It is commonly believed that a high level of aerobic fitness (as assessed by V*O2max) is important for repeated-sprint ability (RSA). However, low correlation coefficients (0.42 < r < 0.56) are typically reported between V*O2max and RSA1. Furthermore, while endurance-trained athletes (ET) are better able to maintain repeated-sprint performance than team-sport athletes2, ET also produce lower initial sprint performances. This is important, as it has been reported that initial sprint performance is strongly correlated with the sprint decrement that occurs during a repeated-sprint test3 and is inversely related to V*O2max4. Thus, the greater RSA reported in ET may actually be associated with their lower initial sprint performance, rather than their greater V*O2max. The purpose of this study, was to investigate the relationship between V*O2max and RSA, while controlling for the effects of initial sprint performance on sprint decrement. This was achieved via two methods: 1) matching females of low and moderate aerobic fitness (V*O2max: 36.4 ± 4.7 vs 49.6 ± 5.5 mL•kg-1•min-1; P<0.05) for initial sprint performance and then comparing RSA, and 2) semi-partial correlations to adjust for the influence of initial sprint performance on RSA. Tests consisted of a RSA cycle test (5 x 6-s max sprints every 30 s) and a V*O2max test. Muscle biopsies were taken before and after the RSA test. There was no significant difference between groups for work (W1, 3.44 ± 0.57 vs 3.58 ± 0.49 kJ; P=0.59) or power (P1, 788.1 ± 99.2 vs 835.2 ± 127.2 W; P=0.66) on the first sprint, or for total work (Wtot, 15.2 ± 2.2 vs 16.6 ± 2.2 kJ; P=0.25). However, the moderate V*O2max group recorded a smaller work decrement across the five sprints (Wdec, 11.1 ± 2.5 vs 7.6 ± 3.4 %; P=0.045). There were no significant differences between the two groups for muscle buffer capacity, muscle lactate or pH at any time point. When a semi-partial correlation was performed, to control for the contribution of W1 to Wdec, the correlation between V*O2max and Wdec increased from r=-0.41 (P>0.05) to r=-0.50 (P<0.05). These results have shown that subjects with a higher V*O2max, but similar initial sprint performance, have a smaller sprint decrement (Wdec). Given no differences for initial sprint performance, muscle buffer capacity and metabolic responses, these results indicate that the smaller Wdec in the moderately-trained group was associated with their higher V*O2max. This suggests that V*O2max does contribute to the maintenance of performance during repeated-sprint efforts. However, the small variance in Wdec explained by V*O2max suggests that other factors also contribute. As the V*O2max of subjects in this study was low to moderate, caution should be used in extrapolating these results to elite, team-sport athletes.

ARE SCALED SOCCER MATCHES SUITABLE FOR THE DEVELOPMENT OF TECHNICAL SKILLS IN YOUNG SOCCER PLAYERS?

Tessitore, A. 1+2, Meeusen, R. 2, Pesce, C. 1, Lupo, C. 1, Benvenuti, C. 1, Capranica, L. 1

1 IUSM of Rome, 2 Vrije University of Brussels, Italy

Introduction

To facilitate the development of technical and tactical skills of youth teams, the Italian soccer federation (FIGC) organizes matches according to the age of the young players. Given the lack of information regarding youth soccer matches (Capranica et al., 2001), the aim of this study is to investigate the differences in technical and tactical skills of youth soccer teams ranging from 8 to 10 years old.

Methods

Three youth soccer competitions (8 yrs: two 15-minute 5-a-side periods; 9 yrs: two 18-minute 7-a-side periods; and 10 yrs: two 18-minute 9-a-side periods) were compared. Players' heart rates (HR) were continuously monitored and the competitions were filmed to evaluate the frequency of occurrence of the following technical parameters: the number of players involved in a single action; the number of passes performed in a single action; the number of players involved in a shooting move. Chi-square test was applied to verify significant differences (p<.05) between ages.

Results

During the matches, HR higher than 170 beats/min were observed (5vs5=90±4%; 7vs7=79±11%, and 9vs9=80±8%), with no significant difference between halves. A significant age-related effect was found for the number of players involved in a single action and the number of passes performed. Although most frequently two-three players (8 yrs: 89%; 9 and 10 yrs 72%) were involved in a single action, with increasing age a tendency for a higher involvement of more than three players (8 yrs: 3%; 9 yrs: 13%; 10 yrs 14%) was found. Within a single action players performed most frequently one pass (8 yrs: 68%; 9 and 10 yrs: 45%). However, older players tended to show higher percentages of occurrence for more than 3 passes (8 yrs: 3%; 9 yrs: 13%; 10 yrs 16%). Post hoc analysis maintained the difference only between 5-a-side and the other type of competitions. During a match, 8-year old players performed shoots (14±2) with respect to both the 9-year (13±3) and 10-year (11±3old players. No significant difference was found between age classes for the number of players involved in a shooting move, with a frequent involvement of two-three players (8 and 10 yrs: 50%; 9 yrs: 46%).

Discussion/Conclusion

In agreement with the literature (Capranica et al., 2001), high intensity activities resulted during the matches. From technical aspects, the 5vs5 matches differ from the other matches, probably due to the limited experience of the younger players, that reduce their ability to cooperate with the other team mates. Even though starting from 9 years of age young players tend to play in a more cooperative manner, the reduction of the number of players, the dimension of the pitch, and the duration of the match does not give enough opportunity to develop the soccer skills of young players. Thus, new competitions aiming at enhancing the development of technical aspects in young players are strongly needed.

PECULIARITIES IN RECOVERY OF CARDIOVASCULAR INDICES OF HIGHLY SKILLED ATHLETES

Poderys, J., Ezerskis, M., Poderyte, K., Vainoras, A.

Lithuanian Academy of Physical Education, Lithuania

We have studied the sequence in recovery of cardiovascular indices after various exercise test protocols and after heavy physical loads. The study participants were 17 voluntary students non-athletes and 17 well-trained athletes of combative events group (box, judo and wrestling). A computerized ECG analysis system "Kaunas-load" was employed for 12 synchronous lead ECG recording and analysis. We used the model of integral evaluation of body functioning during exercising which integrates a changes of three functional elements: P – periphery system, R – regulatory system (brain), S – supplying system (heart, blood-vessel system). Relation between these systems can be specified by several parameters, which we have used as the simplest and easier calculated from ECG and ABP parameters: heart rate (HR), JT interval, systolic (S) and diastolic (D) blood pressure. Also we studied proportions between parameters: (S-D)/S and JT/RR, where RR = 60/HR.

The recovery of cardiovascular indices after the exercise tests used was assessed by evaluation of half period of recovery time i.e. 1/2T. The slowest recovery of cardiovascular indices was observed after the Bosco test (60-s all-out anaerobic test). We analysed the sequence of recovery of various indices. These results indicate that after all exercise tests and in both groups the sequence in recovery of registered indices was the same. The doubtless faster recovery was the ratio JT/RR, after then recovery of heart rate, then – JT interval. The same sequence in recovery of indices of arterial blood pressure was observed. If these sequences to put on the scheme of the used model the directional marker has the same direction. This means the recovery begins from some ratio between the regulatory and supplying systems of the body, then the recovery in regulatory systems follows and the recovery ends by going down the indices of supplying systems.

The results obtained after heavy training loads have shown some changes only. There was no statistically significant difference between obtained averages and the sequence in recovery of cardiovascular indices was the same. But, if to take into account the individual variations the sequence in recovery was destroyed in some cases, which coincident with the changes in the stability of recovery process about which the Liapunov exponent (LE) has indicated. Individual data analysis showed that the cases when the sequence in recovery of cardiovascular indices was destroyed one or a few of LE indices have changed to a positive mark what indicates about negative influence on the stability of the recovery processes of cardiovascular indices. In summarizing we conclude that exist a defined sequence in recovery of cardiovascular indices and destroying of this sequence is a sign may be indicating about overloads or some symptoms of overtraining as a result of performed hard training program.

EFFECTS OF TWO RESISTANCE TRAINING PROGRAMS ON MUSCLE STRENGTH, BODY COMPOSITION AND PHYSICAL FITNESS OF LOCAL POLICEMAN

Olmedillas, H., Delgado-Guerra, S., Guadalupe, A., Bernales, O., Fuentes, T., Calbet, J.A., Dorado, C., Sanchis-Moysi, J.

University of Las Palmas de Gran Canaria, Spain

The work carried out by local policeman often demands vigorous physical efforts that has a crucial importance in their job. Purpose. The aim of this study was to evaluate the effects of two different strength training programs on muscle strength, physical fitness and body composition in middle-aged local policemen. Methods. Twenty-one male untrained local policemen (mean ± SD), age 36 ± 6.4 years, height 177 ± 5.3 cm and body mass 85.4 ± 12.4 kg, participated in a 12-week strength training program. Subjects were randomly divided into two groups: a low repetition group (Low Rep, n = 9) perfoming 5 repetitions with the load corresponding to 10 RMfor 8 sets of each exercise with 2 min rest between sets and exercises and a high repetition group (High Rep, n = 12) performing 10 RM for 4 sets with 2 min rest. Seven exercises were performed 3 days/week, 4 lower body (LB) and 3 upper body exercises (UB). Maximal strength (one repetition maximum, 1RM), maximal leg extension isometric force (MIF) in the squat position with knees bent at 90º and the peak force, mean power, and the maximal positive mechanical impulse (Ipos) and height jumped (Hj) during countermovement vertical jumps (Cj) and squat jumps (Sj) were assessed with a force plate. Additionally, 30-m running speed, 300-m run (anaerobic capacity), and 20-m shuttle-run tests (maximal aerobic power) were performed. Body mass, fat mass and lean body mass (DXA) and anthropometric variables (body circumferences and skinfolds) were also assessed. Results. Maximal strength significantly increased in both groups (28 vs 24 %, for Low Rep and High Rep, respectively, both $P < 0.05$). The Low Rep improved the maximal strength in the LB exercises by 41 % ($P = 0.06$) and the High Rep by 30 % ($P < 0.001$). The MIF was increased by 13% in the Low Rep ($P < 0.05$) but not in the High Rep. In the Low Rep the circumferences of the leg, medial thigh and waist were significantly higher (all, $P < 0.05$) and the leg skinfold significantly lower ($P<0.001$) at the end of the training program. Ipos significantly increased during the Sj in the High Rep ($P < 0.05$). No significant differences were observed in the 30-m running speed, 300-m run and 20-m shuttle-run tests in both groups. The UB maximal strength increased similarly in both groups (14 vs 17 %, for the Low Rep and High Rep respectively, both $P < 0.05$). In the Low Rep group, lean body mass of both arms increased (the dominant arm by 2%, $P= 0.09$ and the non-dominant arm by 4 %, $P< 0.05$). The % body fat of the whole body showed a tendency to be decreased after de Low Rep training program (from 25.3 ± 4.7 to 23.9 ± 4.5 %, $P= 0.08$). Conclusion. Low Rep strength training contributed to a higher increase of the maximal strength of the lower body and to an improvement of the muscle mass and % of body fat of the whole body.

This Study was funded by a grant from Academia Canaria de Seguridad (Gobierno de Canarias, Spain).

HIGH-INTENSITY INTERVAL TRAINING IMPROVES SHORT-TERM PCR RESYNTHESIS AND REPEATED-SPRINT ABILITY

Edge, J., Goodman, C., Bishop, D.

Massey University, New Zealand

Oxidation is essential for PCr resynthesis during the recovery from exercise. This suggests that individuals with an elevated aerobic fitness should be better able to resynthesise PCr following exercise. Indeed, cross-sectional research supports the hypothesis that endurance training enhances PCr resynthesis following low-intensity exercise. However, we have previously reported no effect of training on PCr resynthesis following severe exercise. As we measured changes in PCr resynthesis after 3 min, it may be that we were unable to detect any short-term improvements in metabolic recovery. The purpose of this study therefore was to investigate the effects of interval training on short-term metabolic recovery following severe exercise and repeated-sprint ability (RSA).

Twelve, moderately-trained females (mean ± SD: age 20 ± 3 y, mass 62.3 ± 10 kg, VO2peak 45.6 ± 5.6 mL•kg-1•min-1), performed a graded exercise test to determine VO2peak and the lactate threshold (LT), followed 48 h later by a constant intensity cycle test (CIT: 45 s at 200% pre-training VO2peak) and a RSA test (5 x 6-s, separated by 24 s). There was a 1-min rest period (passive) between the performance of the CIT and the RSA test. Muscle biopsies (vastus lateralis) were taken before, immediately post and 1 min after the CIT to deter-

mine muscle ATP, PCr and lactate concentration. Subjects were randomly assigned to either high-intensity interval training, with 1-min (HIT-1) or 3-min (HIT-3) rest periods between intervals. Each subject had a matched partner (matched on the LT) in the opposing group, with whom they were required to complete an equal amount of work during each training interval and session (6-12 x 2 min at 150% LT, 3 d.wk-1 x 5 weeks).
There were increases in VO2peak (11% HIT-1 v 9% HIT-3; $p<0.05$) and the LT (8% HIT-1 v 15% HIT-3; $p<0.05$) for both groups, with no differences between groups. Both groups also had similar improvements in total work (J•kg-1; 12-13%) and mean peak power (W; 9-10%) during the RSA test. There was an increase in short-term PCr resynthesis for the HIT-1 (12.0 ± 1.6 to 22.2 ± 3.9 mmol•kg-1dm•min-1, $p<0.05$) and HIT-3 (14.0 ± 3.2 to 18.5 ± 2.7 mmol•kg-1dm•min-1, $p<0.05$) groups following training, with no difference between groups. There were no changes to post exercise ATP resynthesis or muscle Lactate/H+ removal.
We have shown that interval training can significantly improve short-term PCr resynthesis and RSA. There were no differences in RSA between the two interval training protocols, indicating that during very intense interval training, the length of the rest period between intervals (1 v 3 min) does not affect improvements in performance. Furthermore, both methods of interval training employed in the present study can be used to improve short-term (~1 min) PCr resynthesis. The similar improvements in short-term PCr resynthesis may be related to the matched training loads and the similar improvements in aerobic fitness.

ENHANCING MUSCULAR STRENGTH QUALITIES IN UNTRAINED WOMEN: LINEAR VERSUS UNDULATING PERIODIZATION

Kok, L-Y., Hamer, P., Bishop, D.

