacity, the 300 yard sprint test.

Methods:

Fourteen basketball players (24.6+/-3.5y, 193+/-10 cm), members of the national team, performed an incremental running test on a treadmill (with 1km/h increments per minute, at a constant inclination of 1.5%) to volitional exhaustion, in order to determine the ventilatory AnT, VO2max, Vmax and AWCd. On a separate day, they performed a maximal 300 yard sprint, as a criterion measure of the anaerobic capacity. Pearson's correlation coefficient was calculated for the relationship between distance run above the speed that corresponds to the AnT up to Vmax, and the speed in the 300 yard sprint test.

Results:

The ventilatory anaerobic threshold was achieved at the running speed of 13.1+/-1.1 km/h (85+/-4% VO2max), the VO2max was 54.3+/-4.4 ml/kg, and the maximal running speed at exhaustion was 18.0+/-1.7 km/h. The distance run in the ramp test above the ventilatory AnT to exhaustion was 247.3+/-101 meters, while the average speed in the 300 yard sprint test was 17.5+/-0.9 km/h. A moderate, but statistically significant correlation was found between AWCd and the result in the 300 yard sprint (r = 0.55, p<.05).

Conclusion:

The results of this study suggest that the distance run above the ventilatory anaerobic threshold in a ramp-pattern treadmill test is related to performance in the 300 yard sprint, and the ability to perform high-intensity exercise. AWCd thus can provide additional information in incremental treadmill tests, as a measure of anaerobic running capacity.

RELATIONSHIP BETWEEN REFLEX EXCITABILITY IN SOLEUS MUSCLE AND ENDURANCE PERFORMANCE IN NORMAL POPULATION

Piscione, J., Grosset, J.F., Rosant, C., Pérot, C.

Université de Technologie de Compiègne, France

The Hoffmann reflex, which informs about excitability of the motor pool and synaptic efficacy, has been commonly analysed in the case of exercise studies (Zehr, 2002). The H-reflex has been found to be higher in long term endurance-trained athletes than in power-trained athletes (Maffiuletti et al., 2001) and to change after endurance training (Pérot et al., 1991). However, we may wonder if this parameter could allow differentiating no specifically trained individuals having various aerobic endurance performances. In the present study, we investigated relationship between H-reflex in soleus muscle and endurance performance in normal population. Forty five university students, sedentary or having a light recreationally physical activity, took part in the study. Aerobic endurance performance was assessed using an indirect continuous running multistage field test, the Université de Montreal track test (Leger and Boucher, 1980), which allowed the estimation of the maximal oxygen uptake (VO2max). Recruitment curves of both H-reflex and motor response (M-wave) were determined in soleus muscle by electrical stimulations of the tibial nerve in the popliteal fossa (stimulation intensity: 0 to intensity inducing the maximal M wave (Mmax); stimulation frequency: 0.2 Hz). Recruitment curves were normalised in amplitude to Mmax and in intensity to the recruitment threshold of M-wave (Mth). Recruitment threshold, increase slope and maximal value of H-reflex (respectively Hth, Hslope, Hmax) and slope of M-wave (Mslope) were determined. Decrease slope of H-reflex (H-slope) and stimulation value for its extinction (Hext) were also characterised. Relationships between each parameter of the recruitment curves and VO2max were assessed using correlation Z test. No significant correlations were shown between respectively Hth (R = 0.062, p = 0.34), Hslope/Mslope (R = -0.002, p = 0.99), H-slope/Mslope (R = -0.308, p = 0.08) and VO2max. On the other hand, a significant correlation between Hmax and VO2max was found (R = 0.342, p = 0.02). More significant correlations were revealed for both Mslope and Hext with the endurance performance parameter (respectively R = 0.490, p < 0.01 and R = -0.471, p < 0.01). Amplitude of H-reflex has been shown to be mainly due to the activation of slow-twitch motor units. This type of motor unit being more adapted for endurance exercise this can explain the positive relation between Hmax and VO2max. Moreover Mslope and Hext could estimate homogeneity in motor unit content within muscle (Hugon, 1973). Thus these parameters could also emphasize endurance muscle capacity.

HEART RATE KINETICS IN TENNIS PLAYERS DURING A 2 MIN GROUNDSTROKE RALLY

Cereda, F., Serena, E., Griner, R., Mondoni, M., Mognoni, P.

Università Cattolica di Milano, Italy

The tennis players have a different physiological profile according to their defensive or offensive type play. Defensive players prefer to hit the balls from the baseline and the mean time of each rally was reported to be 8.2±5.1 s (±SD), i.e. significantly longer than that of offensive players (1). Even in defensive players the effective playing time was less than one third of the total time of a match and the heart rate (HR) changes during actual playing were moderate. We designed a simple and low cost specific test to evaluate the cardiovascular stress in "false" rallies in which couples of players of similar technical level were asked to hit shots as hard as possible parallel to the sidelines for 2 min.

Players were asked to play the balls to the center of the court. HR was continously recorded over 5-s intervals with the aid of a Polar Sport Tester (Polar, Finland). In case of wrong shots a new ball was immediately put on the court. The peak ball velocity of 5 or more shots was measured by means of a radar Stalker ATS SystemTM (Minneapolis, MN, US). A 5 min pause of seated rest was interposed between rallies. The entire experimental session lasted about 50 min. Only forehand (FH) or backhand (BH) strokes were carried out in each of the six rallies. After a week from field measurements the relationship between HR and mechanical power were measured during an incremental walk on treadmill with increasing speed and constant slope (12%). Four players of each gender were studied and all of them took part to official amateur tournements of low or medium level. The mean maximal HRs of males and females were 189.3±8.1 and 193.0±4.3 b/min. No difference in HR kinetics were noted in FH and BH and data were pooled. HR increased in exponential way, the half times being 28.8±10.3 and 31.1±6.3 s, for males and females respectively. The corresponding half times during recovery were 88.5±26.8 and 99.8±32.2 s. The HR kinetics at onset and offset were significantly different (p<0.001) in both genders. The mean HRs in the last 20 s of each rally were 163.5±14.4 and 173.8±3.1 b/min in males and females (p=0.07). At the same HRs the mechanical powers during uphill walking were 195.3±10.0 and 112.7±16.1 W (p<0.001). The strokes per 2 minutes were 82.8±2.6 and 66.2±3.6 (p<0.001) and the corresponding peak ball speeds 106.7±5.3 and 84.3±5.5 km/h. In one subject the ball speed was significantly higher during FH and in two subjects during BH (two hands BH). In summary the cardiovascular stress was similar in both sexes in a 2 min tennis drill while the performance was significantly different.

RELATIONSHIP AMONG AVERAGE ANAEROBIC POWER, FATIGUE INDEX AND AVERAGE SERVICE SPEED IN ADOLESCENT TENNIS PLAYERS: AN EXPLORATORY ANALYSIS

Beisiegel, M., Conte, M., Leitão, M.T., Bergamo, V.R.
Escola Superior de Educação Física de Jundiaí, Brazil

In field tennis there is a predominance of aerobic resistance during a match; on the other hand, service speed and precision are also important for the definition of a set. Therefore, the purpose of this study was to verify the correlation of Average Anaerobic Power, Fatigue Index and Average Service Speed of teenage tennis players. Eight boys (average age 13.87 + 1.95 years) from Jundiai, São Paulo, Brazil were evaluated. The test for determining Average Anaerobic Power (PAM) and Fatigue Index (IF) was adapted from the Rast Test and from the Anaerobic Endurance Tests (Tennis Specific Agility Test - International Tennis Federation). Average Service Speed (VMS) was determined through a radar gun, and consisted of six series of two services that were served between each anaerobic sprint. The main results show a positive correlation r = 0.8839 ($p<0.01$) between PAM and VS, but no significant differences were observed between IF and VS (r = 0.6422), and between PAM and IF (r = 0.6640). The data obtained suggest that in the evaluated group the players with best PAM showed higher service speed, however those who showed a lower fatigue index not necessarily presented higher average service speed or maximum anaerobic power. Finally, the interaction among the metabolisms for the production of anaerobic energy can be observed in the correlation between PAM (glycolytic system) and VMS (ATP-CP system), which is an important aspect for the performance in field tennis.

THE EFFECT OF EXERCISE DURATION ON CALF VOLUME DURING UPPER BODY EXERCISE

Bottoms, L., Carson, R.J., Price, M.J.
Coventry University, United Kingdom

During upper body exercise calf volume decreases with the rate of decrease being slower at 10 minutes when compared to 5 minutes of exercise1. Furthermore, a decrease in calf temperature has been observed during prolonged upper body exercise suggesting that the lower body plays an important thermoregulatory role2. Therefore, the purpose of this study was to examine the effect of exercise duration on changes in calf volume and skin temperature during upper body exercise and recovery.

Eight healthy male subjects (not upper body trained) volunteered for the study, which had received ethical approval. Subjects undertook a seated incremental exercise test to exhaustion on an arm crank ergometer to determine peak power output (Wpeak). Three further trials were conducted in a randomised cross-over design consisting of arm exercise at 60% Wpeak (70 rev.min-1) for either 15, 30 or 45 minutes duration followed by 30 minutes of passive recovery. Aural and skin temperatures (calf, thigh, chest, upper arm, back, and toe) were recorded, as well as heat flow of the upper arm, chest, thigh and calf. Calf volume and blood flow were measured using venous occlusion plethysmography at rest, immediately after exercise, and every 5 minutes during recovery. Expired air analysis was undertaken using an online breath-by-breath gas analysis system. Blood lactate was measured from earlobe capillary samples pre and post exercise. Heart rate (HR) was continually monitored. Data were analysed by separate two factor repeated measures analysis of variance (time x trial) between trials for the first 15 minutes of exercise, between end of exercise values and passive recovery values.

Oxygen consumption (VO2) and HR were similar during the first 15 minutes of exercise, however HR continued to increase during the 30 and 45 minute trials ($P<0.05$). There were no differences in end-exercise VO2 or blood lactate values between trials ($P>0.05$). Calf volume decreased by -1.6±0.6, -2.2±1.0 and -2.2±0.9% during the 15, 30 and 45 minute trials, respectively ($P<0.05$), reaching a plateau by 15 minutes of exercise in all trials. Heat flow from the upper arm increased during exercise with duration and decreased immediately post exercise. Upper arm skin temperature increased during exercise in all trials ($P<0.05$) reaching a plateau at 15 minutes with no differences between trials ($P>0.05$). Although calf skin temperature remained constant during exercise in each trial values decreased during recovery ($P<0.05$) with greater deceases observed during the 30 and 45 minute trials compared to 15 minutes. Calf heat flow remained constant during exercise but decreased during passive recovery in all trials ($P<0.05$). The results of this study suggest a redistribution of blood from the relatively inactive lower body during arm exercise up to 15 minutes after which point calf volume does not significantly decrease further.

HOW DO INSPIRATORY AND EXPIRATORY MUSCLES FATIGUE DURING HEAVY BREATHING?

Verges, S., Renggli, A.S., Notter, D.A., Spengler, C.M.
Institute for Human Movement Sciences, ETH Zurich, and Institute of Physiology and Center of Integrative Human Physiology, University of Zurich, Switzerland

Respiratory muscles are fatigued after intensive hyperpnoea or whole-body exercise (Mador et al. 1996, Johnson et al. 1993). The time course of fatigue development of the different respiratory muscle is, however, unknown. We therefore studied fourteen healthy, young men performing intermittent normocapnic hyperpnoea (HYP), i.e. 8 min HYP (~70% of maximal voluntary ventilation), 6 min pause, etc., until task failure. Twitch transdiaphragmatic (Pdi,tw) and gastric (Pga,tw) pressures were measured during cervical and thoracic magnetic stimulation after full potentiation to assess diaphragm and abdominal muscle fatigue before HYP, after each HYP-interval, at task failure, as well as after 30 and 60 min of recovery. Ventilation, oesophageal (Pes) and gastric pressures (measured by balloon catheters) were recorded continuously during HYP. Inspiratory and expiratory pressure-time products (PTP, an index of respiratory muscle work) were calculated breath by breath. Breathlessness, respiratory effort and blood lactate concentration were assessed before HYP, at the end of each HYP-interval and at task failure. Subjects breathed for 25.3±4.7 min. After 8 min of HYP, Pdi,tw and Pga,tw decreased significantly (-18±12% and -20±7%); after 16 min, Pdi,tw decreased further (-28±7%) while Pga,tw remained unchanged (-21±8%, significantly different vs. Pdi,tw). Both Pdi,tw and Pga,tw did not further decrease until task failure and were still significantly reduced after 60 min of recovery (-9±9% and -9±7%). PTPes,insp / PTPdi,insp (a surrogate for extra-diaphragmatic inspiratory muscle work) increased significantly during the first 16 min of HYP (+11±21%). Similarly, PTPes,exp / PTPga,exp (a surrogate for rib cage expiratory muscle work) increased significantly during the first 8 min (+10±16%). No further change in PTP was observed until task failure. Breathlessness (+1.6±1.8 points), respiratory

effort (+5.9±2.2 points) and blood lactate concentration (+1.1±0.4 mmol·l-1) increased significantly during the first 16 min of HYP with no further increase thereafter. We conclude that, during hyperpnoea, contractile fatigue of the diaphragm and abdominal muscles develops long before task failure and is likely compensated by increased recruitment of rib cage inspiratory and expiratory muscles to maintain target ventilation.

EFFECT OF (-)-HYDROXYCITRATE CO-INGESTED WITH CAFFEINE ON FAT AVAILABILITY DURING EXERCISE IN HUMANS

Kuno-Mizumura, M., Haruyama, T., Miyashita, M.