The University of Western Australia, Australia

Research has suggested that periodized resistance training can help improve muscular hypertrophy, strength and power1,2,3. Despite disagreements in terminology, two periodization models have surfaced, namely linear and undulating periodization (LP and UP). Comparative studies however, have not found agreement whether it is the fluctuations and variability in training intensity and volume, or a greater workload that have resulted in superior results for a particular periodized program2,4. Also, few studies have examined the effects of periodized resistance training on women. Thus, this study examined the efficacy of LP and UP protocols with matched workloads on adaptations in women. Methods 24 active females (mean ± SD: age 20.0 ± 1.9 y, mass 66.1 ± 9.5 kg) with no resistance-training in the previous 6 mth participated in this study. Participants performed pre-training conditioning (3 wk) before being matched and randomly assigned to either LP or UP training, based on their one-repetition maximum squat (1-RM SQ). The LP group varied training intensity and volume every 3 wk while the UP group varied intensity and volume daily, with training (4 upper-body, 4 lower-body exercises) performed 3 d per wk for 9 wk. Overall training volume (LP:175.6 x 103; UP:157.5 x 103, $p = 0.232$) and intensity was similar between groups. Results There were significant improvements in arm (LP:1.14 %; UP:1.73 %) and thigh (LP:1.58 %; UP:1.99 %) girths, rectus femoris (LP:11.4 %; UP:14.8 %, $p < 0.05$) muscle cross-sectional area (CSA), 1-RM bench press (LP:21.8 %; UP:28.3 %) and SQ (LP:34.8 %; UP:41.2 %), average mechanical power output during the bench press throw (BPT) (LP:11.1 %; UP:13.8 %) and countermovement jump (CMJ) (LP:10.4 %; UP:9.5 %), and barbell height during the BPT (LP:56.4 %; UP:44.8 %) and CMJ (LP:28.0 %; UP:21.5 %), but no significant differences between groups except for muscle CSA. Discussion LP and UP training with volume and intensity equalized were equally adept in improving strength qualities, suggesting that higher workloads and repetitions produce superior strength and power adaptations. Furthermore, our results suggest that the differences in total training volume may explain why some previous studies have reported different periodized programs that result in superior gains. Hypertrophic responses were larger and occurred earlier than previously reported3, and are likely to be associated with the improvements in strength and power observed. The non-projected, light-load, explosive training utilized in the study was found capable of bringing about increases in strength and power but should be limited to short periods, as continued use has been suggested to be detrimental to strength and power performances4.

LOAD THAT MAXIMISES AVERAGE MECHANICAL POWER OUTPUT DURING THE BENCH PRESS THROW AND COUNTERMOVEMENT JUMP IN WOMEN

Kok, L-Y., Hamer, P., Bishop, D.

The University of Western Australia, Australia

Training at the load that maximizes mechanical power has been suggested to be more effective for increasing maximum muscular power1,2. Some studies3,4 have therefore examined loads that could maximize mechanical power but have proposed different percentages of one-repetition maximum (1-RM). The variations are likely due to differences in data collection and analysis, exercise performance and training experience of subjects4,5. Thus, more research is required to help establish the appropriate load stimulus to maximise muscle power, particularly for females, since only one study3 has utilized females. Methods 27 females (mean ± SD: age 19.3 ± 1.3 y, mass 64.0 ± 9.0 kg, resistance-training experience 3 – 24 mth) participated in this study. During test I, participants performed the 1-RM squat (SQ). After resting 45 min, a series of countermovement jumps (CMJ) were performed using 30 – 80 % of 1-RM SQ, presented in a random order. Three trials were given for each load. Similar procedures were utilized one week later for the 1-RM bench press (BP) and the bench press throws (BPT). All tests of maximum strength and power were performed using a modified Plyometric Power System. Results The nine strongest (GrpH) subjects were 56 and 59 % stronger than the nine weakest (GrpL) subjects in the 1-RM SQ and BP respectively, and utilized heavier loads during the CMJ and BPT. Average mechanical power output was maximised at 30 % of 1 RM for the CMJ in both GrpH and GrpL. This load however, was not significantly different from 40 % of 1-RM SQ for GrpH, and also not significantly different from 40–60 % of 1-RM SQ for GrpL. Average mechanical power was maximized during the BPT at 60 % of 1-RM for both groups, with no significance difference between this load and 40 -50 % of 1-RM BP for GrpH women, and 50, 70 and 80 % of 1-RM BP for the GrpL women. Discussion These results indicate that different percentages of 1-RM maximize power for the upper- and lower-body. The lack of difference between the optimal loads with other percentages of 1-RM, and conflicting results with some previous studies, indicate that lower percentages of 1-RM may be more suitable for power-training, with heavier loads used for maximal strength training. Comparisons suggest that stronger and more powerful females, and also stronger and more powerful parts of the body within the same subjects, utilize lower percentages of 1-RM to produce high power compared to less strong and less powerful females and body parts. These

lower percentages utilized by the stronger females are heavier in absolute terms, and have more initial inertia to overcome, resulting in optimal power production at lower percentage loads4.

DIFFERENCES BETWEEN 100 M, 400 M AND MIDDLE DISTANCE RUNNERS IN EXPLOSIVE LEG STRENGTH AND LEG STIFFNESS TESTS

Babic, V., Vucetic, V., Sentija, D.

University of Zagreb, Faculty of Kinesiology, Zagreb, Croatia, Croatia

Introduction: The performance in running events is determined by several neuromuscular factors, but the optimal level of muscle power, strength and stiffness for specific running events is not fully elucidated. The purpose of this study is to investigate the difference in those parameters among athletes who compete in different running events.

Methods

Thirty-one regional to national level male athletes: ten 100m (S) (182.6±5.7 cm, 75.7±4.2 kg), personal best (PB) on 100m sprint = 10.87±0.41s, eleven 400m (S4)(181.9±4.7 cm, 74.0±5.0 kg), PB on 400m 49.5±1.9s, and ten middle distance runners (MD) (180.1±5.4 cm, 68.7±6.3 kg) participated in this study. Several biomechanical variables were measured on a force plate (QuadroJump, Kistler) for evaluation of explosive leg strength: the squat jump (SJ), counter movement jump performed with both legs without hands (CMJ) and with hands (CMJH), as well as CMJ performed on each leg separately (CMJL and CMJR). Leg stiffness was evaluated by performing ten successive maximal hops (HOP) on the same force plate. Standing long jump (SLJ), as a commonly used field test, was also measured. Analysis of variance (with Scheffe's post hoc test) was used to determine significant differences between groups of runners.

Results

The 100m sprinters achieved the highest values while the middle distance runners achieved the lowest values in all measured parameters (SJ: 56.4±6.0 cm, 46.3±3.6 cm, 42.0±3.4 cm; CMJ: 62.3±4.8 cm, 52.9±3.5 cm, 45.4±4.1 cm; CMJH: 68.8±6.1 cm, 61.8±3.5 cm, 51.8±4.1 cm; CMJL: 42.5±8.4 cm, 34.1±1.7 cm, 30.4±4.6 cm; CMJD: 41.3±6.6 cm, 34.4±3.6 cm, 29.0±3.8 cm; HOP: 52.5±4.8 cm, 48.6±4.3 cm, 41.8±5.2 cm; SLJ: 276.0±16.1 cm, 255.6±11.8 cm, 231.5±11.9 cm; for S, S4 and MD respectively). The analysis of variance revealed significant differences between 100 m, 400 m and middle distance runners ($p < 0.01$). The only no significant differences between S and S4 were in the HOP test and between S4 and MD runners in the SJ, CMJL and CMJD tests.

Discussion and conclusions

The results of this study indicate the specificity of explosive strength and leg stiffness regarding the considered running events, which increase significantly with the increase in running speed for a specific event.

BODY COMPOSITION AND FUNCTIONAL PROFILE IN ELITE FEMALE PROFESSIONAL YOGA TEACHERS

Boniello, S., Cè, E., Merati, G., Maggioni, M.A., Bertoli, S., Veicsteinas, A.

Institute of Physical Exercise, Health and Sport Activities (IEFSAS), University of Milan, Italy

Introduction – Hatha Yoga is characterized by a sequence of various static postures (asana) of a duration from 8 to 15 minutes. Each asana have to be maintained for at least 30 s up to 60 s and the transition from consecutive postures should be well controlled and slowly performed. A high degree of neuro-muscular control and force is required to correctly perform the entire asana sequence.

Aims – To assess body composition, functional profile and energy cost of asana in a group of elite Yoga Professional females (YP).

Methods – Eight YP (32 [means (SD)] (3) yrs, BMI 21 (2) kg/m2, training hours/day 6 (2)) and 8 sex and age-matched sedentary subjects (C, 32 (6) yrs, BMI (23 (4) kg/m2) participated in the study. Measurement were carried out in 3 different days. In day 1, body composition (Fat Mass, %FM, Fat Free Mass, %FFM and Mineral Bone Density [MBD]) were assessed by means of a Dual X-Ray Absorptiometry (DXA); in day 2, breath-by-breath oxygen uptake (VO_2), pulmonary ventilation and heart rate (HR) were measured during each asana sequence, being each asana maintained for 3 minutes (5 min of rest between 2 asanas) , and during incremental bicycle exercise up to exhaustion (Vo_2 peak); in day 3, the quadriceps Maximal Voluntary Isometric Contraction (MVC, knee angles at 30° and 60°) and the maximal anaerobic power (jump of a force platform, CMJ) were assessed.

Results – % FM was significantly lower (15.5±4.1%) and %FFM and MBD were significantly higher in YP than in C ($p<0.05$ for both comparisons). HR and VE above resting increased by 8±2 bpm and 3.3±1.0 l.min-1 respectively during yoga exercise. VO_2 increased up to 250 ml/min during each asana, and VO_2 peak was 10 % higher in YP than in C (p=ns). MVC values were significantly higher in YP than C at both knee angles ($p<0.01$), despite no differences in CMJ power.

Conclusions – Elite female professional yoga teachers are characterized by significant changes in body composition, with a higher maximal isometric force in lower limbs, compared to sedentary counterparts. However, they appear not to be able to transmit their increased force in powerful dynamic tasks. Due to the high level of training, only a slight increase in the energy cost of each asana was observed. The practice of yoga for years appears to highly improve the body composition and the functional profile of young women as well as the cardiorespiratory adjustment to exercise.

SKILL ACQUISITION IN BASKETBALL AFTER FATIGUING EXERCISE

Augste, C.

University of Augsburg, Germany

Introduction

When children intend to learn a new skill in their sports training, the question arises how much activation is necessary for optimal learning. The theory says that, during a training session, beginners should do skill acquisition training before fitness training (e.g. Schnabel, 1998; Hohmann et al., 2002). However, there exist some findings that even high loads do not influence the learning process negatively when a new simple motor skill is acquired (Olivier 1996). The aim of the present study was to check whether these findings hold in a sport specific setting for a complex task.

Method

122 young basketball players (27 female, 95 male, age 12.3 ± 1.0 years) of 9 different teams learned the hook shot. After a pre-test containing of 15 shots in a relaxed state and 15 shots in a fatigued state the subjects were organised in two parallel treatment groups. One group performed the skill acquisition training after a short warming-up (non-fatigue group (NF)), the other group after a fatiguing basketball specific circuit training (fatigue group (F)). After 12 training sessions the results of skill acquisition were measured in a post-test.

Results

The three-way repeated measures ANOVA showed a significant interaction between the factors time, treatment and skill level (F=8,652; p=0.004) for the shots performed in relaxed condition. While the advanced group had non-significant better learning results when practicing under heavy loads (F=3.059; p=0.089) the group of beginners practicing under fatigue learned significantly less than the relaxed group (F=5.836; p=0.021). The same tendency is found for the transfer test performed under fatigued conditions. For the advanced group again there was no significant difference between the F-group and the NF-group. Beginners of the F-group, however, learned significantly less than the NF-group (F=12.369; p=0.001), even though the situation during training was the same as during testing. This is in contrary to the specificity-hypothesis (Magill, 1998). Nevertheless the study confirms the recommendations for skill acquisition. Absolute beginners should learn complex sports skills under non-fatigued conditions. If the skill is controlled to some extent, however, the combination of fitness training and technical training seems to be more advantageous.

GENDER DIFFERENCE ON MUSCLE AND BONE COMPOSITION IN JAPANESE RHYTHMIC GYMNASTS

Aoba, T., Matsumoto, T., Asakura, M., Tsunoda, N.

Faculty of Physical Education, Japan

Muscle and bone composition were affected by athletic training modes. The characteristics of lean tissue mass (LTM) and bone mineral contents (BMC) on whole body in male athletes were reported previously. Difference of composition characteristics on whole and regional parts of the body between genders in athlete was not yet observed. Thus, the purpose of this study was to observe the effects of gender differences on bone and muscle composition in male and female athletes.

The subjects were forty athletes, 20 college male rhythmic gymnasts (MRG) and 20 college female rhythmic gymnasts (FRG). Theirs mean age was 19.7±1.6 years old, mean height was 169.1±5.7cm, weight was 62.5±4.8kg and 6.0±2.4 years training in MRG. Whereas, mean age was 19.6±1.1 years old, mean height was 161.1±5.3cm, weight was 49.4±3.9kg and 10.2±2.6 years training in FRG respectively. The bone and muscle composition were measured by Dual Energy X-ray absorptionetry (DXA method: XR-26 Norland USA). Each regional parts were measured by a program mode of absorptionetry, and the ratio of regional parts values were calculated on the trunk, arms and legs in whole body from them. Analysis from the unpaired t-test comparison by groups, and the correlation coefficient between LTM and BMC. Statistical significance level was used at $p<0.05$.

LTM was 50.53±3.90kg, BMC was 3.10±0.26kg, bone mineral density (BMD) was 1.086±0.060g/cm2 in MRG, whereas, LTM was 34.91±2.60kg, BMC was 2.54±0.20kg and BMD was 0.995±0.100g/cm2 in FRG. LTM, BMC and BMD values for whole and regional parts of FRG were significantly lower than that of MRG. BMC on whole body was significant related to LTM in MRG ($r=0.648$, $p<0.01$) and FRG ($r=0.669$, $p<0.01$). Relative values of arms to legs for LTM and BMC showed significant higher in MRG than that of FRG.

From these results, it was considered that muscle and bone composition on limbs may affect by gender difference in rhythmic gymnasts training.

ON-ICE PERFORMANCE CHARACTERISTICS OF MEN'S ICE HOCKEY PLAYERS OF TURKISH NATIONAL TEAM

Koz, M., Tasdemir, G., Dogramaci, E.

Ankara University, Turkey

Purpose

The sport of ice hokey has been played in Turkey since 1989, and has developed significanly. Despite its development, there has been no serious study about ice hockey or of players attributes in Turkey either.

The purpose of this study was to evaluate skating performance with on-ice fitness and off-ice fitness testingof elite men's ice hockey players.

Methods

Nine men ice hockey players between the ages of 21 and 28 years (x age = 23.44 ± 2.60 years, x playing experience (PE) = 7.77 ± 2.04 years) participated in the study. All of the players were members of the 2004/ 2005 Turkish National Team.

On-ice tests included (a) agility cornering S turn (AGL), (b) 6.10-m acceleration (ACC), (c) 47.85-m speed (SPD), (d) 15.20-m full speed (FSPD). Two trials of each test were measured with a photoelectric timing system.The off-ice variables that were evaluated included age, years of

playing experience, height, body mass, predicted body fat percentage(BF), sit-and-reach flexibility (SRF), vertical jump height(VJ). Pearson product moment correlations were used to quantify the relationships between the variables.

Results

The mean (± SD) values of AGL, ACC, SPD and FSPD were 9.94 (0.37), 1.63 (0.28), 5.78 (0.33), 1.99 (0.09) second, respectively. The mean (± SD) values of % BF, SRF, VJ were 10.70 (6.01), 31.38(4.39) cm, 56.66 (3.46) cm, respectively. Significant correlations ($p < 0.05$) were found between skating performance tests and off-ice variables. For example, correlation coaficients (r) between ACC and BF, SRF, VJH and PE were -0.64, 0.83, - 0.68, - 0.71, respectively.

Conclusions

The results demonstrate that on-ice performance characteristics of men's ice hockey players of Turkish National Team are very paltry than members of the other national team. Strong significant correlation ($r = 0.83$) between ACC and SRF were not fully explained and required further research. The sports of ice hokey to reach international level in Turkey are needed extra research in this area.

ENHANCING VERTICAL JUMP PERFORMANCE OF VOLLEYBALL ATHLETES - A COMPARATIVE STUDY BETWEEN BALLISTIC AND STATIC TYPE STRETCHING WARM-UP METHODOLOGIES

Angelo, R., Carvalho, A., Mourão, P., Moutinho, C., Carvalho, C.

Higher Education Institute of Maia, Portugal

Introduction: High performance levels all together with the evergrowing abilities of world class athletic performers demand that emerging issues regarding possible competitive performance enhancement techniques, should be brought to light in face of distinct interpretational views, originating from psicophysiology, biomechanics and also from the theoretical basis of different training methodologies. As such, different motor skills play specific roles in the wide array construct of human competitive performance. Thus flexibility training also presents itself as one major determinant of success in volleyball, building the basis for more efficient gameplay through the significant optimization of articular range of motion. In this way our study's main objective was to assess and compare the acute effect of ballistic type and static type stretching on vertical jump performance of volleyball athletes.

Methods: For this purpose we used a sample of 20 volleyball players randomly assigned into two distinct groups of ten athletes, one of which used static type stretching and the other one ballistic type strething. In order to assess the acute effect of each of the specific stretching methodologies, both of the groups were subjected to a pre-post warm up assessment experimental design, in wich all players were assessed in their maximal vertical jump performance ability before and after specific stretching warm-up strategies. All of the exercises defined for group 1 (Static type stretching) consisted in 4 sets of static 20 second stretching, with a 10 second rest interval between sets. In the same way all of the exercises selected for group 2 followed the same volume protocol, however each of the exercises was performed in groups of 20 fast segmental displacements, hence assuming ballistic characteristics.

All test subjects were thouroughly measured in terms of anthropometrical indicators (weight and height), and also in terms of vertical jump blocking and spiking performance expressed in maximal vertical jump height assessed through the use of the Ergojump electromechanical device.

Results: Our results demonstrated a performance enhancement effect of ballistic type stretching exercises on lower limb power output reflected in a stattisttically significant increase in vertical jump height of 4,3 cm in blocking and 5 cm in spiking. In contrast static stretching showed evidence of a performance-damping effect expressed in negative results of a decreased vertical jump height of minus 0,4 cm in blocking and minus 1,9 cm in spiking.

Conclusion: After reviewing our results we may conclude that given the importance of vertical jump height and lower limb power output on volleyball game performance, we strongly suggest that for optimizing jumping performance volleyball coaches should include ballistic type stretching routines in pre-training or pre-game warm-up procedures in order to positively enhance their athletes ability to jump.

METABOLIC CONSIDERATIONS OF STRENGTH TRAINING IN THE ELDERLY, RECREATIONAL AND ELITE SPORTS

Marzin, T., Hartmann, U., Niessen, M.

Departement for Theory and Practice in Sport, Technical University Munich, Germany, Germany

Introduction

Planning strength training intensities mostly refer to the one repetition maximum. This has been subject to several critical reviews (Buskies et al., 1999; Marschall et al., 1999). The influence of metabolic pathways is normally not taken into account. For this reason metabolic and methodical parameters of non-standardised strength training sessions are described.

Methods

A group of 30 subjects (21♂, 42±18 J, 181,9±6,3 cm, 89,2±15,5 kg; 9♀, 31±14 J, 168,5±3,9 cm, 59,0±4,3 kg) participated in the study. Oxygen uptake (VO2), lactic acid (LA), heart rate (HR) and rate of perceived exertion (RPE) where determined during a strength training session (ST). The number of repetitions (reps), duration per set (tset), gross and net training duration (tgross; tnet) were recorded. A caloric equivalent of 5 kcal/l O2 was assumed to calculate the energy demand. Each subject completed an incremental test on a bicycle ergometer (Lode Excalibur) to determine the anaerobic threshold (P4) (according to Mader et al., 1976). Additionally 21 subjects completed a supramaximal test of constant load (100-150 watt > P4) lasting 2-5 min in order to determine VO2 peak (MetaMax I).

Results

Mean VO2 during ST were about 12-15 ml/min*kg, representing average 30,1±5,1 % of VO2 peak. Interindividual differences concerning mean LA concentration were between 2,0±0,4 mmol/l and 9,6±2,6 mmol/l. Resulting gross energy turn-overs were about 6,0-6,5 kcal/min (♂) and 4,0 kcal/min (♀). The average number of reps per set for the entire sample was 26±6 reps, respectively tset 39±10 s. Mean tgross for the three categories was 80-120 min, mean tnet 15-30 min, resulting in a mean work/rest ratio of about 15-30%.

Conclusion

Representing the energy demand of muscle tissue, the VO2 during ST show - with a short time delay – immediate reactions to muscle work. The calculated energy demand of the analysed ST pointed out an increased energy turn-over above resting conditions. However this turn-over was lower than in most aerobic endurance training activities. For that reason described ST seems to be of minor importance in enhancing energy turn-over or reducing body weight compared to typical aerobic endurance sports. LA is not representing the load of ST sufficiently, due to the delayed accumulation in blood. Individual mean LA during ST of 9,4±2,6 mmol/l might have suggested a more extended share of anaerobic supplied work. Furthermore it is not possible to quantify the portions of metabolic pathways in con-

tracting muscle directly. Yet this would be necessary to draw conclusions concerning cellular adaptations in ST. Above all the quantification of the exact muscle power output of active muscle tissue remains a practical problem.

EFFECTS OF REPEATED SPRINTS VERSUS AEROBIC INTERVAL TRAINING IN SOCCER PLAYERS

Ferrari Bravo, D., Rampinini, E., Impellizzeri, F.M.

S.S.MAPEI, Castellanza, Italy, Italy

Repeated sprint ability (RSA) is considered an important fitness component of soccer physical performance and a recent study has shown that RSA test is correlated to high intensity activity during actual match-play. Several studies have also shown that a good level of aerobic fitness is required to meet the physiological demands of soccer and to aid recovery during high-intensity intermittent exercise. While various studies have shown the effectiveness of generic and specific aerobic interval training in soccer players, no studies have investigated the effect of RSA-based training on soccer players physical fitness. Therefore, the aim of this study was to compared the effects of repeated sprint versus aerobic interval training on some physical fitness components included RSA in soccer players. Twenty-six soccer players were randomly assigned to either repeated sprint (RSG)(N=13) or interval aerobic training group (ITG)(N=13). Repeated sprint training consisting of 3 bouts of six sprints of 40-m with direction changes and 20 sec recovery between sprints and 3 min active rest periods between bouts. Interval training consisting of 4 bouts of 4 min at 90 -95% of maximum heart rate with 3 min active rest periods. Both training programs were completed twice a week. The following outcomes were measured at baseline (Pre) and after 7 weeks of training during the regular season (Post): maximum oxygen uptake (VO2max), ventilatory threshold (VT), 10-m sprint test, RSA shuttle test, counter movement jump and Yo-Yo Intermittent Recovery test (YYIR). No interactions were found between groups for the parameters of aerobic fitness. Specifically, the two groups increased VO2max from 54.3 to 57.4 ml/kg/min and VO2 at VT from 45.0 to 46.1 ml/kg/min ($P<0.05$). Significant training group x time interactions ($P<0.001$) were found for the distance covered during YYIR and mean time in the RSA test. ITG increased YYIR by 13% (from 1846 m to 2077 m) while RSG increased by 28% (from 1917 to 2455 m) ($P<0.0001$). RSG also decreased the mean time during RSA test by 2.1% (from 7.53 to 7.37 s, $P<0.001$) while the ITG did not change (7.42 s pre vs 7.40 s post). No changes after the 7 weeks of training were found in both group in vertical jump height, 10-m sprint time and RSA decrement. Our results showed that sprint training and running interval training determined similar improvement in aerobic fitness. On the other hand sprint training induced higher gain in soccer specific endurance characterized by aerobic and anaerobic intermittent activity and direction changes. Sprint training also produced higher improvement in RSA test compared to running interval training. In conclusion, the RSA-based training used in the present study is an effective training for the improvement of important match-related physical performance and physiological characteristics in soccer players.

MONITORING OF TECHNICAL-TACTICAL TRAINING SESSIONS IN BASKETBALL

Ribera-Nebot, D., Reverter, J.

Barcelona University, Spain

Dynamic complex systems theories will provide us the best theoretical basis to construct a specific training science for team sports in which this specific athlete is able to achieve his/her auto-structuring by differential optimization / 1 /. Training monitoring, a necessity to help coach in training guide, is based on recording changes in an athlete during various stages of training or under the influence of main elements of sport activities (training session, competition, microcycle) / 2 /. In team sports the monitoring of technical-tactical training sessions is highly relevant in order to achieve an integrated control of the training load / 3 /.

The aim of this work is to suggest a method for monitoring technical-tactical training sessions as a complex system in basketball. This proposal has been experienced in basketball teams since 2000. It involves evaluating the following training load components of every technical-tactical training session: total duration of every exercise; total rest time in between exercises; approximate number of execution-participations and its duration for a reference player in each exercise; the biological-conditioning load, the technical-coordination load and the tactical-cognitive load of every exercise and of the training session; the volume of each group of exercises classified depending on the type of content and quality level; the biological-conditioning training load structure, the technical-coordination training load structure and the tactical-cognitive training load structure of the training session; relevant individual or group information pointed out by the coaches related to any of the basic training components (biological-conditioning, technical-coordination, tactical-cognitive, social-affective, emotional-volitive, creative-expressive, mental).

The proposed monitoring of technical-tactical training sessions in basketball as a part of the integrated monitoring of training load will provide useful information for making effective changes in training design, mainly on the following: (1) structure of technical-tactical training sessions, (2) structure of microcycles, (3) planning of training loads, (4) planning of selective technical-tactical and physical conditioning capacities.

ACCURACY AND RELIABILITY OF A COMMERCIAL VIDEO-COMPUTERIZED, SEMI-AUTOMATIC, SOCCER-MATCH ANALYSIS SYSTEM: PRELIMINARY RESULTS

Impellizzeri, F.M., Sassi, A., Rampinini, E.

S.S. MAPEI, Castellanza, Italy, Italy

Commercial semi-automated, video-computerized, image recognition match analysis systems can now supply professional soccer teams with match analysis data on all players just a few hours after the end of the game. Despite the popularity of these systems among professional soccer teams and researchers, no data are available about their validity. Therefore, the aim of this study was to provide preliminary evidence on the accuracy and reliability of one of these commercial match analysis systems (SICS, Bassano del Grappa, Italy).

Both radar and video analysis data were collected on a soccer player while performing an intense match phase simulation (350 m) including sprinting, striding and jogging in 4 different zones of the pitch. In a 5th pitch zone, 6 maximal 30-m sprint were also completed. Players velocities measured with the video-analysis system were compared with those measured using a radar system (Stalker, ATS). Data were filtered using a zero lag Butterworth filter, and the first and last 10% of the data were excluded from the computation of TE to avoid the edge effect due to filtering algorithm. Data from video analysis were tracked twice by two different operators. Accuracy and reliability for low intensity running (<15 km/h, LIR), high intensity running (>15km/h, HIR) and total distance (TD) of the intense match phase simulation were determined using the typical error (TE) expressed as coefficient of variation (Hopkins, 2000). Similarly, TE was calculated for sprinting (>19 km/h) and peak running speed (PS) during the 30-m sprints. The mean TE of the instantaneous velocities measured using the video-match analysis system taken with respect to the radar velocities was also calculated as indicator of overall velocity accuracy. During intense match phase simulation accuracy for LIR was 2.1 and 3.1%, for HIR was 3.6 and 5.6% and for TD resulted 1.0 and 1.5%, for the first and second tracking respectively. Reliability was 1.0% for LIR, 3.2% for HIR and 1.0% for TD. During sprinting accuracy was 1.8 and 1.7% for sprinting distance, and 1.3 and 0.9% for PS, for the first and second tracking respectively. Reliability was 3.2% for sprinting and 0.6% for PS. The overall accuracy of displacement data (velocity) was 5.6%. The preliminary results of this study showed high accuracy and reliability of a commercial match analysis system suggesting its validity for the quantification of match-related physical activities in soccer players for practical and research purposes. Further studies with larger sample size and using 90-m soccer-match simulation are necessary to fully validate video-match analysis systems.

Hopkins WG. Sports Med. 30: 1-15, 2000.