Ochanomizu University, Japan

Previous study reported that (-)-Hydroxycitrate (HCA) ingestion can reduce malonyl-CoA concentrations and consequently increase fatty acid oxidation in vivo. However, no studies investigated the effects of HCA and co-ingestion of other supplements, such as caffeine, while co-ingestion might have greater effect on glycogen-sparing than HCA alone at rest or during exercise. The purpose of this study was to investigate the acute effects of co-ingestion of HCA and caffeine on fat availability during low intensity exercise in healthy university students. We examined the effect of HCA co-ingested with caffeine for nine healthy Japanese university students (6 females, 3 males) who performed a random order of four experimental trials consisting of 120 min of steady-state walking on a treadmill at 50 % of maximal oxygen consumption. Fifteen minutes before exercise subjects ingested either 100mg caffeine (CAF), 1200mg HCA (HCA), 1200mg HCA ＋ 100mg caffeine (HCA+CAF), placebo which contained no HCA and CAF, but the same amounts of calories (CON). Oxygen consumption (VO2), respiratory quotient (RQ), and heart rate were measured both at rest and during exercise by K4b2 (Cosmed, Italy). During exercise, blood lactate concentration and RPE were also measured every ten minutes. The ingestion of 1200mg HCA was equal to 21.8±3.5mg/kg and that of 100mg caffeine was equal to 1.8±0.3mg/kg. At rest, there was no significant difference in measured parameters among four experimental trials. VO2 at 30 min, 60 min, 90min, and 120 min was significantly higher in HCA＋CAF than either HCA or CAF. RQ at 30min, 60min, 90min, and 120min was significantly lower in HCA＋CAF than the rest three trials. Significant higher VO2 and lower RQ during exercise with HCA＋CAF would suggested HCA co-ingested with caffeine would induce higher sympathetic nerve activity during exercise. From the results of this study, it is concluded that HCA co-ingested with caffeine has an additive effect on substrate utilization than that by the ingestion of HCA or caffeine alone.

TIME COURSE OF IMPROVEMENT IN ENDURANCE PERFORMANCE DURING ALTITUDE ACCLIMATIZATION

Schuler, B., Thomsen, J.J., Gassmann, M., Lundby, C.

University of Århus, Århus, Denmark

This study tested the hypothesis that maximal O2 consumption (VO2max) and performance increases upon acclimatization to moderate altitude. Therefore, rest capillary blood parameters and exercise performance of eight elite bike racers was evaluated on five different occasions: (1) At sea level, (2) after 1 day of exposure to 2340m altitude and again at the same altitude after (3) 7, (4) 14, and (5) 21 days of altitude exposure. Training intensity and volume was controlled two weeks prior to the experiments, and did not change throughout the study. All training was performed at sea level. Daily iron supplementation (100 mg) was stated two weeks prior to altitude exposure.

Compared to sea level, arterial oxygen content decreased at 1 day at 2340m but increased over time at altitude. VO2max and time to exhaustion decreased on day 1 as compared to sea level, but increased gradually over the next weeks, but always remained lower than the sea level values. The highest improvement was observed between 7 days and 14 days during the altitude acclimatization. We conclude that endurance athletes competing at altitude around 2340m should arrive to this altitude at least 14 days prior to the competition.

VENTILATORY PARAMETERS IN LONG DISTANCE AND SPRINT RUNNERS DURING INCREMENTAL EXERCISE

Soric, M., Vucetic, V., Rakovac, M., Sentija, D.

Faculty of Kinesiology, University of Zagreb, Croatia

It has been shown that ventilatory parameters during incremental exercise differ between athletes and sedentary individuals (1), and even between elite amateur and professional athletes (2). Therefore, the goal of this study was to examine if those differences exist in athletes with different metabolic demands.

A group of 10 male sprinters (S), representing anaerobic, and 10 male long distance runners (LD), representing aerobic athletes, participated in the study. Groups differed significantly regarding age (mean + SD): years 27,4 ± 7,4 vs. 20,5 ± 3,0 years , height: 177,6 ± 6,6 cm vs. 184,9 ± 4,8 cm and weight: 67,6 ± 6,4 kg vs. 76,6 ± 4,3 kg, for LD and S respectively. Before exercise all subjects performed spirometry in the up-right position. Groups were not statistically different regarding forced vital capacity (FVC): 6,1 ± 0,8 L and 6,2 ± 0,6 L, LD and S, respectively. Both groups then completed an all effort minute incremental step protocol test on treadmill. Ventilatory parameters were observed at maximum exercise intensity (MaxPO) and at anaerobic ventilatory treshold (AnT). As expected, groups differed regarding both VO2max (4,8 ± 0,5 vs. 4,4 ± 0,3 l/min,) and AnT (4,0 ± 0,4 vs. 3,7 ± 0,3 ml/min,), for LD and S, respectively.

No significant differences were observed for minute ventilation, tidal volume or breathing frequency at MaxPO or at AnT. Ventilatory equivalents for O2 (VE/VO2) and CO2 (VE/VCO2), as well as end tidal pressures (PetO2 and PetCO2), also were not significantly different at AnT. However, those parameters did differ between groups at MaxPO. Long distance runners exhibited lower VE/VO2 - 33,0 ± 2,4 and VE/VCO2 - 28,6 ± 3,1 than sprinters - 36,2 ± 3,5 and 32,1 ± 3,9, respectively. Regarding end tidal pressures at MaxPO, long distance runners exhibited lower PetO2 (109,8 ± 2,7 vs. 112,8 ± 3,3 mmHg) and higher PetCO2 (40,2 ± 4,5 vs. 36,1 ± 4,1 mmHg), than sprinters.

In conclusion, we observed no differences in ventilatory parameters between long distance runners and sprinters during exercise below anaerobic threshold. After this point, also called respiratory compensation point, LD exhibited lower ventilation for given O2 uptake and CO2 output. This relative hypoventilation in LD is probably due to lower acidemia. Although we did not measure arterial gases, lactate levels at the end of exercise were, indeed, significantly lower in long distance runners (10,1 ± 2,4 mmol/L) than in sprinters (15,0 ± 2,9 mmol/L).

SERUM ANGIOTENSIN CONVERTING ENZYME ACTIVITY AND PLASMA NITRIC OXIDE LEVEL DURING ACUTE EXERCISE IN FOOTBALL PLAYERS

Nakas-Icindic, E., Hadzimuratovic, A., Hadzovic-Dzuvo, A., Huskic, J., Avdagic, N.

Medical Faculty, Bosnia and Herzegovina

Angiotensin converting enzyme (ACE), as a part of renin-angiotensin system, is involved in production of potent vasoconstrictor angiotensin II. Physical activity stimulates the renin angiotensine system. Nitric oxide (NO) is unstable gas radical released from endothelial and other cells in basal conditions and in response to various physiological and pharmacological stimuli. ACE and NO are involved directly or indirectly in cardiovascular response to acute or chronic physical activity. Results of animal experiments showed that NO negatively modulated renin angiotensine system, while angiotensin II positively stimulated synthesis and releasing of NO (1). There was no secure evidence on this relation in humans. The aim of our study was to estimate the correlations among serum ACE activity and NO level during acute exercise in professional athletes.

Eight healthy, young, male volunteers, professional football players carried out dynamic exercise 12 minutes lasting, in upright, sitting position on bicycle ergometer under the protocol of continuous work load (3 W/kg) and cycling rate 60 RPM. Blood samples were collected in the period of rest, during exercise and in the recovery period. The serum ACE activity was determined by spectrophotometric method (2). The plasma NO level has been determined by means of nitrate and nitrite production measurement, using classical colorimetric Griess reaction (3). Results are showed as mean +/- SEM. The t-test for small dependent samples was used for evaluation of differences inside the group. The correlation level between the variables was determined by Pearson s coefficient of correlation.

No statistically significant changes in serum ACE activities were found either during exercise or in the recovery period compared with basal values. Miura et al. (2) also found no changes in serum ACE activity after acute exercise lasting 30 minutes. During exercise, the plasma NO level statistically decreased compared to NO level in the period of rest. The findings of present study indicate that acute exercise may decrease the plasma NO level during exercise. The plasma NO level starts to increase immediately after the end of exercise. At the end of recovery period it was not significantly different from the basal values, although Franco et al. (3) found the significant increase in plasma NO level after 10 minutes of acute exercise. We did not found any correlation among serum angiotensin converting enzyme activity and plasma nitric oxide level during acute exercise in football players.

PHYSIOLOGICAL DETERMINANT OF YO-YO INTERMITTENT RECOVERY TEST IN YOUNG BASKETBALL PLAYERS

Castagna, C. 1+2, Impellizzeri, F.M. 3, Rampinini, E. 3, Marini, M. 1, D'Ottavio, S. 2, Manzi, V. 2

1 Scuola Regionale dello Sport delle Marche, CONI, Ancona, Italy, 2 School of Sport and Exercise Sciences, Tor Vergata University, Rome, Italy, 3 HPL Sport Service MAPEI, Castellanza, Italy, Italy

Yo-yo intermittent recovery (Yo-yo) test has recently been proposed to test team-sport players' endurance. To our knowledge no study has carried out in order to test relevance of Yo-yo to basketball. Therefore the first aim of this study was to examine the relationship between the Yo-yo test and laboratory aerobic-fitness parameters, in well-trained basketball players (population validity). Secondly to assess the degree of association between Yo-yo performance and game-related physical-performance (McInnes, Carlson et al. 1995) to examine test specificity. Twenty-two basketball-players (Stamura Basket, body mass 72.4 ± 11.4 kg, height 181.7 ± 6.9 cm, and age 16.8 ± 2 yrs) were tested for Yo-yo, VO2max, ventilatory threshold (VT), running economy (RE, VO2 at 8 km h-1) and speed attained at VO2max (MAS) on a motorized-treadmill. Gas analysis was performed using a portable gas analyzer (K4b2, COSMED, Rome, Italy). Game-related physical performance was assessed before and after an experimental basketball game (Hoffman, Nusse et al. 2003). Players VO2max, MAS, VT and Yo-yo performance values were 60.4±5.1 ml kg-1 min-1, 40.2±4.7 ml kg-1 min-1 and 1678±397m respectively. Yo-yo performance resulted significantly correlated with VO2max ($r=0.77$, $p<0.001$) and MAS ($r=0.71$, $p<0.001$). During the first and the second half of the experimental-game, players attained 86.2±5.3 and 86.7±4.3% of the individual HRmax, respectively ($p=0.42$). Average experimental-games blood lactate concentration was 3.72±1.39 mmol l-1. Yo-yo was related to pre-post Line-drill (LD) decrements ($r= -0.51$, $p=0.04$). These findings support the likelihood of basic physiological association between Yo-yo performance and the individual level of aerobic-fitness in basketball players. Although observations were made using an experimental-game, the intensity attained by players during competition is in line to what reported for professional basketball players during highly competitive games (McInnes, Carlson et al. 1995). This supporting the validity of the research design devised for this investigation. Being LD considered as a basketball-specific test, the existence of a significant although moderate association between Yo-yo performance and LD post-game decrements promote the relevance of Yo-yo to basketball. Given that, Yo-yo may be regarded as an interesting basketball-specific field-test for specific-endurance. However in order to fully validate Yo-yo test, it should be compared with selected game-activities through sound match and time-motion analysis.

EXERCISE INDUCES BDNF INCREASE IN HUMANS

Rojas Vega, S., Strüder, H.K., Vera-Wahrmann, B., Vafa, R., Im, J.Y., Hollmann, W.

German Sport University Cologne, Germany

Introduction: Brain derived neurotrophic factor (BDNF) and cortisol (COR) have impact on neurogenesis in the brain and directly change its basic structure and morphology. BDNF was shown to promote and improve neuronal plasticity, while chronically elevated COR levels inhibit it. Earlier studies have reported increased serum BDNF after exercise (1) and a recent study confirms this finding in humans (2). The aim of the present study was to investigate the effect of short-term aerobic exercise and ramp incremental cycle ergometry to exhaustion on the acute response of the serum concentrations of brain derived neurotrophic factor (BDNF) and cortisol (COR).

Methods: Eight healthy male volunteers participated in the study. Venous and capillary blood samples were drawn and alterations of lactate, arterial blood gases as well as serum BDNF and cortisol (COR) concentration were measured before (-50), after a 10 min warm-up period (0) after the end of a ramp test (E) and at 3, 6, 10 and 15 min during the recovery.

Results: Capillary blood lactate (LA) concentration and blood gases as well as serum BDNF and COR concentrations did not change during the warm-up period. LA was increased ($p<0.05$) at the end of the ramp test and during the recovery period while bicarbonate concentration, carbon dioxide pressure, pH and base excess were decreased ($p<0.05$) during this period. Serum BDNF was increased at the point of exhaustion ($p<0.05$) while no significant differences were found between values at rest and during recovery period. At 10 and 15 min post incremental exercise COR concentrations increased ($p<0.05$) compared to COR concentrations at rest.

Discussion: The novel finding of this study is that moderate aerobic exercise over 10 min does not affect blood BDNF concentration whereas a following ramp incremental exercise to exhaustion of similar duration increases blood BDNF concentration, pointing to exercise-intensity dependent transient neurotrophic factor induction in humans. The present study also shows that the acute response to high intensity exercise differs between BDNF and COR. Augmented BDNF secretion under exercise does not occur along with changes in blood gases while COR increases concomitant with alterations of blood gases. The augmented exercise-induced BDNF production could result in an increased entry of the neurotrophin into the CNS as demonstrated in vitro. This could allow an influence of the trophin on the central receptors promoting and improving brain neuroplasticity.

THE EFFECT OF OFFICIAL HANDBALL COMPETITION ON SALIVARY IMMUNOGLOBULIN A AND TOTAL PROTEIN IN ELITE FEMAIL HANDBALL PLAYER

Yazdanparast Chaharmahali, B., Azarbaijani, M.A., Talebi, Z.