CHANGES IN THE MAXIMAL STRENGTH AND RATE OF FORCE DEVELOPMENT AFTER A SESSION OF PASSIVE STATIC STRETCHING

Fantini, C., Moreira Júnior, L., Menzel, H.-J., Chagas, M., Schmidtbleicher, D.

Federal University of Minas Gerais, Brazil

The maximal strength (Fmax) is decisive for the efficiency in some sports. However, the maximal rate of force development (MRFD) is one of the main parameters to be considered in activities in which the available time for strength production is limited (Schmidtbleicher, 1992). In spite of the importance of the MRFD for some sports, there is a lack of information related to the stretching effect in this strength component. The purpose of this study was to analyze the Fmax and MRFD performances measured in a maximal isometric muscle action, after a stretching session of the hamstring muscles. The subjects (n=16, age: 24,7±2,7 yrs; height 177,1±8,8 cm; weight: 68,6±12,7 kg) took the strength test followed by the flexibility test in both lower limbs before the hamstring flexibility training session began. The passive static stretching session was made of 3 sets of 3 stretching cycles, 1 minute-pause and the stretch was held for 15s. Immediately after the training session, the flexibility performance was measured. Flexibility training and measurements were performed by a custom made test apparatus (Flexmachine). The participants were seated in a straight-back chair with the limb to be tested elevated at 35o horizontally rested on a padded arm. In order to extend the knee joint passively, a mechanical arm connected parallel to the chair was used. To measure the range of motion (ROM) a potentiometer was fixed on the rotation axis of the arm. The strength test was performed on the IKM-System and the parameters analyzed were Fmax and MRFD. The subject was placed in a supine position with the lower limbs to be tested at 90° of hip and knee flexion. The heel of the lower limb tested was placed over a load cell that registered the isometric strength of the knee flexion. During the test, each contraction lasted 3 to 4 seconds. Three contractions were performed with a 2-minute interval between them. Student's T test was used ($p<0,05$) in order to compare the average values before and after the flexibility training session. The ROM increased significantly (before: 65,7°±15,5; after: 78,3°±16,9). The parameters Fmax and MRFD were reduced significantly (before: 274,69±7,79 N; after: 256,97±2,71 N and before: 2,47±0,93 N/ms; after: 2,23±0,87 N/ms, respectively). A stretching session with characteristics similar to the ones used in this study presents a negative effect on the Fmax and MRFD performance in the single joint isometric test. Different mechanisms have been postulated for the observed impairment in muscle strength output after stretching. Impairment of the strength transmission system via changes in muscle stiffness and changes in motor neuron excitability states has been theorized to reduce muscle strength output. Because stretching routines prior to physical activities are commonly used, more investigations about the transfer of these results to dynamic activities are necessary.

Schmidtbleicher, D. Training for power events In: Komi, P.V.,1992, p.381-395.

DIFFERENCES BETWEEN CROATIAN AND JAPANESE PROFESSIONAL BASKETBALL PLAYERS SHOWN THROUGH STRENGHT AND CONDITIONING INDICATORS

Milanovic, D. 1, Milanovic, M. 1, Pavlicevic, Z. 2

1 Faculty of Kinesiology University of Zagreb, 2 Japan Basketball Federation, Croatia

INTRODUCTION

Some of the previous research has demonstrated the significant differences between male and female basketball players, basketball players of different ages, in other words cadets, juniors and seniors as well as basketball players of different quality levels. The differential analysis through conditioning indicators of Croatian and Japanese professional basketball players as well as national team members is the very subject of this paper.

MATERIALS AND METHODS

The research subjects were selected from two groups of athletes that participated in the preparation process for large competitions in 2005. The first group is comprised of ten basketball players, members of the Croatian senior national team, and the second of 14 members of the Japanese senior national basketball team. The variable sample was made out of ten tests which, in theory, cover some of the typical motor and functional abilities such as: agility, maximum strength, maximum speed, explosive jumping and throwing power, flexibility, and repetitive body power and speed endurance. A multivariate (MANOVA) and univariate (ANOVA) variance analysis was used to determine the differences between the two groups of basketball players through physical conditioning indicators.

RESULTS AND DISCUSSION

The results of the multivariate variance analysis (Wilks Lambda-0,23 and Rao's difference coefficient-4,88) show that the two observed national basketball teams significantly differ (p-0.00) from one another in variables of physical conditioning. The results of the univariate variance analysis in Table 1 show a statistically significant difference between players of the Croatian and Japanese national basketball teams in each of the variables of physical preparedness. The statistically significant differences with a 99% certainty (p=0,01) were obtained in the variables for evaluating explosive throwing power (throwing from the chest line –concentrically (MEBLGk), throwing from the chest line –plyometrically (MEBLGp)), repetitive body power (sit-ups ABC - MRPOT3Z) and absolute power of the arms and shoulder area

(bench press - MASBP). The differences are, before all, determined by the training system and the level of physical conditioning. But the fact is that the basketball players of the two national basketball teams also differ with regard to the region they come from and the level of professional involvement in the training process.

CONCLUSION

The results of this research show statistically significant differences between 12 Croatian and 14 Japanese professional basketball players in some of the ten indicators of physical conditioning status that were used.

RELATIONSHIP BETWEEN JUMPING ABILITY AND MUSCLE ARCHITECTURAL CHARACTERISTICS OF BASKETBALL PLAYERS

Manou, V. 1, Miroti, O. 2, Stavropoulos, N. 2, Kellis, S. 2

1 University of Thessaly, 2 Aristotle University of Thessaloniki, Greece

Introduction: The jumping ability of a basketball player, as an expression of power, is a basic factor for good performance (Klinzing, 1991). This ability requires high shortening velocity which is determined by biochemical and muscle architectural characteristics (Lieber & Friden, 2000; 2001). Purpose: The purpose of this study was to investigate the relationship between jumping performance and muscle architectural characteristics of basketball players. Methods: Thirty four basketball players of Greek national A2 league volunteered to participate in this study (age: 23.5 ± 3.9 years; weight: 92.5 ± 11.8 kg; height: 1.94 ± 7.5 m; fat 13.4 ± 4.0 %). Muscle thickness and pennation angle of of vastus lateralis muscle were measured by B-mode ultrasonography, and fascicle length was estimated (Abe et al. 1999). Three types of vertical jumps performed on a Bertec force plate (type 4060H): squat jump, countermovement jump and counter movement jump with arm swing. The relationship between vertical jump performance and vastus lateralis architectural characteristics was examined using Pearson's product correlation test. Results: There was no correlation between vertical jumping performance (jumping height, take-off velocity, power) and pennation angle which is correlated negatively with muscle fascicle length relative to limb length ($r = -0.79$, $p<0.01$). Likewise vertical jumping performance was not correlated with muscle fascicle length relative to limb length which was correlated positively with muscle thickness ($r = 0.57$, $p<0.01$). Conclusion: The jumping ability as an expression of vertical jumping performance is not related with vastus lateralis architectural characteristics of basketball players. In contrary according to Abe et al. (2001) and Kumagai et al. (2000), sprinting performance is related to sprinter's muscle fascicle length.

SUB MAXIMAL ERGOMETER TEST VALID PREDICTOR OF MAXIMAL ROWING PERFORMANCE

Nederhof, E., Broenink, M., Helmantel, A., Lemmink, K.

University Medical Center Groningen, University of Groningen, Netherlands

Introduction

Rowing performance can be predicted by incremental graded exercise tests and by maximal exercise tests (e.g., Coen et al., 2003; Cosgrove et al., 1999). Sub maximal performance tests are preferred by coaches and athletes, but nothing is known about their predictive value. The purpose of the current study is to investigate the validity of a sub maximal rowing ergometer test.

Methods

The sub maximal rowing ergometer test consisted of three times 20 min at 80% of the heart rate reserve (3x20 test). Heart rate was monitored continuously and registered every 5 min. The test started with a 5 min warming-up followed by the first 20 min of the test with 5 min rest after each bout. The average distance rowed in 20 min was used as the 3x20 test score. The 3x20 test was validated against a maximal test on a Concept II rowing ergometer over 2 km by 35 (22 male; 13 female) rowers of national level. The 3x20 test was also validated against a 3 km maximal performance trial in a skiff (single, two oars) by 19 (9 male; 10 female) rowers. All rowers rowed the skiff trial on the same day. The 2 km test or the skiff trial was performed within two weeks of the 3x20 test.

Results

Performance on the 2 km maximal ergometer test was significantly predicted by gender (β = 0.60, $p < .001$), weight category (β = 0.39, $p < .001$) and 3x20 test score (β = -0.58, $p < .001$). The complete model predicted 91% of the variance. Performance on the 3 km skiff trial was predicted by gender (β = -1.09, $p < .05$) and 3x20 test score (β = -1.66, $p < .01$), but not by weight category (β = -0.27, $p > .05$). This model predicted 55% of the variance.

Discussion

The 3x20 test showed to be a valid predictor of maximal ergometer performance, but showed to be a weak predictor of rowing performance. Close inspection of the data showed that the relationship between 3x20 test scores and rowing performance was particularly weak for slower rowers. A linear trend was visible for those rowers who completed the 3km skiff trial in less than 13min40s. Thus, it is possible that poor rowing technique influenced the relationship between 3x20 test score and 3 km skiff trial performance. It is concluded that the 3x20 test is a valid rowing performance test especially for high level rowers.

HEAT TRANSFER VARIATIONS OF BICYCLE HELMETS--WHAT WORKS BEST?

Brühwiler, P., Buyan, M., Huber, R., Bogerd, C.P., Sznitman, J., Graf, S.F., Rösgen, T.

Empa, Materials Science and Technology, Switzerland

Bicycle helmets exhibit complex structures so as to combine impact protection with ventilation. A quantitative experimental measure of the state of the art and variations therein is a first step towards establishing principles of bicycle helmet ventilation. A thermal headform mounted in a climate-regulated wind tunnel was used to study the ventilation efficiency of 24 bicycle helmets at two wind speeds. Flow visualization in a water tunnel with a second headform demonstrated the flow patterns involved. The influence of design details such as channel length and vent placement was studied, as well as the impact of hair.

Differences in heat transfer among the helmets of up to 30% (scalp) and 10% (face) were observed, with the nude headform showing the highest values. On occasion, a negative role of some vents for forced convection was demonstrated. A weak correlation was found between the projected vent cross-section and heat transfer variations, as well as between exposed scalp area and heat transfer. A simple analytical model is introduced that facilitates the understanding of forced convection phenomena in such helmets. Adding a wig reduces the heat transfer by approximately a factor of 8 in the scalp region and up to one-third for the rest of the head for a selection of the best ventilated helmets. The role of the visor was also studied, and showed large variations from helmet to helmet and as a function of angle. Similar variations were observed with regard to solar radiant heat flow rejection.

The results suggest that there is significant optimization potential within the basic structure represented in modern bicycle helmets. Given the good correlation between heat transfer variations as measured with a thermal manikin, and variations felt by human subjects [1, 2], we conclude that wearer comfort would benefit from a more systematic approach to bicycle helmet design. For elite athletes, performance benefits of improved designs are anticipated on the basis of improved heat transfer.

AGE- AND GENDER-SPECIFIC PHYSIOLOGICAL CHARACTERISTICS OF JUDO ATHLETES

Pocecco, E.

Institute of Sports Science, Austria

Introduction. In judo, besides technical skill and tactical strategies, conditional characteristics are also indispensable for a successful performance. Few studies have examined physiological profiles of judo athletes and apparently no research until now has focused attention on the development of laboratory tests lasting the duration of a judo competition, regarding maximum arm and leg performance.

The aim of this study was to describe gender, age and rank dependent maximum arm and leg performance of judo athletes, derived from laboratory tests, which are similar in duration to a judo competition (5 min).

Material and Methods. The test group consisted of 4 female and 14 male (8 adolescents and 6 adults) judokas of different rank.

Anthropometric measurements included height, body weight and body composition (BIA). Peak oxygen uptake (VO2peak), ventilation (VE), heart rate (HR) and respiratory exchange ratio (RER) were measured during a continuous incremental test with an arm crank ergometer. Maximum power (Pmax) and total crank time to exhaustion were also recorded. VO2peak, VE, HR, RER and mean power (Pmean) were assessed during a continuous 5 min maximum test on the cycle ergometer.

Results. Women – upper body (ub): Pmax=2.3±0.2W/kg, VO2peak=29.5±1.0ml/min/kg; lower body (lb): Pmean=3.1±0.1W/kg, VO2peak=44.1±7.2ml/min/kg; young men – ub: Pmax=2.6±0.2W/kg, VO2peak=35.5±4.3ml/min/kg; lb: Pmean=3.6±0.2W/kg, VO2peak=49.4±5.7ml/min/kg; adult men – ub: Pmax=2.8±0.3W/kg, VO2peak=30.0±3.5ml/min/kg; lb: Pmean=4.0±0.5W/kg, VO2peak=50.2±6.4ml/min/kg.

Concerning relative parameters of the total group, arm Pmax correlated positively with lower body's Pmean ($r=0.812$, $p<0.001$) and VO2peak ($r=0.637$, $p<0.004$), whereas arm VO2peak correlated positively only with legs' VO2peak ($r=0.574$, $p<0.013$).

Discussion. Because the differences in relative upper and lower body power were significant only between men and women, we can assume that gender is more important than age in influencing this parameter. A high relative VO2peak for upper body distinguished adolescent male judokas from the others, suggesting that young athletes' aerobic capacity with the arms is more important than for the older ones, who are more anaerobically dominant. As no significant differences in lower body relative VO2peak were noticed, it is possible that the percentage of the different energy systems involved during this test was about the same for the three groups of judo athletes.

The correlations between upper and lower body's physiological parameters reflected the general state of training of the whole body required in judo.

The only parameter the rank was related to, was relative Pmax of upper body among adult men ($r=0.829$, $p<0.042$). This may be partly due to the higher importance focused on strength training with increasing age and rank, but perhaps also to the high variability of rank across this group. Anyway, apparently no study available in literature has shown such a correlation.

FATIGUE STATES IN COMPETITIVE SWIMMERS DURING A TRAINING SEASON

Alves, F., Pessoa, P., Rama, L.