Islamic Azad University, Varamin branch, Iran

There is growing evidencethat physical exercise and psychological stress can influence cellular and humoral immuno function. Salivary immunoglobulinA (sIgA) by plasma cells in the submucosa is one characteristic humoral factor of the local immune system of the upper respiratory tract, where sIgA is acting as the first line defiance against bacteria and viruses. Many investigators in last 2 decades have performed some serial studies both sport and non sport situation. But there are many so much conflicts in previous studies,Therefore present study was designed to investigate the effect of a real stress situation on salivary IgA and total protein concentraction following handball competition. 7 healthy female elite handball player members of HOMA club participated as a subjects in this study.All were informed about protocol and gave written consent. 5ml unstimulared whole saliva sample were collected 15 min before and 5mint after four league games. Before saliva sampling, subjects were rinse out their mouths with water to remove any substances that may affected sIgA,and total proteins, all samples were kept frozen at -20 degree centigrade until use.sIgA and total protein concentration were measured in duplicate by Neflometry and Bradford method respectively.Means and standard deviations were calculated for all comparison were used to determine significant differences.The level of significance was set at $p<0.05$.The findings of the research are as follow: Concentrations of sIgA significantly decreased after fourth game incomparesion base line(before first game). Cncentrations of total protein went through parallel changes during competition. In summary, these results show that in elite female handball players competition stress elevates sIgA and total protein concentrations, indicating that spesific humoral immune function are decrease by acute physiological and psychological competition stress.

RECOMBINANT HUMAN ERYTHROPOIETIN TREATMENT (R-HUEPO) INCREASES MAXIMAL OXYGEN UPTAKE IN MILD AND MODERATE ACUTE HYPOXIA

Robach, P., Juhl Thomsen, J., Mollard, P., Calbet, J.A., Boushel, R., Lundby, C.

Ecole Nationale de Ski et d'Alpinisme, 74401 Chamonix, France; and The Copenhagen Muscle Research Centre, Rigshospitalet, 2200 Copenhagen N, Denmark, France

Background: In a normoxic condition, prolonged treatment with recombinant human erythropoietin (r-HuEPO) enhances maximal oxygen uptake (VO2max). However, if the incremental exercise is performed in acute hypoxia (above 4,000m) there is no effect of r-HuEPO on VO2max. Thus, there should be an altitude threshold - between 0 and 4,000m – at which the VO2max enhancing effect of r-HuEPO evanishes. The effect of mild/moderate hypoxia on maximal aerobic performance after r-HuEPO has not been investigated, even though several competitive aerobic sports take place in a mild hypoxic environment. Therefore, the aim of this study was 1) to verify that the advantage conferred by r-HuEPO on VO2max at sea level persists during mild and/or moderate hypoxia, and 2) to locate the altitude threshold beyond which r-HuEPO would be inefficient.

Methods: Seven male subjects (VO2max = 52 ± 6 ml.min-1.kg-1) were investigated before and after having received 5000 IU of r-HuEPO every second day for 14 days, and then 5000 IU weekly for the following 14 days. Oral administration of 100 mg iron was initiated 14 days before r-HuEPO treatment started. Red blood cell volume was measured by carbon monoxide rebreathing. Each subject performed five VO2max tests, randomly and in a single-blind manner, one in normoxia and the four others in acute hypoxia corresponding to simulated altitudes of 1,500m, 2,500m, 3,500m and 4,500m. At VO2max, cardiac output was obtained by thoracic bioimpedance, arterial O2 content from capillary blood and lactate from venous blood. Systemic O2 delivery and extraction at VO2max were calculated.

Results: r-HuEPO increased red blood cell volume by 11% ($P<0.05$). The treatment improved VO2max by 5.8% at 0m ($P<0.05$), 8.4% at 1,500m ($P<0.05$), 14.0% at 2,500m ($P<0.05$), 14.7% at 3,500m ($P<0.01$) and 1.4% at 4,500m ($P=0.6$). The r-HuEPO-induced increase in VO2max tended to be higher at 2,500m than at 0m ($P=0.1$) and was higher at 3,500m than at 0m ($P<0.05$). The increase in systemic O2 delivery at VO2max after r-HuEPO (from 14 to 18%) was significant at all the altitudes, except at 4,500m (10%, $P>0.05$). The higher O2 delivery was due to an augmented arterial O2 content and a small increase in cardiac output at VO2max. Systemic O2 extraction at VO2max was reduced with r-HuEPO at 0m and at 4,500m, but not at the intermediate altitudes. Venous lactate at maximal exercise remained unchanged.

Conclusion: The beneficial effect of r-HuEPO on VO2max - observed at sea level - persists at moderate altitudes and VO2max remains elevated at altitudes up to 3,500m after r-HuEPO treatment. The altitude threshold for which the effect of r-HuEPO becomes marginal would be comprised between 3,500 and 4,500m.

EFFECT OF ECCENTRIC EXERCISE ON MUSCULAR DNA DAMAGE IN RAT

Tadano, C., Yona, M., Tajima, T., Seki, H., Muro, M.

Toho university school of medicine, Japan

Introduction

Vigorous exercise induces an increase of oxidative DNA damage evoked by endogenously generated reactive oxygen species (ROS). The DNA damage is frequently observed with muscle damage indicated by circulatory creatine kinase (CK) response. However, direct evidence of the DNA damage is not so clear in skeletal muscle. In this study, we examined the relationship between muscular oxidative DNA damage and exercise induced muscle fiber damage.

Methods

Male wistar rats (10-14 wk) were used in this experiment. The animals were divided into sedentary controls and downhill (-17 degree incline, DH) exercise rats. The DH rats performed an intermittent protocol at 25 m/min for a total of 90 min (5-min bouts separated by 2-min rest, 18 bouts) on a treadmill. Hindlimb muscle samples, including red portion of medial gastrocnemius (GMR), white portion of medial gastrocnemius (GMW) and soleus (SOL) were collected under anesthesia at specific points of recovery and were quickly frozen in liquid nitrogen. Blood samples were concomitantly collected. All samples were stored at -80 degree until analysis. DNA was extracted from the muscle specimens and treated with enzymes to isolate a nucleoside. The 8-hydroxy-2'-deoxyguanosine (8-OHdG) and 2'-deoxyguanosine (dG) were determined with HPLC as an index of the muscular oxidative DNA damage (8-OHdG/dG). Lipid hydroperoxide (LH) content of the muscles was determined. Muscular glutathione contents, and glutathione peroxidase (GPX), glutathione reductase (GR), superoxide dismutase (SOD) activities were also determined. Plasma CK activity was determined as a common indicator of muscle damage.

Results

Plasma CK showed a 2-3 times increase in immediately post-, 24 h post-, and 48 h post-DH exercise. Muscular 8-OHdG/dG level showed a 2-5 times increase from that in the control after DH exercise in GMR, GMW, SOL at those points. The 8-OHdG/dG responses were different from each other. However, it seemed that any responses followed the CK response at the same time points. LH content slightly increased in these muscles. The levels of glutathione, GPX, GR, SOD were different between muscles and portions (SOL>GMR>GMW). These antioxidants correlated with LH. However, 8-OHdG/dG level was not correlated with LH or any antioxidants.

Discussion and Conclusion

Eccentric exercise induced muscular oxidative DNA damage, suggests an involvement of muscle damage to the muscular DNA damage in an intense exercise. Although there were many differences in the antioxidant capacity between muscle types and portions, an acute increase in muscular DNA damage appeared to be independent on the antioxidant capacity in this experiment. The data suggests a weak response of antioxidant system to an acute ROS generation in skeletal muscle in exercise.

THE RELATIONSHIP BETWEEN STATIC AND DYNAMIC LUNG VOLUMES AND BREATH HOLDING TIME IN PREPUBESCENT SWIMMERS

Evangelidis, P., Theos, A., Bogdanis, G.C., Maridaki, M.

University of Athens, Greece

Introduction

In many sports, athletes perform strenuous exercise while holding their breath or breathing in a controlled way (Bjurstrom et al., 1987). Larger lung volumes may enhance performance under these conditions, providing a greater gas exchange reservoir. The purpose of this study was to examine whether static and dynamic lung volumes are related with breath holding time in experienced prepubescent swimmers.

Methods

Seventeen prepubescent children (11 boys and 6 girls; age: 10.6±0.2 years, height: 145±2 cm, mass: 39.4±1.9 kg) were tested in this study. All subjects were swimmers with at least four years of training experience. Forced Vital Capacity (FVC) and Forced Expiratory Volume in 1 sec (FEV1) were measured in a seated position with a Vitalograph spirometer. Two days later participants performed a breath-holding test in the laboratory. Breath holding was performed in a seated position without prior hyperventilation. After a 5-min rest period subjects repeated the procedure and the best time for each subject was recorded. Predicted values for FVC and FEV1 were calculated using Dickman's equations (Dickman et al., 1973).

Results

The measured FVC and FEV1 were 2.67±0.13 and 2.38±0.10 lt respectively. These values were 121±6 % and 124±5 % of the age-matched predicted values. Breath holding time (59±6.4 sec) was significantly correlated to FVC ($r=0.78$, $p<0.001$) and FEV1 ($r=0.80$, $p<0.001$).

Discussion

This study showed that prepubescent swimmers had higher FVC and FEV1 compared with age- matched predicted values for reference children (Dickman et al., 1973). Therefore swimming training at an early age may lead to increased static and dynamic lung volumes. Furthermore, the ability of breath holding may be influenced by lung volumes as indicated by the relationship between breath holding time and FVC and FEV1 values.

PERFORMANCE AND METABOLISM IN REPEATED SHORT-SPRINT EXERCISE: EFFECT OF RECOVERY INTENSITY

Spencer, M., Dawson, B., Goodman, C., Dascombe, B., Bishop, D.

The Univeristy of Western Australia, Australia

We have recently reported that active (~32% of VO2max), compared to passive recovery impairs repeated, short-duration, sprint ability(1). This impairment was associated with a lower [PCr] and a significantly higher [MLa-] when an active recovery was performed between sprints(1). While it has not been previously investigated, it is possible that there may be an intensity affect of active recovery on metabolism and subsequent performance due to differences in the oxygen cost of the exercise and therefore, the resynthesis of PCr, which has been associated with sprint performance(2). Alternatively, as muscle activation is required for the initiation of glycolysis(3), active recovery, regardless of intensity, may result in greater [MLa-] and impaired performance. Therefore, the purpose of this study was to investigate the effect of a low-intensity (LI) versus a moderate-intensity (MI) active recovery (with passive recovery as the control) on sprint performance and metabolism, during a repeated-sprint test that mimics the sprint and recovery durations commonly seen in team sports. These intensities were chosen as the majority of active recovery undertaken during repeated-sprint bouts is reported to be of a 'jogging' or a 'walking' intensity(4). Methods. Nine moderately-trained males performed three repeated-sprint cycle tests (6 x 4-s sprints, every 25 s) in a randomized, counter-balanced order. Recovery after each of the sprints for the MI and LI trials respectively were 60 W (~35% VO2max) and 20 W (~20% VO2max). Needle biopsy samples were taken from the vastus lateralis pre-test and immediately post-test during the MI and LI trials to determine [ATP], [PCr] and [MLa-]. Results. Compared to the passive trial, significant reductions in peak power outputs were recorded in both the MI trial (4 of the 6 sprints; $P < 0.05$) and in the LI trial (2 of the 6 sprints; $P < 0.05$), with no differences between the two active trials. There were no significant differences for total work between the passive, MI and LI recovery trials (255.6 ± 41.5, 245.6 ± 30.5 and 245.2 ± 29.5 J•kg-1, respectively). Furthermore, no significant differences were evident in delta change for [ATP] (3.9 ± 3.5 v 3.4 ± 2.3), [PCr] (39.9 ± 17.6 v 37.8 ± 15.6) and [MLa-] (41.9 ± 24.5 v 46.2 ± 19.8) between the MI and LI active recovery trials, respectively. Conclusions. In summary, peak power indices during the repeated-sprint test were inferior in the MI and LI active recovery trials, in comparison to passive recovery. The similar changes in performance and metabolites between the two active recovery trials suggests that muscle activation is an important factor in recovery during repeated-sprints and that any low-to-moderate level of activation may affect recovery during repeated, short-sprint bouts.

CALF-TOE SKIN TEMPERATURE DIFFERENCE DURING COLD EXPOSURE

Kocjan, N., Mekjavic, I.B.

Jozef Stefan Institute, Slovenia

Calf-Toe skin temperature difference during cold exposure

Nina Kocjan1, Igor B. Mekjavić1

1 Department of Automation, Biocybernetics and Robotics, Jozef Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia

Freezing and non-freezing cold injuries occur primarily in the toes. The cause of such an injury is a cold induced decrease in tissue perfusion. The present study investigated protection from cold injury offered by two different types of hiking boots, by monitoring toe perfusion, as reflected in the calf and toe skin temperature gradient (Tsk-diff), during a 3 hour cold exposure. A total of 10 subjects participated in the study. They were divided into two groups, each wearing a different type of hiking boot. The mean (SD) age, height and weight of the subjects wearing boot A were 33 (6), 177.3 (9.2), 77.2 (6.4), respectively. The mean (SD) age, height and weight of the subjects wearing boot B were 26 (2), 183.5 (8.1), 78.5 (14.0), respectively. Subjects were requested to stand still in a snow covered area for 3 hours. Mean skin temperature (Tsk) was calculated from arm, chest, thigh, calf and back body sites. Calf and toe temperatures (Ttoe) were used to calculate the Tsk-diff. The Tsk-diff response was characterized by its amplitude (A), time delay (TD) and time constant (τ). During the trials, core temperature (Tc) was monitored with a gastrointestinal radio pill. In addition, the environmental data (ambient temperature, Ta; wind speed, vw; solar radiation, R) were continuously monitored. For boot A, the change in Tsk was -3.4 (1.8) and for boot B -2.5 (1.5) °C, the difference was not significant. There was no significant difference in the amplitude of the Tsk-diff response between the two boots, but there was a significant difference in TD ($p<0.05$) and τ ($p<0.05$) between the two boots. Ttoe was significantly higher in boot A than in boot B ($p<0.05$). There were no significant changes in Tc during the cold exposures. Ta, vw and R were 0.8 (0.7) °C, 116 (30) W/m2 and 0.0 (0.1) m/s during boot A trials, and -2.0 (2.8) °C, 15 (11) W/m2 and 18.8 (8.5) m/s during boot B trials, respectively.