Faculty of Human Kinetics, Portugal

The decrease of a ratio (Q) of blood lactate concentration (La) to ratings of perceived exertion (RPE) has been indicated as a marker of overreaching in endurance athletes (Snyder et al, 1993; Bosquet et al, 2001, Garcin et al 2002). The purpose of this study was to compare the effects of three training microcycles (a normal preparation microcycle (MC1), a microcycle of "shock" (MC2) and the first week of taper (MC3) in a group of national level swimmers, using several physiological and psychological markers of fatigue. Ten well-trained swimmers, 5 of each gender (female: 17.36 ± 2.20 years, 58.4 ± 4.92 kg, 171 ± 4 cm; male: 20.08 ±1.79 years, 70.6 ± 2.70 kg, 183 ± 5.83 cm) voluntered for this study. Q (multiplied by 100) was determined using an adapted "2 speed test" (Olbrecht et al, 1985) of 2 x 200m in the

best stroke with full rest. The first bout was submaximal (85% of best time), and was repeated at a fixed velocity in the three moments of evaluation. The second bout was performed at maximal intensity. OBLA was detemined. All the measurements were done in the beginning of the first training session of the week, after 36 hours of rest. Blood samples were collected one and three minutes after the end of each exercise bout. RPE was inquired at the completion of each repetition using the Cr-10 Borg's scale. Before each testing situation, swimmers were asked to fill a short version of POMS inquiry (BAM - Brief Assessment of Mood, developed by Dean et al, 1989) regarding the mood states dominant in previous training weak. Average swim velocities and submaximal La did not change among the evaluations in spite of a clear reduction of the latter displayed by some swimmers and an OBLA increase from MC2 to MC3, indicating a positive effect of the taper on the energy cost of submaximal swimming. Maximal average velocity decreased from MC1 to MC2, with recovery and overcompensation in MC3. Submaximal RPE scores were consistently higher after MC2. Maximal Q was significantly reduced from MC1 to MC2 but only some of the subjects returned to MC1 levels after the first weak of the taper phase. BAM scores variation was highly sensitive to changes in weak work loads. None of the swimmers evaluated showed signs of overreaching. Utilization of submaximal Q seems to be a good indicator of the fatigue state of swimmers during heavier work load periods, showing several swimmers an increase of RPE for the same swim velocity.

EFFECT OF PROPRIOCEPTIVE TRAINING ON AGILITY PERFORMANCE

Simek, S., Jukic, I., Milanovic, L.

University of Zagreb, Croatia

Only few studies on effects of proprioceptive training focused on physical characteristics improvement such as leg muscles strength (Heitkamp et al., 2001; Tropp & Askling, 1988) or jumping ability (Ziegler, 2002). The purpose of this study was to determine proprioceptive training effects on agility performance. Seventy-five healthy and physically active men participated in this study (age: 19 ± 1.2 yr). They were randomly allocated into experimental (n=37) and control group (n=38). Agility was assessed before and after the experiment using three tests: 20 yards running with 180° turns (y20), lateral shuffle 6x4m (LAT) and lateral hops over 30cm high bench in 10 seconds (HOPS). Experimental group carried out a 10 week proprioceptive training program. Differences within and between groups were analysed using repeated-measures two-way ANOVA and Post hoc Tukey test. Results in y20 showed significant changes induced by experimental program. Post hoc Tukey test revealed that the difference between groups exists at the end of experiment ($p<0.01$), but also that the significant difference exists in pre- and post- experiment results in control group ($p<0.05$). Specifically, control group had lower values achieved in this test at the end of experiment, while the results of experiment group did not differ significantly from their pre-test values. In LAT and HOPS no significant changes were found as a result of experimental program.

Although previous results showed improvement in strength of leg flexors and extenstors and foot flexors and extensors, as well as higher force development after ground contact in jumping (Bruhn et al., 2004) after proprioceptive training that could possibly lead to changes in agility performance, in this study no significant changes in agility performance were found. Since the agility is a complex movement, possible partial effects did not result in improvement of total task efficiency. Kaminski et al. (2003) did not found improvements in strength of foot invertors and evertors after the proprioceptive training program. According to specificity of lateral movement, strength of those muscles and leg adductors and abductors could have high influence on test result. This training program was more focused on anterio-posterior direction exercises, than medio-lateral ankle joint movements. Also, leg adductors and abductors were not specifically targeted. Further research on proprioceptive training effects on agility performance is needed.

QUANTIFICATION OF HIGH INTENSITY ACTIVITY FROM THE ENERGY COST OF SPEED CHANGES MEASURED DURING PROFESSIONAL SOCCER MATCHES

Sassi, A., Rampinini, E., Impellizzeri, F.M.

S.S. MAPEI, Castellanza, Italy, Italy

The distances covered in selected speed zones measured by video match-analysis systems are commonly used to evaluate the physical work of soccer players during match-play. However, the use of speed ranges to quantify the effort may underestimate the physiological strain because it does not take into account the short sprints and striding, where the player does not reach speed values classified as high intense activities. The aim of this study was to compare the quantification of the high intense match activities using the classification based on running speed ranges, to that determined from the estimation of the energy cost of running including acceleration and decelerations. Match speed raw data of 10 players during official matches (Serie A) were determined using a commercial video-computerized, semi-automatic, match analysis system (SICS, Bassano del Grappa, Italy). Three intensity zones based on speed ranges were determined: walking (0-2.2 m/s), running (2.2-4.4 m/s), and sprinting (>4.4 m/s). For the same intensity zones, the speed thresholds were converted in metabolic power: 0-5.4 W /kg for walking, 5.4-16.2 W/kg for running, and >16.2 W/kg for sprinting. The movement energy cost including speed changes was calculated adding, to the cost of walking (2.5 J/kg/m) or running (3.6 J/kg/m), the energy spent for kinetic energy variations. The latter was calculated assuming a player's body mass of 75 kg, and an efficiency of 25% for the mechanical work performed while accelerating, and four times higher for the negative work performed while decelerating. Using the speed ranges method, the distances covered while walking, running and sprinting were 4094±454 m, 5067±1182 m and 1585±381 m, respectively. These values corresponded to 38%, 47% and 15% of the total distance covered (10745±1072 m), respectively. Using the metabolic power thresholds the distance covered while walking and running decreased to 2721±355 m and 4094±723 m ($P<0.001$) corresponding to 25% and 38% of total distance, respectively. The distance covered sprinting increased to 3930±672 m ($P<0.001$) or 37% of total distance.

During soccer match, the total energy cost estimated from the average distance covered at the various intensities was 29.6±3.6 kJ/kg. If speed changes were taken into account the energy cost increased by 77%, i.e. 52.4±5.4 kJ/kg (P>0.001). Our results confirmed that classifying the physical strain using the speed categories method the physiological effort is underestimated. In fact, taking into account the frequent acceleration and deceleration running phases, the distance covered at high metabolic cost increased from 15 to 37%. However, the total energy cost estimated with the present method is still lower than the about 70 kJ/kg reported in the literature, suggesting that the total energy cost is influenced by other factors such as the additional cost of unorthodox movements and running with the ball, or a higher cost of running on grass surface.

EFFECTS OF 8-WEEKS STRENGTH AND POWER TRAINING ON MAXIMAL CONCENTRIC FORCE, MAXIMAL AEROBIC POWER, ALACTACID ANAEROBIC POWER AND BODY COMPOSITION IN ELITE RUGBY PLAYERS

Cè, E., Biasetti, F., Dugnani, S., Calì, S.

Faculty of Exercise Sciences, University of Milan, Italy

Introduction – Rugby player is characterised by high levels of maximal force and power, high anaerobic power and fairly good level of maximal aerobic power. However, the effects of a strength or a power training on such parameters are still controversial.

Aims – To compare the effects of 8-weeks strength or power training on maximal concentric force, maximal aerobic and anaerobic power and body composition in elite rugby players.

Methods – Thirty-six elite rugby players participated in the study. Players were divided in 2 groups, based on their role: midfielder (MF) (n = 20; 25 (3) [mean (SD)] yrs; 187 (6) cm; 106 (8) kg) and three-quarters (TQ) (n = 16; 24 (4) yrs; 181 (5) cm; 86 (8) kg). The members of each group were randomly assigned to an 8-weeks strength training program (ST, n =18) or an equal period of power training (PT, n =18) 2 times a week. ST consisted in 6 series of 6 repetitions with a load equal to 80%1RM. PT consisted in 3 series of 3 repetitions using 80%1RM + 5 repetitions with 30%1RM. During both trainings, a pause of 3 minutes through the series was observed. The exercises adopted for both the trainings were those used during 1RM Pre-Post-test. Loads were adjusted each 7 weeks. Training programs were carried out during off-season period. Pre-Post-test consisted in: 1RM assessment during the exercises of Bench Press, Throw; Squat, maximal repetition number of Body Weight Traction (BWT), 10 Meters Speed Test, 30 Meters Speed Test and a Modified Leger Test. Body mass (BMI) and composition (%FM and Lean Body Mass [LBM]: skin-folds technique) were assessed before and after the training period.

Results – After ST, 1RM test significantly increased in Bench Press in MF but not in TQ; Throw (TQ); Squat (MF and TQ), $p<0.05$. 30 Meters Speed Test results were significantly higher in MF, $p<0.05$. Modified Leger Test significantly increase in both MF and TQ, $p<0.05$. After PT, 1RM test significantly increased in Bench Press (TQ), Throw and Squat (MF and TQ), $p<0.05$. 30 Meters Speed Test increased in TQ only, $p<0.05$. BWT slightly increased in both MF and TQ. No significant differences were found in BMI, %FM and LBM after both training programs in both groups.

Conclusions – In rugby players power training seems to be generally more appropriate to increase maximal concentric force irrespective of the role of the players. Strength training seems to improve maximal aerobic power both in MF and TQ. Maximal anaerobic power response seems to be role-dependent. Finally, body composition seems to be unaffected by the proposed training programs.

ANTHROPOMETRIC CHARACTERISTICS OF ELITE TURKISH WEIGHT LIFTERS

Akkus, H.

Selcuk University, Turkey

Studies show that there are differences between athletes of different events and even different categories of the same event on anthropometric characteristisc (3,8,9,11,17).

Weight lifters have different structures and body weights in terms of anthropometric data. They compete in different categories according to their age and body weight.

In this study, a total of 50 elite Turkish weight lifters served as subjects. They were the members of the turkish national team.

The aim of this study was to investigate the anthropometric characteristics, body compositon and somatotype of weight lifters and to compare with both reference data and data reported in previous studies especially very old olympic games on weightlifting competing at international events.

Material and Methods

50 elite turkish weight lifters investigated whose average age was 24,65±2,08 years who were medalists in national and international competitions.

Anthoropometric Parameters

1. Body weight (kg) using a steelyard, with allowance of 20 gr, with the subject undressed.

2. Height (cm) in the erect position, was measured with a Holtain yard stick, with allowance of 1 mm.

3. The body mass index (BMI) was obtained according to the following formula:

Weight (kg)/height(m)2

4. The relationship between the trunk and the lover limbs, was obtained by appliying the following formula:

Sitting height (cm) x 100 / height (cm)

5. The extension of the arms (cm) or the armspan, was taken with the subject in the upright position, arms streched out and the backs of the hand pressed against the graph paper placed on the walls.

Body Composition

1. The thickness of subcutaneous peniculus adiposus was evaluated by means of biceps, triceps, subscapular and suprailiac skinfolds.

The measurements, which were carried out by one operator only, were taken from the left half of the body using a Holtain Skinfold Caliber (10 gr/mm2) with allowance of 0.2 mm.

2. Body Density= 1,1369-0,0598 * (sum of the skinfolds)

3. The percentage of body fat was calculated according to Siri's formula:

% Fat= ((4,95/body density)-4,5)*100
Somatotype
The method of somatotyping used in this study was the Heat-Carter method.
Statistical Analysis
Weight lifters were groupen into four weight groups: Less than 60 kg, 60-79,9 kg, 80-99 kg, and 100 kg or more.
For all variables, mean and standard deviation were calculated.
As can be seen from somatocharts, the somatoplot distribution of olympic weightlifters and the Elite Turkish weightlifters are similar except group of <60 kg.
This study shown that there were many similarities between Elite Turkish Weightlifters and very old Olympic Games' weightlifters.
To sum up, it can be said that there exists a universal physique specific to any event because weigth categories and lifting style and training methods changed many times in last 40 years in weightlifting but somatotype and anthropometric characteristics are still same.

EFFECT OF PLAYING BASKETBALL IN YOUNG BASKETBALL PLAYERS

Castagna, C. 1+2, Manzi, V. 2, Marini, M. 1, Annino, G. 2, Padua, E. 2, D'Ottavio, S. 2
1 Scuola Regionale dello Sport delle Marche, CONI, Ancona, Italy, 2 School of Sports and Exercise Sciences, Faculty of Medicine and Surgery, University of Roma Tor Vergata, Rome, Italy , Italy

Competitive basketball is considered as an intermittent high-intensity physical activity that requires a well-developed aerobic and anaerobic fitness (McInnes, Carlson et al. 1995). However the information available is almost all related to adult basketball. Therefore the aim of this study was to assess the physiological demands of youth basketball, in order to obtain information useful for training and competition. Twenty basketball-players (Stamura Basket Ancona, body mass 72.4 ± 11.4 kg, height 181.7 ± 6.9 cm, and age 16.8 ± 2 yrs, VO2max 60.4±5.1 ml kg-1 min-1, VT 40.2±4.7 ml kg-1 min-1) were observed during between-peers games consisting in two 10 min periods of effective play (30 min total play) interspersed with a 2 min interval without substitutions. Heart rate (Polar Team System, Polar Electro Oy, Kempele, Finland) and earlobe blood-lactate concentration (Lactate Pro, Arkray, Tokyo, Japan) were monitored throughout the games. Before and after competition vertical jump (CMJ, Muscle Lab, Bosco System, Rieti, Italy), 15m shuttle running sprint (15mSR, Microgate Polifemo, Bolzano, Italy) and line-drill (LD) performance were assessed in random order in each player (Hoffman, Nusse et al. 2003). Games were performed in a air-conditioned gymnasium in order to keep environmental condition constant. During the first and the second half of the experimental game, players attained 86.2±5.3 and 86.7±4.3% of the individual HRmax, respectively (p=0.42). Average game intensity was 71.5 and 105% of the VO2max and VT, respectively. Experimental-games blood lactate concentration was 3.72±1.39 mmol l-1. Pre to Post games Counter-movement jump, 15mSR and LD scores were 39.9±5.9 vs 40.3±5.7 cm, 5.80±0.25 vs 5.77±0.22 and 26.7±1.3 vs 27.7±2.7 s. Line-drill performance significantly decreased post-game (p=0.001). Although observations were made using an experimental-game, the intensity attained by players during competition is in line to what reported for professional basketball players during highly competitive games (McInnes, Carlson et al. 1995). This supporting the validity of the research design devised for this investigation. Only LD showed significant post-game decrements. The results of this study showed that youth basketball imposes physiological stresses similar to those reported for adult basketball. Performance decrements of prolonged basketball-specific sprinting suggest that the ability to repeat sprint may be a limiting factor in basketball performance. However conclusion about the actual game-limiting factors may be drawn only after specific time-motion analyses.