Due to the cold-induced vasoconstriction, as reflected by lower Ttoe and higher Tsk-diff, boot A posed a greater risk for cold injury. Despite colder ambient conditions, the greater TD and higher Ttoe observed in boot B trials, suggests better cold protection offered by this boot. We conclude that lower extremity Tsk-diff and Ttoe during cold exposure reflects the cold protection offered by footwear.

LONG-TERM STRENGTH TRAINING AND SKELETAL MUSCLE DNA-TELOMERE LENGTH

Kadi, F., Ponsot, E., Welin, L., Mackey, A., Kjær, M., Oskarsson, E., Piehl-Aulin, K.

Department of Health Sciences, Sweden

Introduction

Long-term strength training lead to a significant remodelling of several morphological parameters in skeletal muscles together with the activation, proliferation and differentiation of satellite cells in order to sustain muscle fibre hypertrophy and to repair micro-injuries caused by the mechanical stress (Kadi et al. 2005). Considering the important role played by satellite cells in the adaptation of skeletal muscle to exercise and knowing that satellite cells are responsible for the regenerative capacity of skeletal muscle, it is of outmost importance to improve our knowledge on the effects of regular strength training on the regenerative capacity of skeletal muscle. This can be achieved

by the analysis of muscle DNA telomere length, which is an indicator of a cell's potential for further cell division. The aim of this project is to compare muscle DNA telomere length in a population of athletes with a long strength training history compared to a healthy active population

Methods

Five young male athletes (mean age 27 years) regularly involved in strength training were included in the study. They have practised strength training for a period of more than 5 years. They trained 3 to 4 times a week and 5 to 10 hours/week. This group has been compared to an age-matched group of healthy active individuals not involved in regular strength training. Muscle biopsies were taken from vastus lateralis muscle. Total DNA extraction is achieved by incubation in proteinase K digestion buffer. The genomic DNA is then digested with a restriction enzyme to generate a smear of DNA fragments containing telomeres with different lengths of the TTAGGG repeat sequence. Mean and minimum telomere length is determined by southern blot analysis. The telomeres are detected by hybridization to a 32P-labelled (TTAGGG)4 probe, followed by exposure to x-ray film.

Results and conclusion

The signal obtained provides a distribution profile of telomeric lengths of all myonuclei and satellite cells present in the tissue. Average telomere length indicates the most frequent DNA telomeric lengths of the tissue whereas the minimal telomere length indicates the shortest DNA telomeric lengths found in the tissue. We found no significant differences between the long-term strength trained individuals and the control group both with respect to the mean telomere length (11.8 ± 1.4 kbp in athletes vs 10.6 ± 0.5 kbp in controls) and the minimal telomere length (5.2 ± 0.8 kbp in athletes and 4.6 ± 0.3 kbp in controls) .

Although strength training is known to alter satellite cell behaviour, the telomere length in long-term strength trained athletes are altered compared to healthy active individuals. The high mechanical stress put on skeletal muscle during long-term strength training is not associated with a decrease in the regenerative capacity of muscle fibres.

CHANGES IN FLUCTUATION PATTERN OF CARDIOVASCULAR SIGNALS DURING SYMPATHETIC ACTIVATION

Kiviniemi, A.M., Huikuri, H.V., Hautala, A.J., Tiinanen, S., Seppänen, T., Mäkikallio, T.H., Tulppo, M.P.

Merikoski Rehabilitation and Research Centre, Finland

Cardiovascular signals as R-R intervals and blood pressure fluctuates at the frequency of ~0.1 Hz known as a low frequency oscillation pattern (LF). The altered LF oscillation of R-R intervals to higher frequencies (>0.1 Hz) is a strong predictor of mortality among cardiac patients (1). However, the physiological background of altered fluctuation pattern of cardiovascular signals is not well known. PURPOSE: To test the hypothesis that LF oscillation pattern of R-R intervals and blood pressure shift to higher frequencies during increased sympathetic outflow. METHODS: R-R intervals, beat-to-beat systolic blood pressure and muscle sympathetic nervous activity (MSNA) from the peroneus nerve were measured for 11 healthy males (age 34±6 years) during 5-min supine rest followed by 5-min isometric handgrip at the intensity of 20% of maximal voluntary contraction. The prevalent LF oscillation was determined by the frequency (Hz) at peak power within LF band (0.04-0.15 Hz) from R-R interval and systolic blood pressure power spectra. The MSNA burst frequency (bursts/min) was analyzed by standard methods. RESULTS: The mean R-R interval decreased (from 1129±197 to 939±108 ms, $p<0.001$) and MSNA increased (from 22±5 to 30±8 burst/min, $p=0.002$) during isometric handgrip as an evidences of increased sympathetic outflow. The prevalent LF oscillation shifted to higher frequencies in both R-R interval (from 0.081±0.014 to 0.097±0.011 Hz, $p<0.001$) and systolic blood pressure (from 0.070±0.017 to 0.094±0.013 Hz, $p=0.002$) during isometric handgrip. CONCLUSION: LF oscillation pattern of R-R interval and blood pressure is shifted to the higher frequencies during sympathetic activation caused by isometric handgrip. The frequency of spontaneous cardiovascular signals fluctuations may provide unique noninvasive information of sympathetic autonomic regulation.

THE EFFECT OF THE NECK MUSCLE RESPONSES TO SUDDEN FALL OF THE HEAD DURING VOLUNTARY- AND TVR-CONTRACTIONS IN MASSETER MUSCLE

Muro, M., Tadano, C., Kamibayashi, K., Seki, H., Shimoshikiryo, S., Oka, K., Yona, M., Naito, Y.

Toho University School of Medicine , Japan

Introduction

It has been demonstrated that stretch reflex in neck muscles play an important role in controlling head righting such as rapid head fall. In rapid head fall, the onset of EMG in sternocleidomastoid (SCM) occur earliest response by a vestibulo-collic reflex. However, it has been reported that the vestibula contribution gives an advantage over stretch reflexes alone and also assists in voluntary enhancement of reflex responses. These advantages could be caused by the activation of the masseter muscle because SCM is synergistic muscle in masticatiory function. The present study was undertaken to clarify the pattern of the reflex responses of the neck muscles to abrupt free fall of head during contractions in masseter muscle.

Methods

Eight healthy subjects participated in this experiment. Subjects were lying supine and well supported on a platform. The head extended beyond the edge of the platform in longitudinal alignment with the body and was supported by a head-platform at the occipital position. The head- platform was released a few times and could be performed manually by a hook. The release at random intervals dropped the head, which then fell freely until it hit a cushioned surface 20 cm from occipital position to the sufficient extended neck. Each drop was performed without the biting force and with the biting force (1kg, 3kg) in voluntary contractions and tonic vibration reflex (TVR) at mandibular tip. Head-acceleration and neck-displacement was measured by using an accelerometer and a goniometer mounted on the mandibular tip and rear neck position, respectively. Muscle activity (EMG) was recorded in the both SCM, masseter, and digastricus muscles. EMG responses of 5 trials were rectified and averaged. EMG latencies were measured from onset of head acceleration and neck displacement.

Results

In biting force of voluntary and TVR's contractions, EMG latency in SCM was about 19.3 ± 7.0 ms but short latency response (stretch reflex) was shorter than without biting force, and short latency in TVR was longer than with volunatary biting force. The EMG amplitudes in-

creased with biting force in both voluntary and TVR's contractions. However, EMG latency and short latency response in digastricus muscle showed the same changes as bite force in SCM. The mean latency between biting force in voluntary and TVR's contractions was 18.2 ± 5.6 ms and 23.4 ± 7.7 ms, respectively.

Discussion and Conclusion

The EMG onset latencies and amplitudes changed with contraction of masseter muscle in free head fall. The results of the synergistic study suggested that the neck muscle reflex was facilitated by readiness to execute head fall task and that the vestibula contribution by contraction in masseter could be an advantage in assisting voluntary enhancement of reflex responses.

THE EFFECT OF TRAINING ON THE RESPONSE OF PLASMA VASCULAR ENDOTHELIAL GROWTH FACTOR TO EXERCISE IN PATIENTS WITH PERIPHERAL ARTERIAL DISEASE

Wood, R.E. 1, Stewart, I.B. 1, Sanderson, B. 2, Askew, C.D. 2+3, Walker, P.J. 2, Green, S. 4

1 Queensland Univeristy of Technology, 2 University of Queensland, 3 University of the Sunshine Coast, 4 University of New England, Australia

Introduction. Peripheral arterial disease (PAD) is a manifestation of atherosclerosis resulting in stenosis of one or more major arteries that supply blood to the lower extremity. During exercise, some patients with PAD experience intermittent claudication (IC), which is pain associated with inadequate blood flow. Exercise training can delay the onset of IC, and improve maximum walking time (MWT) and peak oxygen consumption (VO2peak). This has been shown to occur in the absence of an improvement in blood flow, indicating other factors at the level of the muscle may be involved. Angiogenesis, or expansion of the capillary network with exercise training is well-documented and serves to optimise oxygen transport from the blood to active skeletal muscle fibres. Vascular endothelial growth factor (VEGF), an endothelium-specific mitogen, appears to be necessary for this process. Purposes. The aims of this study were to examine the plasma VEGF response to acute exercise (Part A), and to establish whether exercise training altered this response (Part B) in patients with IC. Methods & Results. Plasma VEGF was determined using high-sensitivity ELISA on blood collected from patients (Part A, n=18) before and after an incremental maximum walking test (+20 and +60 minutes post-exercise). VEGF was present in the plasma of patients but was unchanged in response to acute exercise (rest: 41.39 (28.03-53.22), +20 minutes: 41.94 (29.34-53.94), +60 minutes: 37.22 (28.52-52.79) pg.mL-1, p=0.674, data are median and interquartile range). For Part B, patients were randomly assigned to a treatment group (TMT, n=7) or to a control group (CON, n=6). Three times per week, for six weeks, the TMT group completed intermittent high intensity (80-100% VO2peak) treadmill training. Each session comprised ten, two-minute bouts of exercise with two minutes of rest between each bout. All patients completed an incremental maximum walking test before and after the intervention, with blood samples drawn as for Part A. Training had no effect on plasma VEGF at rest (Week 0: 39.27 (20.57-45.27), Week 6: 27.68 (16.67-47.08) pg.mL-1, p=0.949). The response to acute exercise was also unchanged (p=0.199) despite a significant increase in MWT in the TMT group (15:15+/-8:53 to 20:06+/-8:20 minutes, p=0.009). Conclusions. The major findings of this study were that in patients with IC: 1) acute exercise had no effect on plasma VEGF, and 2) plasma VEGF at rest, and in response to acute exercise, was unaltered by training despite an approximate 45% increase in MWT.

COMPARATIVE PHYSIOLOGICAL ANALYSIS BETWEEN INTERVAL AND INTERMITTENT PROTOCOLS IN TREADMILL

Argemi, R., Ortega Gallo, P., Liotta, G.

Club Atletico Boca Juniors., Argentina

Objectives: The purpose of this study was to compare interval and intermittent protocols in treadmill of 4 youth soccer players from the Athletic Club Boca Juniors.

Methods: On different days with 2 weeks interval between tests. Four 17 year old soccer players perform, in random order, two different incremental tests with velocity increase every 3 minutes.

Both test begun with 8 km/h of velocity and increased 2 Km/h each 3 minute step.

In the Interval protocol (IDO) the player runs 90 seconds followed by 90 seconds of pause.

In the Intermittent protocol (ITE) they run 15 seconds followed by 15 seconds of pause.

We measured Oxygen uptake (VO2) (Sensormedics), Heart Rate (HR) (Polar Xtrainer), Respiratory Quotient (RQ) and blood lactate (Accusport).

Results: The average maximal velocity was 18.5 km/h and 22.25 km/h. in IDO and ITE (p=< 0.001). The average oxygen uptake in the 3 minute step had a correlation of 0.90 between protocols. The correlation of HR, lactate and Respiratory Volume was 0.99, 0.48 and 0.97. The average RQ for both tests was 1 and 0.91 to IDO and ITE. (p =<0,005).

Conclusion: During maximal intermittent exercise we had similar VO2 peak and HR, with less RQ and lactate than with the interval protocol and the final velocity reached was greater.

For the same VO2 and HR was less lactate and RQ, and more velocity during intermittent protocol; the exercise lipid substrate was 35 % of the total substrate, vs. great percentage of carbohydrate in the interval exercise.

PRE-MATCH MAXIMAL AEROBIC POWER IS SIGNIFICANTLY RELATED TO MATCH-PLAY WORK INTENSITY IN THE 2ND HALF OF PROFESSIONAL AND RECREATIONAL SOCCER MATCHES

Mann, M., Clark, N., Edwards, A.M.

Universal College of Learning, New Zealand

Introduction: The ability to attain a high maximal aerobic power has consistently been linked to success in soccer; primarily through the association between high distances covered during match-play and the sustained high-intensity effort over a 90-min game. The aim of this study was to compare continuous markers of match-play work efforts with baseline cardiopulmonary fitness to establish whether, or at what stage, this might become a significant factor to performance in both professional and recreational match settings. Methodology: Seven professional male soccer players and 8 recreationally active male players agreed to undertake baseline measurement of cardiopulmonary fitness on a motorized treadmill to volitional fatigue. Gaseous exchange was measured breath-by-breath at the mouth. Match-play heart rates were collected from both a professional soccer match and a recreational game. Heart rates were collected at 5-s

intervals using a Polar Heart Rate Team system and were batched into the mean of 5 min intervals for the purposes of statistical comparisons with baseline fitness variables. Results: The baseline measurements of maximal aerobic power were not related to match-play heart rates in the 1st half of either professional or recreational level match play. 1st half heart rates were significantly higher than those attained in the 2nd half of both matches (Rec: 159.2 ±3.9 bּmin-1 and 153.2 ± 3.3 bּmin-1, P<0.05; Pro: 164.4 ±4.1 bּmin-1 and 159.1 ±2.9 bּmin-1). In both matches, baseline cardiopulmonary fitness become a significant in the latter stages of match-play. In Rec, there were significant associations between maximal aerobic power and the average heart rate of 80-85 min (R2 = 0.46; P<0.05) and also with the average heart rate of 90-95 min (R2 = 0.50; P<0.05). In Pro, baseline fitness correlated with average match-play heart rate at 90-95 min (R2 = 0.55; P<0.05) and with the 2nd half average (R2 = 0.69; P<0.01) but were not significantly related with other match-play heart rates. Conclusion: The significant associations between baseline maximal aerobic power and 2nd half heart rates of both professional and recreational soccer match-play suggest that cardiopulmonary fitness is only of significant importance during the latter stages of a game when fatigue is most prevalent on performance. This observation supports earlier work demonstrating significant reductions in 2nd half distances covered, with the difference particularly large in players of low level fitness. The contribution of skill, team tactics, match conditions and importance make the identification of limiting factors difficult to quantify; however, maximal aerobic power appears to exert a significant influence on performance.