Hoffman, J. R., V. Nusse, et al. (2003).

THE REACTION OF BLOOD BIOCHEMISTRY AND METABOLISM BY INHALING HYPEROXIA (97%) IN RECOVERY PHASE AFTER HIGH ANAEROBIC INTENSITY EXERCISE

Jang, J.T., Smith, R.W., Huang, L.C.
Institute of Coaching Science, Taiwan

Abstract
The three purposes of this study were to investigate: (1) whether the metabolism of blood lactate is in any way influenced by inhaling hyperoxia (97%) during interval and after an exercise session? (2) will blood ammonia (NH3) be removed quicker by inhaling hyperoxia (97%)? and (3) whether hyperoxia (97%) inhaled after intense exercise will produce free radicals?
Seven 800-meter female runners participated in this study which consisted of two tests (2xTest). Test one (T-1) was conducted using normoxia, and after one day of rest, test two (T-2) was conducted using hyperoxia (97%) and nitrogen (3%) during a 10 min rest interval after Set-1 and 15 min after Set two(Set-2).
Results showed that in the two tests, there were no significant differences in blood lactate and NH3 in Set-1 ($p>0.05$). However, in Set-2 the metabolism rate of blood lactate was significantly decreased ($p<0.05$), while, NH3 showed no difference in Set-2 ($p>0.05$). The production of Hydrogen Peroxide (H2O2) was not affected by the inhaling of hyperoxia. In conclusion, the intake of hyperoxia after exercise had a positive effect on reducing blood lactate, but no effect on blood NH3 or increasing the reaction of free radicals.

ACUTE EFFECTS OF PASSIVE VS. CONTRACT-RELAX STRETCHING MODALITIES ON THE NEUROMUSCULAR PROPERTIES OF PLANTAR FLEXOR MUSCLES

Babault, N., Kouassi, B.Y., Desbrosses, K., Cometti, G.
UFR STAPS Strasbourg, France

Acute passive stretching is now well known to have detrimental effects on strength production capacity (Cramer et al., 2005). The present investigation aimed to determine whether these effects could be reduced by modifying stretching modalities. We therefore tested the hypothesis that neuromuscular properties of plantar flexor muscles were better maintained using a contract-relax stretching modality than with passive stretches.
Eight male volunteers took part in the experimentation. Subjects were tested on two separate sessions, before and immediately after a 15min passive or contract-relax stretching program of plantar flexor muscles (20 stretches). Passive stretching consisted in 30s stretches to the point of discomfort. For the contract-relax stretching modality, subjects performed 6s sub-maximal isometric plantar flexion before 24s passive stretches. 15s rest periods were allowed between stretches. Stretching modalities were presented in a random order with at least two weeks between sessions. Measurements included maximal voluntary isometric torque (MVT) and the corresponding electromy-

ographic activity of soleus and medial gastrocnemius muscles (quantified by RMS values), as well as maximal peak torque (Pt) elicited by single supramaximal electrical stimulation of the tibial nerve.

The repeated measures ANOVA only revealed significant time effect (pre vs. post-stretching) for MVT ($P < 0.01$) and soleus RMS ($P < 0.05$). After stretching, the mean MVT and soleus RMS decreases were -10.3 ± 14.2% and -8.2 ± 12.8%, respectively. No significant change was obtained neither for Pt nor medial gastrocnemius RMS. Although MVT and soleus RMS changes were more pronounced after passive stretches, no significant stretching modality effect was obtained. For example, after passive and contract-relax stretching modalities, MVT decreases were -17.1 ± 9.9% and -3.4 ± 15.0%, respectively.

Performing passive or contract-relax stretching modalities had detrimental effects on the neuromuscular properties of plantar flexor muscles. Inclusion of short isometric contractions before stretch did not reduce this negative effect. After 15min stretch, the decreased strength production capacity appears to be primarily related to neural factors, as exhibited by the reduced soleus RMS. The lack of Pt modification after stretch suggests a reduced contribution of mechanical properties on MVT reduction. However, contractile properties alterations, such as a shift in the length-tension properties, may account for the unmodified Pt (e.g., Weir et al., 2005).

CHANGES IN ENERGY ABSORPTION CAPACITY OF RUNNING SHOES FOLLOWED BY SIX MONTHS OF WEAR

Koivu, M., Aschan, C., Mäki, S., Santtila, M., Kyröläinen, H.

Finnish National Defence College, Finland

Human movement is a complex phenomenon, where physiological components interact with the external conditions of the shoe and the surface. One of the purposes of the present study was to determine energy absorption capacity of the running shoes in association with the level of physical activity.

The number of steps of 41 volunteered conscripts was measured by pedometers (OMRON walking style II) for evaluating the physical activity of the conscripts. Changes in properties of athletic shoes were tested before and after wearing for six months. The energy absorption of seat region of four different brand running shoes was tested by using the standardized test method described in EN ISO 20344:2004, Personal Protective Equipment - Test methods for footwear. In the test procedure, the running shoe sample was placed on a steel base and a test punch was pressed against the bottom unit from the inside at the centre of the heel area until the force of 5000 N was obtained. In addition, running shoes repeated energy absorption capacity was tested by pressuring them twice a day for 20 times in total.

During a day, the conscripts took an average of 12524 steps, corresponding to about 10.9 km. The highest energy absorption capacity of the new running shoes varied between 38 J and 41 J in two brands. However, during the basic training period of six months, energy absorption capacity of those running shoes decreased significantly (38 ± 2 J vs. 35 ±2 J, $p < 0.01$ and 41±3 J vs. 37±2 J, $p < 0.05$, respectively). Among all the tested shoes, the energy absorption of seat region differed (36 ± 5 J vs. 33 ± 3 J, < 0.001) between the new and worn running shoe samples. These changes were, however, smaller in those two brands of which initial energy absorption capacity also were the smallest. Energy absorption capacity of worn running shoes never reduced below the requirements set for professional, e.g. safety, footwear.

The results obtained after repeated tests were of the same order of magnitude than those obtained after wearing them six months by conscripts. This may indicate that the repeated tests could be used to simulate the effects of wear on footwear on energy absorption of seat region. These findings demonstrate, furthermore, that the basic training of six months alters statistically significantly energy absorption capacity of some running shoes. Thus, it might be questionable to wear same running shoes again with the next incoming conscripts. It is noteworthy that the significant decline in energy absorption occurred with the two highest scoring running shoes. This might indicate that energy absorption capacity of unused running shoes might not be an only criterion that should be used when purchasing them. Furthermore, the results from the repeated energy absorption test proved that this test can be used to simulate ability of running shoes to maintain energy absorption capacity. For that reason it carries an important role when establishing a purchasing criterion for running shoes, which enable safe physical activity without injury risks.

ELABORATING PLAYING TEAMS BASED ON BEHAVIORAL SAFETY OF HANDBALLERS

Ortanescu, D., Ortanescu, C.

University of Craiova, Romania

Introduction: Elaborating the team is a difficult task, for the coach, based on complex data, on feeling or interests adjacent to performance. Considering the usual approaches the physic factor is of the main variables that we follow for choosing the team's components. Although some coaches prefer rather a sportive with lower results in selection tests who is constant in his performances, then one with high physic performances. The practice has shown that the coach isn't always right.

Method: The need of objectivity for the selection of team's components for certain competitions has lead to elaborate present work which approaches aspects of constant technique and tactic executions during the game of handball. For these we have chosen a sample made of 20 sportive of 11-12 ears old with perspectives to become titular, 2 on the post of goalkeeper and 3 for each post of field player, with the intention to determine the correspondences between establishing motrical emotional balance, vestibular and motor coordination and stability, certainty of technique and tactic execution during official games.

The testes were: Chappuis test for valuing emotional balance, from Bruininsk – Obseretsky battery, test used to estimate the direction of the movement and 8 items for valuing static and dynamic balance whose data were correlated to those obtained after registering of 4 games, where the number of tactic and technical mistakes was registered for each sportive involved in our study.

Discussions: After data centralization we can notice the existence of a positive correlation between metrical and emotional balance and between these and the number of succeeded technical and tactic actions. The safety of executions during registered games is correlated to the motrical balance, while complex actions – technical and tactic actions too – involve more the emotional balance. We noticed that good technical training affects the safety of executions, motrical balance and the capacity to estimate distances and the experience from competitions influence positively the results of the test regarding emotional balance.

Conclusions: Standard tests can be instruments of selection for participant groups in competitions, stability and safety of executions being preferred. It is in teams' advantage to rely on balanced and not on inconstant components, even if they have from time to time excellent success. Regarding the games' level all sportive have to play, to gather experience and self trust, to sustain the activity during training as well as during competition.

VARIABLES THAT EMPHASIZE THE QUALITY OF LEARNING TECHNICAL ACROBATIC ELEMENTS

Ortanescu, D., Ortanescu, C.

University of Craiova, Romania

Introduction: Representing one of the basic factors for obtaining sportive performance, the technical training relies on the quality of motrical training. Emphasized through accurate and stable exercises, it is considered as synthesis of complex of congruent components, aspect that makes difficult to study the weight of each one, and establishing interdependence relations even if considering one sportive branch.

Method: The present work is orientated only on establishing the correspondence between basics parameters of visual, auditory and motrical memory, of focused and distributive attention, and of the quality of acrobatic, creative combinations considering the learning process, for a group of 10 gymnasts, 10/12 years old, registered in 10 training lessons assigned to each tracked structures using a constant and unique dosing.

Chosen testes were: Ray test, Lalaumé test, Praga test, Toulouse-Pieron test and a motrical memory test made by us concerning 10 bounded elements specific for artistic gymnastics, executed after first visualization and registered as number of mistakes. The results of the tests were correlated with the number of wrong answers from the execution of each learned element, of manifest interferences during variants and their combined errors, respective to acrobatic elements: flick backwards, grouped backward jump, square and stretched, tempo-jump and the combinations: flick - tempo-jump – flick, flick - grouped backward jump, flick– stretched jump, flick - square jump, flick - tempo-jump - grouped backward jump, summarizing 5 unique tracked answers and 5 answers for the combinations.

Discussions: The data was statistically worked, arithmetic averages identify 2 categories of subjects: some gives constantly good answers, average or wrong and others and inconsequent. For the first category we must notice: constant values of the memory and attention, daily insignificant differences, a positive correlation index for these values and the motrical answers, between the auditory memory, focused attention and unique answers, with negative transfer for bonding elements; between visual memory, distributive attention and acrobatic combinations with positive transfer based probably on the complete idea - motor image at an individual level less ordinate or led by a coach. The second category of subjects manifested inconsequence in the results, only at 1 test or several, and we noticed a positive correlation between them and the number of errors. We notice the direct involvement of the quality of focused attention but also of visual memory, which low values in certain training days directly influenced the rise of the error number in motric answers.

Conclusions: There is direct correspondence between the memory qualities, attention and the fidelity of technical executions, each of them contributing to certain steps of learning for a correct apprehension.

DISPLACEMENT VELOCITY IN TEAM SPORT: RELIABILITY OF A NEW AGILITY TEST

Benvenuti, C. 1, De Pero, R. 1, Tessitore, A. 1+2, Capranica, L. 1

1 IUSM od Rome, 2 Vrije University of Brussels, Italy

Introduction

Agility is a crucial aspect for team games performance where the players have to move according to the uncertainty of the game (Rosch et al., 2000, Benedek & Palfai, 1980). Although several tests aim at evaluating agility (Draper & Lancaster, 1985; Butifant, Graham, Cross, 1999), there is a lack of information regarding the athletes' ability to accelerate, decelerate, and change direction of movement according to the changing requirements of the environment. Thus, the aim of the present study was to investigate the reliability of a field test developed to evaluate the athlete's ability to run according to unexpected visual stimuli.

Methods

Thirty athletes (15 females: age 22±2, body mass 59.5±7.08 kg, height 166±5 cm; 15 males: age 23±3, body mass 71.8±8.4 kg, height 174±5 cm) practicing futsal, gymnastics, or martial arts volunteered in this study. Four luminous semi-spheres were placed at the corners of a 7.5x7.5 m court. Three sequences of 6 successive lightings (total distance: 51 m; lighting sequence: A=321241; B=231421; C=342123) were randomly administered with a 5 min rest between trials. The time needed to run and kick the lighted semi-spheres to switch them off was calculated. Participants were administered the sequences during three experimental sessions, with a three-day rest in between. ANOVA was applied to verify significant ($p<0.05$) differences between trials and experimental sessions, while intraclass correlation coefficients (ICC) were calculated to verify the reliability of the test.

Results

No significant difference was found for trials and experimental sessions (first session: sequence A = 203.3±13.5 s, sequence B = 200.0±9.6 s, sequence C = 199.4±11.2 s; second session: sequence A = 197.8±8.9, sequence B = 198.4 ±15.6 s, sequence C = 198.7±11.9 s; third session: sequence A = 195.2±8.2 s, sequence B = 195.1±8.4 s, sequence C = 194.9±12.3 s). The average ICC was .80.

Discussion/Conclusion

The present test aimed at evaluating the athletes' ability to move according to unknown visual stimuli, especially relevant for team sports players. The test showed a good internal consistency (Vincent, 1999) and no learning effect emerged. Given the lack of significant difference between sequences performed in the three experimental days, a single experimental session and a single sequence can be used. However to evaluate the athlete's best performance, it could be advisable to administer three different sequences within a single session.

EFFECT OF 4 WEEKS SPORTS TRAINING ON ENDURANCE PERFORMANCE OF THE PLAYERS OF FUTSAL EVALUATED BY MEANS OF A NEW FUTSAL INTERMITTENT ENDURANCE TEST AND THE 20 METER SHUTTLE RUN TEST

Barbero-Álvarez, J.C., Granero, P., Miladi, I., Castagna, C., Granda, J., Ahmaidi, S.

Granada of University, Spain

In professional soccer indoor or futsal players, many physiological stresses associated with the competition require great physical fitness. To perform at the higher level, players need a well-developed capacity to perform high intensity activities such as cruising and sprinting, as well as the capacity to quickly recover during low-intensity activities.

Physical capacity in multiple-sprint athletes is often evaluated using sport-specific field tests. Actually, the most used common test for assessing aerobic fitness is the multistage 20 meter shuttle run test (Léger and Lambert 1982, Ahmaidi et al. 1992). Recently, a new developed futsal intermittent endurance test (FIET) was developed to simulate the exercise and rest rates observed during a futsal match-play (Barbero et al. 2005). The aim of this study was thus to compare the FIET and the conventional 20 meter shuttle running test (SRT) in 14 in Spanish Futsal League athletes before and after a pre-season training period.

All subjects have performed both SRT and FIET tests in random order. The SRT was performed according to Léger and Lambert (1982) and Ahmaidi et al. (1992) studies.

The FIET consisted of 45 m shuttle runs (3 x 15 m) with a progressive increased speed through recorded beeps. Between each running bout, the participants have a 10 s active rest based on jogging after 30 s period of passive recovery. For both tests, when the subjects have failed twice to reach the finishing line in time with respect to the beeps, the distance covered (m) and final speed (Km/h) are recorded representing the tests results.

The results obtained for the two tests before and after pre-season training showed that the distance covered and the final speed reached (peak running speed) in the FIET are significantly increased (1433.7 ± 171.9 vs. 1587.9 ± 166.9, $P<0.001$). However, distance and speed remain without improvement during SRT (2057.8 ± 347.2 vs. 2097.8 ± 252.9). Moreover, strong correlation ($P<0.001$) was found between the maximal speed and total distance attained in both tests (PRE and POST).

It is concluded that FIET, which is more specific to the activity carried out by the futsal players, is able to assess satisfactorily aerobic fitness in futsal athletes. Moveover, the FIET was shown as acceptable tool to follow the training adaptations produced in the players. At least, FIET performance appears a more sensitive measure for variations in futsal performance than SRT and can thus be used to detect level differences between players.

PEDALLING CADENCE DOES NOT INFLUENCE TIME TO FATIGUE OF PHYSICALLY ACTIVE MALES IN A PROGRESSIVE MAXIMAL RAMP TEST

Ansley, L., Noakes, T.

Kingston University, United Kingdom

Introduction

Recent technological advances have resulted in the widespread adoption of electrically-braked cycle ergometers for exercise testing. These developments have facilitated the use of a continuously increasing, or ramp, workload protocol to measure work capacity; which was identified early on as the ideal protocol for testing maximal effort (Taylor, 1941). Furthermore, in contrast to the traditional ergometers, electrically-braked ergometers also allow for the workload to be applied independent of the pedalling frequency that the subject adopts. However, unlike prescribed-cadence tests in which the test is halted when the required cadence can no longer be maintained, during preferred-cadence tests cadence drops off towards the end of the test (Katch, 1973); potentially extending the duration of the test before fatigue is reached. This study attempts to determine whether the potential extension afforded to subjects during a preferred-cadence test results in a significantly improved maximal work output.

Methods

Nine physically active individuals performed in random order a maximal incremental ramp test (0.5 W.s-1) on four occasions at a fixed cadence of 60, 80 or 100 rpm and at their preferred cadence (PC). Cadence was measured throughout each trial and averaged over 10s. Testing order was randomised. Mean (+/-SE) cadence data for the 1st minute, 3rd minute and final minute are presented. A repeated measures ANOVA was performed with significance accepted at $p<0.05$.

Results

Peak power output was similar for all cadence conditions (60=371+/-10rpm; 80=376+/-11rpm; 100=372+/-12rpm; PC=383+/-11rpm) ($p=0.86$). The mean cadence during the PC condition (88+/-2.9rpm) was not significantly different from the mean cadence for the 80rpm condition (81+/-0.6rpm) ($p=0.38$). Cadence during the PC trial declined significantly over the final 60s compared with the 1st ($p=0.05$) and 3rd ($p=0.01$) minute.

Discussion

The main finding of this study was that during a progressive maximal ramp test, the peak power attained is similar regardless of the cadence that is employed. Interestingly, although the preferred cadence was similar to the 80rpm trial, the cadence in the PC trial dropped off progressively in the final minute while subjects were able to maintain their cadence during the 80rpm trial. This suggests that the drop-off in cadence was probably not due to selective fatiguing of fibres (Beelen et al, 1991) otherwise this would have also manifested in the 80rpm trial. It is difficult to explain how the decline in cadence appears to pre-empt the completion workload.

INTERLIMB COORDINATION, STRENGTH, AND POWER PERFORMANCES FOLLOWING A SOCCER MATCH

Perroni, F. 1, Tessitore, A. 1+2, Pesce, C. 3, Cortis, C. 1, Lupo, C. 1, Capranica, L. 1

1+3 IUSM of Rome, 2 Vrije University of Brussels, Italy

Introduction

The deterioration of motor ability attributed to fatigue could affect the systems responsible for the planning and execution of motor behaviour and enhance the chances of injuries. Thus, the aim of this study was to verify differences in inter-limb coordination, force, and power performances following a soccer match.

Methods

Ten soccer players (age: 18 ± 1 yrs; body mass 73 ± 6 kg; Labasal 1.6 ± 0.4 mM) were administered handgrip, counter movement jump (CMJ), and inter-limb coordination (in-phase and anti-phase flexions and extensions of hand and foot at 120, and 180 bpm velocities, for 60 s maximum) tests before and after a friendly match. Heart rates (HR), blood lactate (La) and rate of perceived exertion (RPE) were used to evaluate the intensity of the match. Differences in pre-post handgrip, CMJ and inter-limb coordination performances were assessed (ANOVA, $p<.05$). For inter-limb coordination, also the factors coordination mode and velocity were considered (Capranica et al., 2004).

Results

At the end of the match, 3.4±1.4 mM peak La and 12.4±2.1 RPE were recorded. Performances were enhanced from the pre- to the post-match condition for CMJ (34.8 vs 37.8 cm), handgrip (462 vs 449 N), and inter-limb coordination both in-phase (120 bpm: 58.2 vs 60.0 s; 180 bpm: 47.6 vs 50.9 s) and anti-phase (120 bpm: 36.6 vs 42.4 s; 180 bpm: 16.8 vs 18.9 s), even though no significant difference emerged.

Conclusions

Although soccer matches put a heavy physiological and psychological burden on athletes (Mohr et al., 2005; Reilly and Rigby, 2002), players maintain or even enhance their ability to coordinate movements. Both central and/or peripheral factors might be responsible for this phenomenon. Probably, the positive effect of intense exercise on motor coordination reflects, at least in part, the facilitation of the peripheral motor processes involved in response execution.

BODY CHARACTERISTICS OF WORLD CLASS SPORTS & FITNESS AEROBIC ATHLETES

Aerenhouts, D., Clarys, P., Deriemaeker, P., Taeymans, J., Duvigneaud, N., Vandenabeele, E., Clijsen, R., Duquet, W.

Vrije Universiteit Brussel, Belgium

Introduction

Sports (SA)– and Fitness Aerobics (FA) is a growing sport which is being more and more professionally practised in its different disciplines (solo, mixed pairs, teams in SA and step, group aerobics, funk in FA). Literature on the body characteristics of world class athletes in this sport is scarce.

Aims

The aim of this study was to determine the somatotype (ST) of world class athletes in SA and FA and to make a comparison between the different disciplines.

Methods

During the world Championships SA and FA (Ghent, May 2005) athletes were invited for anthropometry for the determination of ST, BMI and percentage of body fat (%BF). ST was calculated using the Heath-Carter method (J.L. Carter and B. H. Heath, 1990) and %BF was estimated by body-impedance (TANITA TBF 410). Descriptive (Mean ± S.D.) and statistical analysis were made with the SPSS 13.0 program using a Oneway ANOVA with LSD post hoc test ($p < 0.05$).

Results

In total 113 (aged 21.6 ± 5.2 yr) female and 23 (24.4 ± 5.1 yr) male athletes volunteered. Mean BMI was 21.2 ± 1.8 for the female and 24.2 ± 2.5 for the male subjects. %BF was 19.3 ± 4.8% and 12.7 ± 6.6% for female and male athletes respectively. As a whole, both female and male athletes can be described as endomorphic mesomorphs (3.5 ± 1.1; 3.9 ± 1.0; 2.8 ± 1.0 for female and 2.7 ± 1.4; 6.0 ± 1.2; 2.0 ± 1.0 for male athletes). Only the women performing in funk could be described as mesomorphic endomorphs (4.4 ± 1.1; 3.5 ± 0.8; 2.8 ± 0.6). There were no significant differences for BMI and %BF between the different disciplines. Women performing solo were significantly smaller than their colleagues performing in group aerobics and step (160,0 ± 6,9 cm vs. 164,3 ± 6,2 cm and 166,7 ± 7,0 cm). Women performing in step were also significantly taller compared to the women of the mixed pairs (166,7 ± 7,0 cm vs. 159,6 ± 2,6 cm). Women performing in step and team were significantly heavier than those performing solo and in group aerobics (59,0 ± 7,5 kg and 58,8 ± 5,1 kg vs. 52,7 ± 5,3 kg and 55,2 ± 5,4 kg). For men, there were no interdisciplinary comparisons made due to the low number of subjects.

Conclusion

World-class athletes in SA and FA can be described as endomorphic mesomorphs. This is in contrast to other esthetical sports such as artistic gymnastics where the ectomorphic component is more and the endomorphic component is less present (J.L. Carter, 1982). Especially for the women performing in the funk discipline, the higher body weight resulted in a more endomorphic ST. This may be an indication for specific training demands in this discipline. In general, these results point to the importance of a certain muscularity especially for male but also for female athletes in SA and FA.

CORRELATION BETWEEN STRENGTH, POWER AND INTER-LIMB COORDINATION IN SOCCER PLAYERS

Lupo, C. 1, Tessitore, A. 1+2, Cortis, C. 1, Perroni, F. 1, Pesce, C. 3, Capranica, L. 1

1, 3, IUSM of Rome; 2 Vrije University of Brussels, Belgium, Italy

Inter-limb coordination is related to age (Capranica et al., 2004) and activity level (Capranica et al., 2005). Although a relation with strength has been assumed, no data support this hypothesis.

Methods: To verify differences between soccer players and sedentary individuals in inter-limb coordination, force, and power performances in relation to age, 47 soccer players (20 children: 12 ± 1 yrs; 21 adults: 28 ± 5 yrs; 6 old: 66 ± 6 yrs) and 47 co-aged sedentary individuals were administered handgrip, counter movement jump (CMJ) and inter-limb coordination (flexions and extensions of hand and foot in the sagittal plane with1:1 frequency, in-phase and anti-phase modes at 80, 120, and 180 bpm velocities, for 60 s maximum) tests. A 3 (Age) x 2 (Activity) ANOVA was applied to handgrip and CMJ performances ($p < .05$). For inter-limb coordination an ANOVA for repeated measures was applied (between factors: Age and Activity; within factors: mode, and velocity). Correlation coefficients were calculated between variables.

Results: For CMJ and handgrip performances a main effect ($p < .01$) was found for age and activity, with soccer players always showing better performances. Significantly worst CMJ performances in older (soccer players: 16.7 ± 4.2 cm; sedentary: 5.9 ± 1.7 cm), intermediate in young (soccer players: 24.7 ± 2.4 cm; sedentary: 19.3 ± 4.8 cm), and best in adults (soccer players: 37.9 ± 4.8 cm; sedentary: 30.6 ± 5.2 cm) individuals were found. For handgrip, significantly better performances in adults (soccer players: 481 ± 65 N; sedentary: 455 ± 94 N), intermediate in old (soccer players: 429 ± 56 N; sedentary: 320 ± 115 N), and worst in young (soccer players: 224 ± 43 N; sedentary: 218 ± 54 N) were found. For inter-limb coordination, main effects emerged for age, activity, mode, velocity, and the interactions velocity x activity x age, mode x velocity x activity, and mode x velocity x age. Soccer players always showed better performances, especially with increasing velocity and in the anti-phase mode. Low correlation was found between CMJ and inter-limb coordination tests for children (range: -.05; .36) and adults (range: .08; .29), while higher coefficients were found for older individuals (ranging from .47 to .87; in-phase mode: $p<.05$). Also the correlation between handgrip and inter-limb coordination tests was low for children (ranging from -.04 to .16) and adults (ranging from -.04 to -.27), while higher coefficients were found for older individuals (ranging from .52 to .60; 80 bpm in-phase mode: $p<.05$).

Conclusions: Soccer proved to be beneficial not only to develop strength, power, and synchronization capabilities in children and to reach higher levels of proficiency in adults, but also to maintain central and/or peripheral factors in older individuals. Data suggest that strength per se is not strictly related to coordination.

ARCHITECTURAL CHARACTERISTICS OF GASTROCNEMIOUS MEDIALIS IN TRACK AND FIELD ATHLETES

Manou, V. 1, Tasopoulos, S. 2., Saraslanidis, P. 2., Kellis, S. 2

1 University of Thessaly, 2 Aristotle University of Thessaloniki, Greece

Introduction: Many researchers are investigating the relationships between muscle architectural characteristics and athletic performance. Abe et al. (2000), found that the relative fascicle length of vastus lateralis and gastrocnemious medialis and lateralis is significantly greater in elite sprinters than that observed in elite distance runners. Furthermore it was found that muscle architectural characteristics are related to joint angles (Maganaris et al. 1998; Narici et al. 1996). Purpose: The purpose of this study was to compare the architectural characteristics of relaxed gastrocnemious medialis in track and field athletes from different events at three ankle angles. Methods: Thirty four high-level Greek track and field athletes [10 throwers (TH), 8 sprinters (S), 8 long distance runners (DR) and 8 jumpers (J)] and 10 untrained individuals (C) volunteered to participate in this study. Muscle thickness (MT) and pennation angle (θp) of gastrocnemious medialis muscle were measured by B-mode ultrasonography, and fascicle length (FL) was estimated at -15 deg (dorsiflexion), 0 deg (neutral position) and 15 deg (plantarflexion) ankle angles (Abe et al. 2000; Kumagai et al. 2000). A One-way ANOVA was used to determine the effect of group and Tukey post hoc tests were used to locate the significantly different means. The level of significance was set at $p<.05$.