HOW DO REPEATED ACUPUNCTURE-SHIATSU TREATMENTS INFLUENCE MUSCULAR STRENGTH?

Tirelli, S., Perotta, B., Trachelio, C., Casolo, F., Rodano, R., Preatoni, E.

Università Cattolica del Sacro Cuore, Milano, Italy

Introduction

Modern sport science looks at the athlete's performance as the outcome of many physiological, psychological and energetic factors taken as a whole [1,2,3]. Some authors suggest that Chinese and Japanese medicine can be successfully applied to sport [3,4,6,7]. Quantitative clues on the effect of shiatsu treatments have been found [7], but, the attempts to scientifically prove the benefits of Shiatsu are still few. This work tries to assess the effectiveness of digital pressure stimulation on acupuncture points by evaluating its influence on muscular strength after repeated treatments. Isometric tests were used.

Methods

12 healthy female basketball players (29.5±2.2 y; 64.7±10.7 Kg; 173.2±3.7cm) were randomly divided in two homogeneous groups (A and B). A double blind approach with cross-over was used: A underwent shiatsu treatments [5,7] while B was subjected to sham-interventions. Each athlete was submitted to 5 consecutive weeks of treatments, one treatment every week. After a 2-weeks wash out, the groups were crossed over and the same procedure was repeated: this time A underwent sham-interventions, while B received shiatsu treatments. Each subject's isometric strength level was measured (knee flex-extension), before the first shiatsu/sham treatment and after the last one, with an isokinetic machine (REV9000,Technogym). Peak moments and integrals of moments versus time were estimated. All the subjects were familiar with the testing protocol to avoid learning effects. A non parametrical within-groups test (Wilcoxon) was used.

Results

The Wilcoxon-test results always showed, in case of real treatments, a high significative increase (p<0,01) of both peak knee flex-extension moment and moment-time area. In contrast, sham-intervention variables kept stationary or showed a slight decrease, significative just for extension with knee angle at 40° and 45°.

Discussion/Conclusion

The reported results suggested a positive effect of repeated shiatsu treatments on isometric muscular strength, both in its maximal expression (peak moment) and in moment-time area. This conclusion is supported by control group trends and confirms what previously found about single treatments outcomes. Therefore further investigations are encouraged: other aspects of muscular strength or other factors influencing sport performance should be studied.

CAN CENTRAL LIMITATION EXPLAIN DEPRECIATED ENDURANCE PERFORMANCE IN HYPOXIA ?

Millet, G.Y., Aubert, D., Favier, F., Benoit, H.

University Jean Monnet Saint-Etienne, France

Endurance performance is worsened in acute hypoxia (HYP) without any effect on muscle contractile properties. By opposition to the role of oxygen delivery, the central governor model suggests that this depreciated performance in HYP is due to motor unit recruitment modulation, i.e. to central limitation. To test this hypothesis, 11 healthy men performed four intermittent isometric all-out tests (Tlim) on separate days. The four conditions were two environmental conditions (HYP : FIO2 = 11% vs. normoxia, NORM), each of them being performed with (W) and without (WO) the application of a pressure cuff (blown up at 250 mmHg) at the top of the thigh to prevent knee extensors (KE) oxygenation. In particular, we hypothesized that central limitation would be evidenced if the number of repetitions is lower in HYP-W than in NORM-W condition. The Tlim consisted in repetitions of 10 s isometric knee extension at 50% of maximal voluntary contraction followed by a 10 s rest until exhaustion. Single maximal electrical stimulations were delivered to the femoral nerve with a constant current stimulator at the 5th second of each 10 s rest. KE evoked force (peak twitch, Pt) and EMG (M-wave) were measured. EMG of rectus femoris, vastus lateralis, vastus medialis and biceps femoris were also continuously recorded during Tlim. The root mean square (RMS, expressed in % RMS during MVC) and median frequency (MF) values were calculated during each contraction over a 2 s period at the beginning of the 10 s contraction. These analyses were done for the three knee extensors explored here and their values were averaged (RMS KE, MF KE).

The oxygen saturation was reduced during HYP (84.7 ± 3.8% vs 97.3 ± 0.8%, P < 0.001). The number of repetition was 21.5 ± 8.7, 15.6 ± 4.5, 10.0 ± 3.2 and 8.5 ± 2.8 for NORM-WO, HYP-WO, NORM-W and HYP-W, respectively. For this variable, the difference between NORM-W and HYP-W was significant (P < 0.05). During Tlim, RMS KE increased significantly between the first and the last repetition for the four

conditions and the value reached at the end depended on the number of repetitions. The M-wave amplitude did not change significantly in any condition. On the contrary, MF KE and Pt decreased significantly but their values were not significantly different among the four conditions at the last repetition. Pt values changed from 15.1 ± 3.4 to 7.4 ± 3.6 kg for NORM-WO, from 16.1 ± 3.7 to 6.6 ± 3.0 kg for NORM-W, from 15.9 ± 3.8 to 7.6 ± 3.0 kg for HYP-WO and from 16.6 ± 2.8 to 7.4 ± 3.0 kg for HYP-W.
These results show that the exercise was ended at a given "peripheral state" but it is not known whether this is due to peripheral muscular limits or to central limitation due to neural afferences. However, the smaller number of repetitions in HYP-W than in NORM-W suggest that a direct central limitation due to hypoxia occurs. Because statistical significance was hardly reached for this fundamental variable, additional subjects will be incorporated to the study in the near future.

EFFECT OF PRIOR INCREMENTAL CYCLING ON VO2 KINETICS DURING MODERATE AND HEAVY INTENSITY CYCLING EXERCISE

Stasiulis, A., Dubininkaite, L.

Lithuanian Academy of Physical Education, Lithuania

The purpose of the present study was to examine the changes in VO2 kinetics during constant work rate (CWR) cycling with moderate and heavy intensity after incremental cycling exercise.
Methods
Fourteen healthy, physically active male subjects (age 21.1 (2.0) yr, height 181.8 (7.8) cm, and weight 78.9 (9.3) kg, VO2max 52.2 (5.0) ml kg-1 min-1, gas exchange threshold (GET) 53.0 (6.1)% of VO2max) volunteered to participate in this study. Subjects visited the laboratory on two occasions over a 1-wk period. During the first visit an incremental exercise (IE) test (work rate from 70 W was increased by 21 W every min, 70 rpm) until limit of tolerance was performed on a mechanically braked cycle ergometer (Monark 834E) in order to determine the maximal oxygen uptake (VO2max), GET and the intensity of CWR exercise. After the IE the subjects were divided into two groups: low intensity (LI) and high intensity (HI). In the second examination each subject performed two CWR exercises (6 min cycling preceded by 3 min of unloaded cycling) interspaced with IE. The time intervals of passive rest between CWR exercise, IE and repeated CWR exercise were 10 min. The intensity of CWR exercise in the LI and HI groups was set at approximately 45% of VO2max and 70% of VO2max, respectively. Pulmonary gas exchange was measured breath-by-breath throughout all tests. The VO2 response during low intensity CWR was fitted the mono-exponential function and that during high intensity CWR exercise was fitted the bi-exponential function. First 20 s were always removed from the analysis. The slow component of VO2 was calculated as the difference between the end exercise VO2 and the 3rd min VO2.
Results
The intensity of CWR exercise in LI and HI groups averaged 115.1 (17.2) and 215.7 (43.5) W or 48.8 (3.06) and 69.4 (8.58)% of VO2max, respectively. The mean blood lactate concentration just before the start of repetitive CWR exercise was 6.01 (1.1) and 6.04 (1.6) mmol l-1 in LI and HI groups, respectively, indicating the presence of a residual metabolic acidosis. The absolute VO2 values were significantly higher at rest, during unloaded cycling, at third and sixth min of repetitive CWR exercise in both groups. Prior IE had no effect on the amplitude and time constant of the VO2 response in LI group. Similarly, the phase II VO2 kinetics did not change during repetitive CWR exercise in HI group. The time constant of VO2 kinetics in phase III was significantly decreased, both the amplitude of phase III response and the VO2 slow component showed a tendency of decrease in this group.
Conclusions
Prior incremental cycling exercise had no effect on the fast component of VO2 kinetics neither during moderate nor during heavy intensity cycling exercise, whereas the slow component of the VO2 kinetics during heavy intensity exercise was reduced under these conditions. The absolute VO2 was higher both during low and high intensity CWR exercises performed in the presence of metabolic acidosis.

CARDIAC EFFECTS OF PHYSICAL ACTIVITY IN ADULT SUBJECTS

Pavlik, G., Kneffel, Z., Horváth, P., Németh, H., Sidó, Z., Frenkl, R.

Semmelweis University, Facuty of P.E. and Sport Sciences, Hungary

Both in the endurance performance and in the primer prevention it is a very important question how do characteristic features of the athlete's heart develop if regular physical training is started not in the childhood but in the adult age.
Echocardiographically measured data (2D-guided M-mode and Doppler-recordings) of subjects who have began regular physical training in their adult age (later than 18 yr., group A) were compared with data of athletes started their sports activity in their younger age (group Y) and with non-athletic healthy subjects (N) (altogether 1050 individuals).
Characteristics of the left ventricular hypertrophy (wall thickness/BSA½, muscle mass /BSA3/2) and training-bradycardia developed something less in the A than in the Y group. The effect of regular physical training to diminish age-related impairment of diastolic function manifested stronger in the Y group, although the difference between the two athletic groups decreased in the oldest age.
In females differences between the A and Y groups were higher in all parameters than in the males.
Our results indicate that regular physical training started in the young age develop more markedly the characteristics of the athlete's heart, but to begin regular physical activity in the adult age is also useful.

PERIPHERAL SYMPATHETIC OUTFLOW CORRELATES WITH THE RESPONSE TO ENDURANCE TRAINING

Hautala, A.J., Kiviniemi, A.M., Mäkikallio, T.H., Tiinanen, S., Seppänen, T., Huikuri, H.V., Tulppo, M.P.

Merikoski Rehabilitation and Research Center, Oulu, Finland

Individual responses to endurance training vary from almost none to 40% increase in endurance performance in healthy subjects, but the reasons for differences in training response are not well known. We recently showed that cardiovascular autonomic function, in terms of cardiac vagal activity, is an important determinant of the response to endurance training in sedentary subjects (1). In the present study, we assessed whether variability in peripheral sympathetic outflow has a role in the training response. METHODS: The study population included 14 male club level runners (age 33+/-5 years and VO2max 56+/-2 ml/kg/min). The baseline measurements were performed after two weeks of wash out (non-running) period. The training period was 4 weeks, including 6 sessions a week at an intensity of 70-80% of the maximum heart rate for 40 min/session. Muscle sympathetic nervous activity (MSNA; microneurography) from the peroneal nerve was assessed at 5 min supine rest before the training period. Time to exhaustion (TE) was measured at maximal treadmill test

before, after 2 weeks and after 4 weeks of training. RESULTS: After the first 2 weeks of training, TE increased by 4+/-5% (from 940+/-109 to 975+/-85 seconds, P=0.005). During the last 2 weeks of training, TE increased further by 6+/-3% (from 975+/-85 to 1030+/-96 seconds, P<0.0001). Baseline MSNA (bursts/min and area under the curve) did not associate with the change in TE after the first two weeks of training (P=ns for both), but had a strong negative correlation with the change in TE (r= -0.67, P=0.008 and r= -0.61, P=0.020, respectively) during the last 2 weeks of training. CONCLUSION: Baseline muscle sympathetic nervous activity correlates with the response to endurance training among the healthy males. A low peripheral sympathetic activity at baseline condition is associated with a better improvement in running performance after a short-term intensive training period.

EFFECT OF REPETITIVE EXERCISE ON NITRIC OXIDE EMANATING FROM HUMAN SKIN

Itoh, H., Ohkuwa, T., Yamazaki, Y., Goto, N., Washiya, T., Takakusagi, A., Matsue, S., Shimada, K., Takahashi, H., Tsuda, T.

Nagoya Institute of Technology, Japan

Introduction

Nitric oxide (NO) is the most important endothelium-derived relaxing factor, which plays a pivotal role in modulating smooth muscle tone in the human conductance and resistance vessels (Moncada & Higgs 2006). Jungersten et al. (Jungersten et al. 1997) have suggested that NO is increased with increased cyclic wall stress associated with increased pulsatile blood flow during acute exercise. Recently, some volatile gases emanating from human skin have been detected (Nose et al. 2005). NO is also a gas, however, no one has confirmed the changes in NO concentration from human skin. Therefore, we examined whether NO gas would change or not after exercise.

Methods

Ten healthy male students (21.6 ± 1.8 years; mean ± SD) volunteered as the subjects, and none of them were smokers. The subjects performed the repetitive wrist flexion-extension exercise at 25% maximal voluntary contraction at a pace of a time per second until voluntary exhaustion. The skin-gas samples were obtained by covering the non-dominant hand for 3min with a polyfluorovinyl bag (Tedlar bag; GLScience, Tokyo, Japan) in which pure nitrogen gas was introduced, and collected in a sampling bag at rest and after exercise (2-5, 7-10, 12-15, 17-20, 22-25 min). The concentration of NO in the skin-gas was measured by a chemiluminescence analyzer (Hamamatsu Photonics, Hamamatsu, Japan).

Results

The mean (± SD) time to exhaustion of the repetitive wrist flexion-extension exercise for the subjects was 160.0 ± 51.6 sec. The skin-gas NO concentrations significantly increased after the exercise compared to the resting values, and significantly higher levels were remained throughout the recovery period ($p<0.01$). The mean peak NO concentrations of each subject were about 1.8-fold from the resting values (44.8 ± 19.9 to 79.8 ± 42.7, $p<0.05$).

Discussion/Conclusion

It has been well known that forearm exercise increases local blood flow (Green, 2005), and that an increase in blood flow stimulates vascular endothelial cells and advances the production of NO (Jungersten et al. 1997). The changes in the skin-gas NO concentrations observed in this study have suggest that the repetitive wrist flexion-extension stimulate endothelial NO production by increases in shear stress during the exercise. Furthermore, sympathetic nervous activity, circulating hormones, exercised muscle-derived metabolites may also affect the production of NO during and after the repetitive exercise. We conclude that the repetitive low intensity exercise increases NO concentrations emanating from human skin.

EFFECTS OF A 12-WEEK EXERCISE PROGRAMME ON HEART RATE VARIABILITY IN PATIENTS WITH INTERMITTENT CLAUDICATION

Leicht, A., Crowther, R., Spinks, W., Sangla, K., Quigley, F., Golledge, J.

James Cook University, Australia

Several studies have demonstrated significant improvements in exercise performance following regular aerobic exercise in peripheral vascular disease patients with intermittent claudication (IC). However, mechanisms for these improvements have not been well established. In healthy and heart disease populations, regular exercise has been reported to increase the neural control of heart rate (i.e. heart rate variability, HRV) thereby reducing the risk of further cardiac events. To our knowledge no such studies of HRV and regular exercise with IC patients have been conducted. Therefore, the current study examined the effects of a 12-week supervised exercise programme on resting HRV in IC patients. Seventeen IC patients were randomly allocated to either regular exercise of 3 days per week, 20-40 minutes per day (EX, n=9) or no regular, supervised exercise (NEX, n=8) while another 7 age-matched healthy adults served as controls (CON). Time and frequency domain measures of HRV and cardiorespiratory measures were determined during rest in the supine (15 mins) and standing (5 mins) position. Following orthostatic challenge (i.e. standing), patients undertook a graded exercise treadmill test to determine pain free walking time (PFWT), maximal walking time (MWT) and peak cardiorespiratory measures including VO2peak. Variables were obtained prior to and following the 12-week period and analysed via repeated measures ANOVA. Compared with CON, EX patients exhibited significantly greater resting HR (75.7 vs 60.8 bpm, $P<0.05$) and significantly lower resting HRV (i.e. various time and frequency domain measures). Orthostatic challenge significantly increased HR and most respiratory measures, while reducing HRV similarly for all groups prior to and following the 12-week period. HRV was not significantly modified over the 12-weeks for any group. There were no significant changes in peak cardiorespiratory measures over the 12-week period for any group although CON exhibited significantly greater VO2peak compared with EX and NEX (37.6 vs 21.3 and 21.1 ml.kg-1.min-1, $P<0.001$). Despite these similar peak exercise measures, MWT was increased over time for all groups, although to a greater extent for EX compared with NEX and CON

(130% vs 46% vs 12%, P=0.11), while PFWT was increased similarly for EX and NEX (132% vs 60%, P=0.20). These preliminary results indicate that regular, supervised exercise training increases walking performance while maintaining peak cardiorespiratory measures and resting HRV. Peripheral factors rather than central neural adaptations appear to contribute to the increased walking performance of IC patients following regular supervised exercise.

EFFECTS OF FOOT IMMERSION IN COLD WATER ON HEART RATE, BLOOD PRESSURE AND CARDIAC AUTONOMIC NERVOUS SYSTEM MODULATION

Nishimura, M., Shigeno, M., Kato, T., Onodera, S.

Tottori University, Japan

The purpose of this study was to make clear the effects of foot immersion in cold water on heart rate, blood pressure, rectal temperature, mean skin temperature and cardiac autonomic nervous system modulation in male. Seven males served as subjects. Descriptive data (means ± SE) are as follows: age 22.0 ± 1.2 yeas, height 171.8 ± 6.4 cm, body weight 63.4 ± 6.0kg and body fat 12.6 ± 3.2 %. All subjects gave informed consent before participating. All subjects wore only swimming trunks during the experiment. Subjects rested on chair for 20 minutes. The final 5 minutes of rest (BASE; baseline period) followed by foot immersion and recovery for 15 and 5 minutes, respectively. The subjects performed foot immersion at 5, 10 and 15 degrees Celsius at random, during different days, but always at the same time. Experiments were performed from 1 p.m. to 5 p.m. All subjects were instructed to breath gently in time with a metronome signal set at 15 breaths/min (0.25Hz). Heart rate was derived by calculating the number of R waves of ECG. Blood pressure and rectal temperature (Tre) were measured every minute. Skin temperatures were obtained from three sites by using dermotherm every minute. The magnitude of changes in rectal temperature (ΔTre) during the immersion and recovery period was calculated as immersion or recovery minus BASE. Analysis of heart rate variability (HRV) was performed off-line on a personal computer. Cardiac autonomic nervous system modulation was estimated with the power spectrum analysis of heart rate variability (HRV) by using the Fast Fourier Transformation (FFT). The areas of the two frequency components of HRV were measured by integrating low frequency (LF; 0.04- 0.15 Hz) and high frequency (HF; 0.15-0.40Hz). HF was used as an indicator of cardiac vagal modulation and was showed logarithmically (LogHF). Heart rate during WT5 and WT10 increased significantly during foot immersion compared with BASE value ($p<0.05$). Systolic blood pressure during WT5 and WT10 increased significantly during foot immersion compared with BASE value ($p<0.05$). Mean skin temperatures and rectal temperature in all conditions didn't change compared with BASE value. LogHF during in all conditions didn't change compared with BASE value.

It is concluded that foot immersion into the cold water range from 5 to 10 degrees Celsius for 15 minutes dose not affect Cardiac autonomic nervous system modulation, rectal temperature and mean skin temperature, although it cools the immersion part.

AEROBIC FITNESS PROFILE OF FUTSAL PLAYERS OF DIFFERENT COMPETITIVE LEVEL: A PILOT DESCRIPTIVE-STUDY

Barbero-Álvarez, J.C., D'Ottavio, S., Castagna, C.

Granada University and Tor Vergata University , Spain

Futsal or 5-a-side indoor soccer is a popular team sport played all over the world. However despite its popularity only limited scientific literature is available regarding the physiological demands of the game and players' fitness (Barbero et al., 2004a; Barbero Alvarez et al., 2004b). The first aim of this descriptive research-design was to examine the aerobic-fitness (Pate and Kriska 1984) level of players of different competitive levels in order to study whether aerobic fitness is a discriminative variable in Futsal success. Secondly to establish normative data of aerobic fitness to be used to guide futsal coaches and fitness trainers, in designing specific training interventions. Participants were 24 male futsal players randomly chosen from three teams of different competitive levels: A Spanish professional top ranked second division team (PST n=11, 22.8±1.5 years, weight 75.2±6.2 kg, height 178±7.4 cm), a youth Spanish team (YST n=7, 17.1±1.1 years, weight 65.9±8.9 kg, height 171±7.3 cm) and a semi-professional Italian top ranked Third division team IT (n=6, age 24.5±2.2 years, weight 69.6±6.8 kg, height 175±4.9 cm). Maximal oxygen uptake (VO2max), Ventilatory Threshold (VT) and Running Economy (RE, VO2 at 8 km h-1) were assessed using a progressive protocol (1 km h-1 min-1speed increment until exhaustion) on a level motorized-treadmill. Gas analysis were performed using a portable gas analyzer (K4b2, COSMED, Rome, Italy). Between groups comparisons were performed using the Kruskal-Wallis test with post-hoc multiple comparisons. PST, YST and IT VO2max was 62.9± 5.34, 68.6 ±6.2 and 55.0±7.1 ml kg-1min-1 respectively (YST vs IT, $p<0.05$). RE was 34.1± 2.7, 38 ±3.1 and 32.4± 2.7 for PST, YST and IT respectively (YST vs IT, $p<0.05$). PST, YST and IT attained VT at 70.5± 2.7, 67.9 ±5.2 and 71.3± 5.2% of VO2max respectively. Results show that well-trained professional futsal players possess a VO2max well above 60 ml kg-1 min-1. Specifically adults players (PST plus IT) in order to successfully play competitive futsal seems to require a VO2max around 60 ml kg-1min-1 (59.33±7 ml kg-1min-1) whatever the level is. Percentage of VO2max at VT seems not to be related to competitive level in Futsal. In light of this study results futsal coaches and fitness trainers once promoted a VO2max level around 60 ml kg-1 min-1 should implement training programs oriented to other components of futsal performance.

PERFORMANCE ON REPEATED MAXIMAL SHORT SPRINT CYCLING: PASSIVE VS ACTIVE RECOVERY

Matsushigue, K., Hoinaski, L.F., Schneck, H.C.

Pontifical Catholic University of Parana, Curitiba, Brazil

The purpose of this study was to verify the effect of active recovery on peak and mean power during an intermittent exercise of short effort periods.

Fifteen male subjects gave their informed consent prior to participation in the study. Subjects were physically active but not exercising on a regular basis or a similar sports activity. Each subject performed two intermittent exercises (IT) on two occasions and all subjects were

tested the second time at least 48 hours after the prior test. The format of the IT involved ten all-out 10-s cycling sprints interspersed with 30 seconds of active (A-IT) or passive recovery (P-IT). The sequence of the tests was randomly determined. The sprint bouts were carried out on a friction-braked cycle ergometer, loaded at 0.075 kp per kg of body mass and separated by 30-s of active recovery at a workrate of 1 kp and at a frequency of 60 rpm (A-IT) or by 30-s of rest on the cycle bench (P-IT). Flywheel rotations were recorded each second by an eletronic revolution counter in order to obtain peak (PP) and mean power output (MP) of each of the ten bouts. For each subject a linear regression was fitted over the ten PP points and the fatigue index (FI) was determined by calculating the difference between the preditcted values of the 10th PP and the first PP. The angular coefficient (AC) was adopted as decrease rate of the peak power output (AC-PP) and of the mean power (AC-MP) . A two-way Anova for repeated measures was used to compare bouts and recoveries and Student t-tests were used to compare passive and active recovery. Where significant differences were found, Tukey post hoc tests were employed to determine which means were different. Statistical significance was accepted at the 0.05 level. All results are presented as means (standard deviation).

There were no significant differences between passive and active recovery (P-IT vs A-IT) in peak power (675.8 (87,2) vs 692.3 (92.9) W), mean power (544.9 (79.9) vs 494.4 (140.1) W), FI (236.7 (64.7) vs 225.2 (94.6) W), or AC-PP (-26.3 (7.2) vs -25.0 (10.5) Watts per bout). The AC-MP in passive recovery (-25.7 (6.8) W per bout) was signicantly higher (p=0.02) than in active recovery (-25.0 (10.5) W per bout). However, this characteristcs could be due to a not perfect fit over the points, since there always was a significantly lower mean power output during the second sprint in A-IT. The coefficient of determination (R2) was 0.8 (0.1) to linear regression on peak power of P-IT and A-IT and on mean power of P-IT and 0.6 (0.2) on mean power of A-IT. There were no significant differences in peak or mean power among the 6th to 10th bouts in P-IT and A-IT tests.

During intermittent exercises of short bouts of high-intensity effort periods the active recovery seems thus not to benefit the performance.

ANTROPOMETRIC AND FUNCTIONAL CARACTERISTICS OF BASKETBALL PLAYERS DURING DISTINCT PHASES OF TRAINING

Djuric, I.

School of Medicine Belgrade, Serbia and Montenegro

The aim of this study was to determine antropometric (body weight ,body mass index) and functional caracteristics (VO2max,HRmax) of Serbian proffesional club basketball playersduring 3 distinct phases of their training.17 male basketball players (age 23+/-5)were tested.Players who wer enot available for all evalations sessions wre exluded.Phase 1 took place at the end of season, phase 2 tested fitness and aerobic capacity before preseason practice began, and phase 3 occured after preseason practice.Firstly morfological indices of participants wre determinated.Standing height was measured ti the nearest 1.0 cm using a stadiometar. Body weight was measured to the nearest 0.1 kg using digital scale. Basketball players performed an incremental ramp protocol on treadmill. OO2max anh HRmax wre measured directly. The highest mean estimated body weight (93.77+/-10.86 kg)and body mass index(24.87+/-4.86 m2/kg0wre measuredat the end of preseason practices,and the lowest values for body weight (92.75+/-10.94 kg)were found at the end of the season. Statistical differences were found in body weight between phase 1 and phase 2 ($p<0.05$). The mean estimated VO2max were the lowest (49.30+/-2.78 ml/kg/min) at the begining of preseason practice and the hightest at the end of preseason practice (54.45+/-6.23 mil/kg/min). Comparing the results in phase 1 and phase 2 it is found statistical differences between them ($p<0.05$). It is hoped that these informations will be very helpful for both doctors and trainers in tracing basketball players' health state and physical condition.

EFFECTS OF PREVIOUS AEROBIC EXERCISE PERFORMED AT DIFFERENT PEDAL CADENCES ON MUSCULAR STRENGTH

Greco, C.C., Ruas, V.D., Figueira, T.R., Denadai, B.S.

Human Performance Laboratory, Brazil

Some studies had demonstrated that previous aerobic exercise can compromise subsequent strength (Leveritt and Abernethy, 1999; Sporer and Wenger, 2003), but the mechanisms which can explain this influence are not well identified. In cycling, pedal cadence can influence metabolic (Ahlquist et al., 1992) and neuromuscular (Farina et al., 2004) responses, which can be an important factor on the subsequent strength performance. The objective of this study was to verify the effects of the aerobic exercise performed at different pedal cadences on the muscular strength. Seven active males (21.86 + 3.18 yr., 74.86 + 9.42 kg, 179.28 + 4.92 cm, 13.30 + 2,85 % of body fat), performed in different days and in a random order, the conditions control (C), experimental at 50 rev.min-1 (R50) and experimental at 100 rev.min-1 (R100). At C condition it was performed 3 series of maximal repetitions in the leg-press 45 degrees, with workload corresponding to 10 maximal repetitions. In the conditions R50 and R100 theses series were performed after an aerobic exercise of 30 min duration at the intensity corresponding to the anaerobic threshold (AnT) (3.5 mM of blood lactate) with pedal cadences of 50 and 100 rev.min-1. During constant workload exercise, heart rate (160.21 + 6.77 and 162.21 + 11.26 bpm) and blood lactate (4.02 + 1.12 and 4.34 + 0.88 mM) were not significant different at conditions R50 and R100, respectively. There was a significant reduction in the number of repetitions performed at R100 (23.42 + 5.56) in relation to C conditions (29.85 + 0.37). At R50 (29.14 + 2.26) the number of repetitions performed was similar to C condition. Thus, the effects of aerobic exercise performed in cycling at similar physiological conditions (heart rate and blood lactate) on subsequent strength, can be dependent on the pedal cadence, probably in function of different muscular contractions velocities.

LUNG FUNCTION IN TUNISIAN CHILDREN: RELATIONSHIP WITH PUBERTAL STATUS

Trabelsi, Y., Tabka, Z., Gharbi, N., Richalet, J.P., Guenard, H., Zbidi, A., Buvry, A.

Sousse Faculty of Medicine, Tunisia

Puberty is one of the most important steps in life, involving dramatic morphological and physiological changes. In Tunisian children, nothing is known about growth of ventilatory function and pubertal stage.

The purpose of this study was to identify the relationship between lung function and pubertal stage in Tunisian children using anthropometric parameters.

Pulmonary function parameters were measured with a Minato portable spirometer in 684 healthy Tunisian children (351 males and 333 females) from 8 to 16 years old. Pubertal status was assessed for males and females according to the Tanner Method.

A large variation was found in the distribution of children's age and height by pubertal stages in both sexes. Height increased with age and pubertal stage in males and females. Our results also show a significant increase in parameters of lung function (FVC, FEV1, PEF, MEF 50 and MMEF 25-75) with pubertal stage in Tunisian children. Females enter and achieve each stage of puberty earlier than boys.

Parameters of pulmonary function for healthy Tunisian school children increased proportionally with age, height and pubertal stage. The present study confirms that, in females, lung growth is of short duration and occurs earlier than males in the pubertal process.

These data are of importance to follow the children suffered from chronic pulmonary diseases during the puberty.

Poster presentation (PP)

PP2-02 Training and Testing 1-7 - "Exhibition Hall"

DISCRIMINATIVE BASKETBALL GAME-STATISTICS BETWEEN WINING AND LOSING TEAMS FROM THE EUROBASKET 2005' (BELGRADE)

Sampaio, J., Lorenzo, A., Gómez, M., Ibáñez, S., Refoyo, I.

University of Trás-os-Montes e Alto Douro, Portugal

The aim of this work was to identify the discriminative power of basketball game-related statistics between the winning and the losing teams from the 2005 Eurobasket championship. Also, we contrasted the relationships between game-related statistics in winning teams and in losing teams. Data was gathered for all 31 games from the Male Senior European Championship held in Belgrade (2005). All game-related statistics were normalized to 100 ball possessions and they were later analysed with a descriptive discriminant function. The relations between the game-related statistics were investigated through Pearson product-moment correlation coefficient. From the discriminant function results we have identified two powerful game-related statistics: missed 3 point shoots and assists. The remaining game-related statistics were not very relevant in order to discriminate between winning and losing teams. We have identified common correlations between game-related statistics in wining and losing teams (missed 2 point field goals and offensive rebounds; made 3 point field goals and assists; Defensive rebounds and steals) and also specific correlations to winning (made 3 point field goals and missed free throws; made free throws and fouls) or to losing teams (made 3 point field goals and turnovers).

RESISTANCE TRAINING EFFECTS ON PARAMETERS OF AEROBIC AND ANAEROBIC CAPACITY

Marsic, T., Sentija, D., Dizdar, D.

Faculty of Kinesiology, University of Zagreb, Croatia

Background:

Resistance training has several potential benefits on health and performance. Recent research has shown contradictory results on the inluence of strength & power training on parameters of aerobic capacity. The purpose of this study was to examine the effects of a 12 week resistance training program on parameters of anaerobic and aerobic endurance.

Methods:

Eleven male PE students (24±1.5 y, 75.8±6.4 kg) underwent a resistance (Olympic weight lifting) training program for 12 weeks, 3 times per week. Basic and specific exercises were used to develop weight lifting technique and maximal strength and power. Training intensity and volume were determined according to the individual capacity of the subjects. During the training period, they were not engaged in any other formal exercise or training. Pre- and posttraining the subjects performed an incremental running test on a treadmill (with 1km/h increments per minute, at a constant inclination of 1.5%) to volitional exhaustion, in order to determine the running speed at the ventilatory anaerobic threshold (AnT), maximal oxygen uptake (VO2max), maximal running speed (Vmax) and the distance run above AnT to the point of exhaustion (AWCd), as a measure of anaerobic capacity. Student's paired t-test was used to compare the results obtained before and after the training period.

Results:

After the training period a small, but significant increase in VO2max was found (56.4±5.3 vs. 54.9±5.4 ml/kg, $p<.05$), that was related to a small, but also significant increase in body mass (76.6±6.4 vs. 75.8±6.4 kg). The subjects achieved a lower AnT (11.9±1.7 km/h vs. 12.3±2.0 km/h), and a higher Vmax (17.1±1.8 km/h vs. 16.7±1.7 km/h) after training, but the differences did not reach statistcal significance; however, the distance run (AWCd) above the anaerobic threshold up to maximal running speed at exhaustion, was significantly greater after strength and power training (285±98 m vs. 212±104 m, $p<.01$).

Conclusion:

The results of this study indicate that resistance training can lead to a small, but significant improvement in VO2max in young men not engaged in any form of athletic training. However, caution is needed in interpretation of this results, as the increase in VO2max was very small and within the range of measurement error. The significant increase in AWCd after resistance training, confirms that changes in anaerobic capacity can be effectively monitored with a standard ramp-pattern test.

MASKEL TRAINING IN AEROBIC GROUP

Wolinska, K., Cybulska, A.
The University of Physical Education and Sport in Gdańsk, Poland

Locomotive speed belongs to one of the most important group of motoric abilities, which has significant meaning in the structure of footballers movement actions.
106 players had been researched in all age categories.
Tests of the locomotive speed of the footballers were executed on light-athletics runway with the tartan surface. 5 m, 10 m, 15m, 20 m, 30 m, 40 m lengths were measured to straight run from stopped position and running start from 2 meters and lengths 5 m, 10 m, 15 m, 20 m, 25 m to swinging run. Time of the run in each probe was electronically measured with the precision to 0,01 s, with Italian Globus photocells set usage (Ergo-tester).
Researched players were in age section 9,72±0,22 years (youngster beginners) and 24,7±4,49 years (seniors). Results from the run tests reflect views of the pertained authors, that after puberty period strength and speed development in sport groups is the biggest. Based on this we can assume, that in 16-17 year of life footballers achieve level of locomotive speed preparation close to maximal.

POSTURAL SWAY RESPONSE TO DIFFERENT FORMS OF RESISTANCE EXERCISE

Zemková, E., Hamar, D., Pelikánová, J., Schickhofer, P.
Faculty of Physical Education and Sport, Comenius University, Slovakia, Slovakia

It has been documented that running, cycling, walking, as well as repeated heel rising and sustaining stance on tiptoe adversely affect balance. However, there is no information on the effect of exercises performed with upper extremities on postural stability. In addition, the fatigue has been proposed as a principal factor responsible for post-exercise impairment of balance without paying any attention to the hyperventilation. The aim of the study was to compare the parameters of balance and ventilation after resistance exercises involving activation of different muscle groups. A group of 22 physical education students (age 21.2 ± 2.1 years, height 178.2 ± 4.4 cm, weight 73.6 ± 9.4 kg) performed 20 squats, calf rises, biceps curls, and presses behind neck with an additional load of 50% 1RM. Thirty seconds prior to and two minutes after exercises a velocity of the centre of pressure was registered at 100 Hz by means of stabilography system FiTRO Sway check based on dynamometric platform. While exercising and standing on stabilographic platform, parameters of ventilation were continuously monitored using breath-by-breath system MMC Horizon. Results showed significantly ($p < 0.05$) higher increase in velocity of the centre of pressure after squats (16.4 ± 1.4 mm/s) and no significant increase after calf rises (15.2 ± 1.3 mm/s) than after biceps curls (14.0 ± 1.1 mm/s) and presses behind neck (13.6 ± 0.8 mm/s). Also ventilation was significantly ($p < 0.05$) higher after squats (59.1 ± 6.6 l/min) and calf rises (48.2 ± 5.8 l/min) than after biceps curls (40.0 ± 4.6 l/min) and presses behind neck (38.9 ± 3.8 l/min). In both parameters a significant ($p < 0.01$) increase to pre-exercise level has been found (8.6 ± 0.2 mm/s and 12.3 ± 0.1 l/min, respectively). In phase of recovery, there was a close correlation between sway velocity and ventilation after squats ($r = 0.939$), calf rises ($r = 0.919$), biceps curls ($r = 0.896$), and presses behind neck ($r = 0.889$). More profound impairment of postural stability in an early phase of recovery after resistance exercises performed with lower than upper extremities is very probably due to more pronounced ventilation. This assumption may be corroborated by finding that sway velocity after squats and calf rises remained temporarily elevated and only after about 25 and 10 seconds a gradual decrease back to the resting level set in. It may be a consequence of delayed activation of ventilation in an early phase of recovery after such exercises. On the other hand, its values after biceps curls and presses behind neck being reached a maximum at the end of exercise and started to decline immediately in recovery phase. It may be concluded that rather than fatigue a more marked ventilation is responsible for more profound impairment of balance after resistance exercises performed with lower (squats and calf rises) than upper extremities (biceps curls and presses behind neck).

SWIM VOLUME, RESTING HEART RATE, 50 METRE SWIM TIME, AFFECT AND FELT AROUSAL IN COMPETITIVE YOUNG SWIMMERS

Stoedefalke, K., Parfitt, G., Richardson, M.J.
University of Exeter, United Kingdom

The purpose of this pilot study was to explore the effect of swim volume on resting heart rate, 50 metre swim time, affect using the feelings scale and felt arousal in competitive young swimmers over a four week period. Young competitive swimmers can spend up to 17 hours training per week in the pool. Attrition rates are high, with the highest percentage of children who drop out of swimming doing so between the ages of 12-14 years. To date, there are few studies that have examined swim training in competitive young swimmers. Twelve competitive swimmers (10-15yrs) participated in the four week study. Swim volumes and best 50 meter swim times were collected for four weeks. In addition, the swimmers wore heart rate monitors while sleeping three times per week over the four week period to measure resting heart rate. Swimmers also reported their affect (-5 = very bad to +5 = very good) before, during and after swim practice on three separate occasions during data collection weeks. The same protocol was used for determining felt arousal (scaled 1 to 6). Finally, the swimmers were interviewed in an attempt to identify the perceived impact of the training regime on motivation and feelings towards swimming. Analysis failed to show any clear relationship between the swim volume and other variables. Analysis of variance across time indicated that all variables remained stable. However, the coefficients of variability (cf %) for individual results varied greatly for the psychological variables. The affect cf % ranged from 16.4% to 235% and the cf % for felt arousal ranged from 10.9% to 154.6%. Conversely, the physiological variables had a much smaller cf % with resting HR ranging from 1.52%-8.9%, swim volume ranging from 2.10%-43.9% and 50 meter swim time ranging from 1.6%-6.79%. The qualitative data supported the high individual variability in psychological response, with individuals expressing various impacts on motivation. These have the potential to influence long-term involvement in the sport and would support the systematic exploration of these variables in swimmers between the ages of 10-15 using a longitudinal design.

THE EFFECT OF 2-MONTH OF PROPRIOCEPTIVE STIMULATION ON STRENGTH ABILITIES IN ELDERLY WOMEN

Schickhofer, P., Hamar, D., Zemková, E., Gazovic, O., Böhmerová, L.

Faculty of Physical Education and Sport, Comenius University, Slovakia, Slovakia

The aim of the study was to examine the long term effects of whole body mechanical proprioceptive stimuli on strength parameters of lower extremities in elderly women. Altogether twenty women randomly divided into experimental and control group respectively (n =10, mean age 61.8 ± 8.1 years, height 164.0 ± 4.7 cm, weight 77.4 ± 12.6 kg and n =10, mean age 60.1 ± 4.9 years, height 164.2 ± 5.5 cm, weight 70.5 ± 11.7 kg) volunteered to participate in the study. During initial 4 weeks experimental group was exposed to proprioceptive stimuli (generated vertical counter shocks by special platform with the frequency of 10 Hz, eliciting force peaks of 2 g within 3 ms) in standing position (6 sets of 45 seconds, separated by 2 minutes of rest, 3 times a week). Following 4 weeks standing alone was replaced by semi-squats with an additional load of 20 % of body weight (6 sets of 10 reps, separated by 2 minutes of rest, 3 times a week). Force in initial 300 ms (F300) and maximal force (Fmax) produced during maximal isometric contraction in semi-squat position were evaluated prior to, after 4 weeks and after 8 weeks of the training using strain gauge force plate. The best one out of the 2 attempts were taken in account. Results showed a significant improvement ($p < 0.05$) of F300 and Fmax in experimental group (from 249.7 ± 136.5 N to 385.0 ± 136.2 N in F300 and from 731.1 ± 447.3 N to 848.5 ± 399.8 N in Fmax, respectively). No further improvements were registered in the following 4 weeks. In control group there were no significant changes of parameters measured. Positive change may be ascribed to the improvement of neuroregulatory functions, namely increased rate of motoneuron firing and better synchronisation of motor units activation. It may be concluded that already 4 weeks of systematical application of mechanical proprioceptive stimuli in nonfit elderly women applied to lower extremities brings about the major part of improvement of both, maximal strength as well as the rate of the force development in elderly women. The continuation of the same regiment despite of slightly increased intensity does not further enhance the parameters of strength.

ASSESSMENT OF ANTHROPOMETRIC, BIOMOTOR AND BIOENERGIC CHARACTERISTICS OF NATIONAL IRANIAN FEMALE TAEKWONDO ATHLETES AND ITS RELATIONSHIP WITH THEIR COMPETETIVE PERFORMANCE

Jafari, A., Moradi, M., Salehi, S.

Islamic Azad University Research and Science Branch, Iran

The awareness of anthropometrical and physiological characteristics of athletes of each sport is very important and has close relationship with their successful performance. Success in taekwondo needs some factors such as: speed, agility, flexibility, anaerobic power and capacity.

The aim of this study is assessment of anthropometric and biomotor and bioenergic characteristics of Iranian female taekwondo athletes and its relationship with their competetive performance

This research was attended by 25 national female taekwondo athletes (age 21±1/78, weight 57/76 ±8/63, height 166/6±6/86).

Anthropometric characteristics composed of height (m), weight (kg), body fat (percentage), BMI (kg/m2), thigh length (m). Biomotor characteristics composed of agility (Illinois test), speed (20 m Run test), flexibility (set and reach test), balance (Strok test) and reaction time (reaction time test). Bienergic characteristics composed of aerobic power (20m shuttle run test) and anaerobic power (sarjent jump and bosco test).for Evaluationof competetive performance we used of video system.

Descriptive statistical and analysis pearson correlation were used for analyzing data. The result showed that there was a significant relationship between percent body fat, BMI, speed, anaerobic power, agility and reaction time and national female taekwondo athlete's competetive performance

Based on result, these factors have an important role in female taekwondo athlete's competetive performance and must be considered by athletes and coaches in conditioning programs. It also recommended considering these factors in talent identification.

SERVICE AND RECEPTION TECHNIQUES AND TACTICS IN WORLD CLASS BEACH VOLLEYBALL

Koch, C., Karacsonyi, D., Staber, G., Tilp, M.

Karl-Franzens-University Graz, Austria

The quality of the reception of the opponents serve is the basis for a good setting and consequently for a successful attack in volleyball and beach volleyball. Investigations with focus on reception and setting in indoor volleyball underline the importance of this skill (Papadimitriou et al., 2004). Our aim was to analyse service and reception with regard to technique, quality and tactics in world class beach volleyball. A method formerly used for game analysis of U18 and U21 beach volleyball (Tilp et al., 2005) was applied to analyse the playing habits of senior World Class players.

By defining 105 categories it was possible to classify all service and reception actions. The analysed videos were taken at the FIVB Grand Slam in Klagenfurt 2005. 28 matches (15 ♀, 13 ♂) were included in the investigation. Data gathering was performed with the digital game analysis system STATSHOT (see Tilp et al., 2005). The data were processed with basic statistics tools included in the program and MS.EXCEL®. Like in similar systems (e.g. FOCUS X2 from ELITE sports analysis) the assessed actions and the associated video scenes were stored in a database. This allows observing all video scenes of interest after the categorization.

Our results show that male world class players used jump serve more often then female players. While men played jump serves with a percentage of 48 (♀ 20%) women preferred to the same amount float serves without jumping. Female athletes used even more jump float serves than jump serves. In both sexes the jump serve was the most successful technique in terms of direct points (♀ 9%, ♂ 5%) but also the one with the highest error rate (♀, ♂ ~17%). Male and female reception tactic consisted of playing the ball to a central zone between the two players near the net. Players at this level applied predominantly the frontal reception technique (♂ 44%, of which 67% were perfect). The high quality of some service types forced the reception player to use the lateral reception technique (♂ 37%), of which 57% were executed perfectly. Especially men are able to cover a large area with just one step (~80%).

The results bare room for improvement especially for female players in the usage of the effective jump service. A reduction of mistakes and a more frequent use could improve the service performance. In conclusion the results demonstrate that the reception quality is on a high level. It is necessary to serve in an excellent way to put pressure on the opponent. A future aim of our research is to develop a database to place the findings at the disposal for Austrian players and trainers.

COMPARING SOME OF THE MENTAL SKILLS BETWEEN SUCCESS AND NON-SUCCESS NATIONAL IRANIAN FEMALE TAEKWONDO ATHLETES IN INTERNATIONAL COMPETITION OF ISLAMIC COUNTRY IN 1384

Jafari, A., Moradi, M., Salehi, S.

Islamic Azad University Research and Science Branch, Iran

In sport world, competition among athletes is very near and sensitive. In the past, superiority in a special sport in countries was almost simple, but now, some of the athletes in throughout world do serve exercises with regular and yearly planning in a special sport, so that, in high comparative level of skills is often equal. Therefore, athletes need a thing higher than pressed exercises and continue struggles and that is mental skill; because without using mental skill, reach to peak in sport performance is not possible. The purpose of this research comprises some of mental skill between success and non-success national Iranian female taekwondo athletes in international competition of Islamic country in 1384 and 1382. They were 20 players (11 success and 9 non-success athletes). For comprising subjects mental skills was used Winter's mental skills assessment questionnaire that is special for athletes. In addition used a questionnaire including questions about age, record of activation in taekwondo sport and acquired position in 5 years ago. Results were analyzed with t-test. Results are indicator of significant difference in motivation between two groups that was lower in non-success and higher in success athletes. In addition to, we found significant difference in concentration and imaging among tow group that is indicator of being in success athletes and lower in non-success athletes. Results of this research are indicator of concentration and imaging importance at taekwondo player's success that is necessary for coaches and athletes in this sport to attend it.

SPECIAL STRENGTH AND ENDURANCE CHANGES OF ELITE TAEKWONDO ATHLETES DURING THE PREPARATION FOR A WORLD CHAMPIONSHIP

Ribera-Nebot, D., Garcia-Navarro, F.J.

Barcelona University, Spain

The impact of special strength and endurance training was studied in three elite taekwondo athletes, aged 23-26-27, who were preparing for the 7th Open World Taekwondo Championship. During the final preparatory period (16 weeks before competition), special strength and endurance training was performed 4-1 days/week for 14 weeks. The following special strength and endurance tests were performed at the beginning of the final preparatory period and after 12 weeks: a) test of special strength for short movements: 6 sets of 15 seconds (15 seconds rest in between) performing specific short movements with a 5, 10 and 15 kg disc –the number of performed actions is evaluated; b) test of special strength for kicks: 6 sets of 15 seconds (15 seconds rest in between) performing specific kicks with a 5, 10 and 15 kg disc –the number of performed actions is evaluated; and c) test of special endurance: 6 sets of 1 min 30 seconds (30 seconds rest in between) performing specific short movements and kicks –the number of performed actions and recovery heart rate is evaluated. The three athletes demonstrated a significant increase in the number of actions performed in all the special strength and endurance tests, although it was not found significant changes in the recovery heart. The present data suggest that special strength and endurance training added to the technical-tactical training can produce an important improvement of special strength and endurance capacities in elite taekwondo athletes. It should finally be pointed out that these significant increments of special strength and endurance capacities become a relevant component of the technical-tactical performance in many sports.

MANIPULATING HIGH-INTENSITY INTERVAL TRAINING: EFFECTS ON VO2MAX, THE LACTATE THRESHOLD AND 3000M RUNNING PERFORMANCE IN MODERATELY TRAINED MALES

Esfarjani, F., Laursen, P.

esfahan university, Iran

The aim of this study was to compare the effects of two high-intensity interval training (HIT) programmes on maximal oxygen uptake (vo2max), the lactate threshold (LT) and 3000m running performance in moderately trained male runners.vo2max , the running speed associated with vo2max (vVo2max), the time for which can be maintained (Tmax), the running speed at LT (vLT), and 3000m running time (3000mTT) were determined before and following three different training programmes performed for 10 weeks. Following the pretest, 17 moderately trained male runners (=51.6 ± 2.7 ml.kg-1.min-1) were divided into training groups based on their 3000m running times (Group 1, G1, N=6, 8x60% of Tmax at , 1:1 work:recovery ratio; Group 2, G2, N=6, 12x30s at 130% , 4.5 min recovery; control group, GCON, N=5, 60 min at 75%). G1 and G2 performed two HIT sessions and two 60 min recovery run sessions (75%) each week. Control subjects performed four 60 min recovery run sessions (75%) each week. In G1, significant improvements ($p<0.05$) following HIT were found in (+9.1%), (+6.4%), Tmax (+35%), vLT (+11.7%) and 3000mTT (-7.3%). In G2, significant improvements ($p<0.05$) following HIT were found in (+6.2%), (+7.8%), Tmax (+32%) and 3000mTT (-3.4%), but not in vLT (+4.7%; $p=0.07$) . No significant changes in these variables were found in GCON. The present study has shown that 3000m running performance,vo2max ,vVo2max and Tmax can be significantly enhanced using different HIT programmes in moderately trained runners.

ARTISTIC GYMNASTIC FLOOR EXERCISE: COMPARISON BETWEEN EXECUTION ON TRAINING AND ON COMPETITION EQUIPMENT

Minganti, C., Piacentini, M.F.

University Institute of Motor Sciences (IUSM) Rome, Italy

Introduction: Artistic Gymnastic floor exercise is performed on a padded carpet 12 x 12 meter which is necessary for the athletes' take-offs and landings. FIG approved International sprung floor area is manufactured from plywood base panels containing a springing system (fastfoam and/or springs). In Italy many clubs don't have space and/or economical resource to have a regular floor exercise equipment, so training is performed on a track (2x12 m) with a springing system less effective than FIG approved floor area.

Due to these considerations, the purpose of the present study was to analyze Heart Rate (HR) response and blood lactate (BL) concentration during floor routine performed on the two different apparatus.

Methods

Six female gymnasts that were all been competing at the national level, volunteers participated in the study (age: 20 ±2 yrs; height: 159,5 ±9,7 cm; weight: 50 ±7,1 Kg; B.M.I.: 19,6 ±0,9 kg∙m-2). Gymnasts performed their floor competition routine on the two different apparatus. Exercises were performed in two different days (day 1: on track; day 2: on FIG approved floor area) and the same warm up protocol was used. HR was continuously recorded with a Polar sport tester (Polar S810i). Blood samples were drawn, from the ear lobe, at rest and 2, 5, 10 min after the end of performance and analyzed for lactate concentration (Accusport, Accutrend, Germany).

Means and standard deviations were calculated for all data. Comparison between BL concentrations was made using AN.O.VA. with repeated measures. Non parametric Chi2 test was used to evaluate differences in HR response.

Results.

Blood Lactate (mmol•l-1) maximal concentration (BLmax) and increase from rest (∆BL) were higher on track than on FIG approved International sprung floor area (BLmax track: 5,7 ±1,6; 12x12: 4,4 ±0,3; ∆BL track: 4,6 ±1,7; 12x12: 3,3 ±0,5). No statistically difference were found (probably due to the small sample). The average HR were 85% HRmax on track and 80% HRmax on 12x12 sprung floor area (Mode: 90% and 86% HRmax). Also HR statistical analysis didn't show significative differences.

Discussion

Difference between BL concentrations after floor exercise executed on the two different surface, show a higher muscular effort on track; higher exercise intensity on track is confirmed by HR monitoring. These differences are probably explained by the track' springing system less effective.

ASSESSMENT OF LOWER LIMBS' MUSCLES EXPLOSIVE POWER: DIFFERENCES BETWEEN JUMP TEST VS PUSH TEST

Faina, M., Dell'Acqua, M., Gianfelici, A., Mirri, G.B., Besi, M., Mondoni, M., Galvani, C.

Italian National Olympic Committee , Italy

Jump Test is widely accepted in order to assess explosive power of lower limbs. However vertical jump is a complex movement which can cause some problems of repeatability; it can also induce some overload on spine. Push Test on a leg press does not give such problems and has been already used in different studies. However, in our knowledge, no information about the correlation between these two tests is available. Therefore the purposes of this study are to verify the correlation of a Push Test (SP) vs a Jump Test (SJ), to verify if the two tests are comparable and to focus on the optimal load that elicits maximum power output.

19 physically active men attended 2 separate testing sessions: a) SJ were performed from a semi-squat position (knee angle 90°), without lower limbs counter-movement or an arm swing; b) SP were executed on a leg press with the subject seated with a knee and a trunk angle of 90°; the subject was asked to push maximally with both feet while the carriage was free to move backwards on two rails. During each of the 2 testing sessions, 3 repetitions were completed under each of the test conditions: SJ at 100-110-120-130-140-150%BW and SP at 100-120-140-160-180-200%BW. During both tests load displacement was detected by an electronic encoder and data were elaborated by a customized software. Average force and power and jump height have been used to compare the tests. Furthermore force/velocity and power/velocity curves were drawn in order to obtain average peak power and force.

A significant correlation was obtained for all parameters between the 2 different test methodologies, while they resulted significantly different when compared with a T-test, being SJ higher than SP (54% for power, $p<0.0001$). Besides peak power was obtained with 114%BW during SJ and 180%BW during SP.

The results of this study provide the validity of Push Test to assess lower limbs explosive power. For this reason this test can be used for a comparison between subjects and also for a longitudinal monitoring of training program. It can provide different advantages: better protocol standardization, less intervention of coordination and no overload on the spine. However the lower values detected with SP indicate that there is a minor intervention of trunk muscle groups in SP than in SJ. Therefore this test results more specific for lower limbs power assessment, not considering the overall capability of a subject to jump. In both tests, according with different other studies, peak power has been obtained with an overload in comparison to body weight. 180%BW in SP can be explained by the presence of a came on the leg press which decreases the load in the fist angle of the movement.