Results: Standing height and shank length were similar among all groups. Body mass was significantly greater in throwers than all the others participants. Pairwise comparisons between groups showed that there were significant differences ($p<.05$) in: a) MT at all three angles between C and TH, b) MT at -15 deg and 0 deg between C and J, c) MT at -15 deg between TH and DR, d) θp at -15 deg between TH and C and J, e) FL at all three angles between C and TH, S and J, f) FL at -15 deg between DR and TH and S, g) FL at 0 deg between DR and TH, S, J, h) relative FL at -15 deg between C and TH and S, i) relative FL at -15 deg between TH and DR and J, j) relative FL at 0 deg between C and TH, S, J, k) relative FL at 0 deg between DR and TH, S, J. Conclusion: TH, S and J indicated greater FL and relative FL than DR and C at -15 deg and 0 deg which is in agreement with the results of Abe et al. (2000). Furthermore the results of the present study confirmed the fact that the FL decreased and θp increased from dorsi to plantar angle flexion (Maganaris et al., 1998; Narici et al., 1996).

OVERHEAD ATHLETES AND SPORTS PERFORMANCES ON THE FIELD

Forthomme, B., Crielaard, J.M., Croisier, J.L.

University of Liege, CHU Sart Tilman, Belgium

Throw, spike and serve actions represent complex skills that require many components of movement, technical and muscular qualities. Effectiveness of overhead tasks has been attributed to an energy transfer in a kinetic chain concept from the lower limb to the upper extremity, depending on flexibility, strength and coordination. The purpose of this study was to examine, among overhead athletes, the relationship between the isokinetic strength developed by the dominant shoulder and a specific performance on the field.

Sixty-eight highly skilled overhead athletes (from the highest Belgium national divisions or highest final placing) took part in the experiments: 21 tennis players, 19 volley-ball players, 17 badminton players, 11 javelin throwers. They performed an isokinetic assessment of the external (ER) and internal (IR) rotators of the dominant shoulder and a specific evaluation on the field following a standardized protocol. The isokinetic installation corresponded to the lying position, arm abducted at 90° in the frontal plane, through a constant range of motion (50° in internal rotation and 70° in external rotation). The isokinetic speeds selected were 60 deg/s, 240 deg/s and 400 deg/s in the concentric mode, and corresponded to 60 deg/s in the eccentric mode (3 to 5 maximal repetitions according to the mode of contraction and speed). Performances on the field corresponded to a determining action in each sport: serve in tennis, spike action in volleyball and badminton, and throw in javelin. The best performances were measured, among six attempts, using either a radar gun (ball speed, in km/h), a digital camera (shuttlecock speed, in km/h) or a string (javelin throw distance, in meters).

Based on the correlative analysis, maximum strength developed by the IR muscle group was significantly ($p < 0.05$) correlated with the javelin throw in all isokinetic conditions ($0.62 < r < 0.67$) and with the volleyball spike velocity in the concentric mode ($0.47 < r < 0.63$). The ER isokinetic performances were in relation with the javelin throw in the concentric mode at 240 deg/s ($r = 0.79$) and 400 deg/s ($r = 0.78$). The ER/IR ratios were negatively correlated with the volleyball spike velocity ($-0.52 < r < -0.62$) and positively with the tennis serve speed ($0.42 < r < 0.61$). The spike speed in badminton did not show any relation with the maximum strength developed isokinetically.

Even if overhead action is a multijoint action, these results highlighted some original correlations between analytic strength isokinetically developed by the dominant shoulder and field performance into high-level overhead athletes. These data could provide useful information for training management. For instance, strengthening the IR could seem to be relevant in volleyball performance optimization [1]. Nevertheless, we advise against entailing an agonist / antagonist imbalance which could possibly increase the risk of further shoulder injury.

COORDINATION ABILITIES OF SHOOTERS IN AGE 15 – 22 YEARS

Poliszczuk, D., Polishchuk, T.

The Jozef Pilsudski Academy of Physical Education in Warsaw, Poland, Poland

Movement precision in sport is one of the most fundamental features of movement potential of an athlete; consequently, development of methods for its control and evaluation plays a substantial role in shooting. Shooting imposes difficult requirements with regard to psychophysiology of persons willing to practice this sport discipline, particularly in relation to the aiming precision, which is a prerequisite for achieving proper sport results.

The aim of this study was an evaluation of coordination abilities in the scope of minor motor abilities and components of speed in youth practicing shooting as a sport.

The tests were carried out on 27 shooters (13 female shooters and 14 male shooters) aged 15 - 22 with training experience of 2 to 6 years. Results were obtained using the Vienna Test System. The analysis comprised the obtained parameters, medians of reaction time and time of simple movement, tapping-test, tremor and indices of linear tracking and aiming for the right and the left hand. The study involved an analysis of the level of coordination abilities, such as: differentiation, coupling and adaptation of movement with regard to minor motor abilities.

In the training process, abilities of aiming accuracy indicate a growth trend both for the right and left hands; nevertheless, the right hand is much more efficient than the left one. The better the result, the better the ability of high accuracy and sensitivity are, as well as the ability to effective tensioning and relaxation of muscles.

An analysis of the performed tests show that when commencing shooting training the shooters have similar values of coordination dexterity in both hands. However, with time, after continued training exercises changes occur that increase the difference between the dominating hand of the shooter and the other hand.

In the execution of Tests manifestations of asymmetry in movement of the upper extremities in shooters were observed. The tests showed that the 'better' hand dominates, i.e. the right one. This is connected with adaptation to the specific character of this sport discipline – shooting from one hand only, which is also visible in training, which to a large extent is unilateral in character. As may be seen, considerable differences occur between the right and left hands. This constitutes proof that the dominating hand has a much better coordination level. In the attempt of aiming and tremor, the difference between the right and the left hand amounts to 62.5%, and in the test of linear tracking 71% to the advantage of the right hand.

The occurring differences in the level of studied coordination abilities in persons of both sexes, and manifestations of asymmetry in movement of the upper extremities in execution of the Tests were subject to analysis. The structure of speed components were determined: reaction time, time of simple movement and frequency of movements of the tested subjects.

EMG AND PLANTAR PRESSURE APPROACH TO KINEMATIC ANALYSIS OF CARVING TURN IN SNOWBOARDING

Yamauchi, T., Takato, J., Okutsu, M., Yasuda, T., Kitamura, K.

Ishinomaki Senshu University, Japan

[Purpose] The majority of snowboard hobbyists today are youths and only a few are in middle age or older. However, with the prospect of the age range of snowboarders expanding to include children and the elderly in the near future, it is important to establish guidelines in order to ensure safety in snowboarding. In the present study, electromyographic (EMG) activity and plantar pressure were measured during the carving turn in order to determine the motion characteristics of the snowboarder. [Method] The experiment was carried out on the medium slope (50 m x 100 m) at Spring Valley Ski Course in Miyagi Prefecture, Japan. The subjects, consisting of two instructors from the Japanese Snowboarding Association, were asked to perform the long-turn carving turn while wearing soft boots. Surface EMG activity was measured using a portable measuring device at a frequency of 1 kHz. Measurements were taken for the vastus lateralis, tibias anterior, and the soleus. Plantar pressure was measured by inserting a load cell sandwiched between flat sheets of stainless steel and aluminum inserted into the space between the board and the binding, and using a portable strain recorder. Sensors were placed at the big toe and little toe sides of the toes and the heel, for a total of four measurement points. Video footage was recorded at the same time as EMG and load data using an ordinary digital video camera. [Results and Discussion] Vastus lateralis: Marked muscle activity was observed in the rear leg compared to the front leg during the uphill phase of the frontside and backside turns. Tibialis anterior: no consistent muscle activity patterns were observed. Soleus: Predominant muscle activity was observed in the uphill phase of the frontside turn. The load was placed on the toes during the frontside turn and on the heel during the backside turn. The little toe side of the heel in the rear leg carried a relatively small load in comparison to the other points during backside turn. Electromyographic analysis of the long-turn

carving turn shows that muscle activity was unevenly distributed between the front and rear legs during the downhill-uphill phases. The vastus lateralis of the rear leg indicated a larger EMG amplitude than that of the front leg, particularly in the uphill phase of the frontside and backside turns. Muscle activity of the soleus muscle correlated with the motion of the plantar flexion in the frontside turn, but the role of the tibialis anterior could not be ascertained in the present study and requires further investigation. The load cell measurements imply that the frontside turn can involve the internal rotation of the hip joint in the front leg, while the backside turn can involve the adduction of the hip joint in the back leg.

SPEED-STRENGTH EXERCISES IN PRACTICE OF SKILLED FENCER PREPARATION

Driukov, V., Mistuloa, T., Pavlenko, Y.

State Scientific-and-Research Institute of Physical Culture and Sports, Ukraine

High level of sports results in fencing mainly depends on the level of speed-strength fitness of athletes. Aim of work - to determine the optimum amount of weights utilized in special preparatory exercises for development of speed-strength capacities in skilled fencers.

16 skilled fencers served as the subjects of studies. 2 groups of athletes (8 in each group) performed special preparatory exercises aimed at the development of speed-strength capacities, during training sessions 5 days per week for the period of 4 weeks. 1st group used the weights in the range of 20% of maximum muscle strength, whereas the second one - in the range of 40%. Both programs were the same in physiological cost determined during preliminary studies according to total time of heart rate recovery during training session and mean value of heart rate during work.

Results. Multiple repetitions of training sessions for development of athlete's speed-strength capacities being different in the amount of utilized weights and equal in physiological cost have resulted in different increase of indices characterizing special work capacity of athletes. Utilization in special preparatory exercises of weights in the range of 20% of maximum strength has contributed to preferential development of dynamic strength, speed of single movement, maximum frequency of movements and speed endurance, whereas weights in the range of 40% of maximum strength have promoted to preferential development of maximum static strength The process of special work capacity development as a result of prolonged utilization of special preparatory exercises has been characterized by rather phases than linear character. Phase of fluctuations of increase in the range of initial level, phase of intensive increase, phase of stabilization in the range of achieved level. Besides, the following body adaptation changes have been observed: repeated utilization of training sessions with weights have been accompanied with decrease of heart rate response to suggested loads which is indicative of positive training effect; recovery processes during training sessions have occurred faster reaching the lowest indices by the end of studies; indices of latent time of muscle tension and relaxation during performance of special preparatory exercises have decreased in all measurements, however, the greatest reduction of latent time of tension has been noted as a consequence of usage of weights in the range of 20% of maximum strength, whereas that of latent time of relaxation - during usage of weights in the range of 40%; precision of coordination structure of movements in subjects during special preparatory exercises performed with weights in the range of 20% of maximum strength was higher than during utilization of weights in the range of 40%.

Conclusion. Obtained data may be used for development of speed-strength capacities in fencers during weekly (3-5 sessions) and monthly (10-12 sessions) cycles of training process.

DIFFERENT PHYSICAL, PHYSIOLOGICAL AND BIOMECHANICAL DETERMINANTS OF SWIMMING PERFORMANCE IN YOUNG SWIMMERS

Jürimäe, T., Lätt, E., Haljaste, K., Cicchella, A., Purge, P., Leppik, A., Jürimäe, J.

University of Tartu, Estonia

The performance in swimming has been related to different anthropometrical, physiological and biomechanical parameters in adults. Specifically, maximal performance in swimming depends on the amount of metabolic energy spent in transporting the body mass of the athlete over the unit of swimming distance and on the economy of locomotion. Very few studies have investigated the importance of different anthropometrical, physiological and technical parameters to determine swimming performance in children. To our knowledge, no studies have performed to investigate the energy cost of swimming (Cs) in prepubertal swimmers. In addition, the changes from prepuberty to puberty are important and include different anthropometrical, physiological and mechanical parameters. The purpose of this study was to examine the influence of Cs, anthropometrical/body composition and technical parameters on swimming performance in young swimmers. Twenty nine swimmers, 15 prepubertal (11.9±0.3 yrs; Tanner stages 1-2) and 14 pubertal (14.3±1.4 yrs; Tanner stages 3-4) boys participated in the study. Cs and stroking parameters were assessed over maximal 400 metre front crawl swimming in a 25 metre swimming pool. The backward extrapolation technique was used to evaluate peak oxygen consumption (VO2max). A stroke index (SI; m.2 s.-1cycles-1) was calculated by multiplying the swimming speed by the stroke length. VO2max results were compared with VO2max test in the laboratory (bicycle: 2.86±0.74 l.min-1 vs on-water: 2.53±0.50 l.min-1: R2=0.713; P=0.0001). Stepwise regression analyses revealed that SI (R2=0.898), on-water VO2max (R2=0.358) and arm span (R2=0.454) were the best predictors of swimming performance. In summary, the results of our study suggest that the backward extrapolation method for the assessment of VO2max after maximal 400 metre front crawl swimming in prepubertal and pubertal swimmers is a valid method and may be of value in the training and testing programmes for competitive young swimmers. The evaluation of Cs in young swimmers allows the estimation of energy expenditure during swimming training and could be used to evaluate the training load taking into account both aerobic and anaerobic pathways of energy production. The SI, arm span and VO2max appear to be the major determinants of front crawl swimming performance in young swimmers.

Poster presentation (PP)

PP2-03 Health and Fitness 1-5 - "Exhibition Hall"

THE INFLUENCE OF EXPERIENCE OF WEARING HIGH HEELED SHOES ON POSTURAL CONTROL

de Melo, F., Crisóstomo, R., Cabri, J.

Faculdade de Motricidade Humana, Portugal

The use of high heeled shoes is related to degenerative muscle and joint alteration (Kerrigan et al. 1988), as well as to different biomechanical parameters (step length and width, center of mass position) (Snow et al., 1994).

The risk of falls is known to increase in women, usually wearing high-heeled shoes, who change to flat-heeled shoes (Chang et al., 1994). However, there is not enough knowledge concerning the area of contact between the heel and the ground, in tasks needing balance and postural control.

The purpose of this study was to understand the influence of daily life experience in wearing different shoe formats on postural control tasks.

Thirty-six women aged 21 to 53 years old, were divided into three groups: 13 experienced in flat shoes (EFH group), 12 experienced in wide high-heeled shoes (EWH group), and 11 experienced in thin high-heeled shoes (ETH group). The protocol used included: Limits of Stability, Walk and Weight Bearing tests. We compared the directional control, reaction time, and postural sway in both anterior-posterior and lateral directions during standing and walking. All tests were performed using a Balance Master System (Neurocom Inc, USA) and the data (reaction time, movement amplitude and speed of the center of gravity) were acquired from the system test reports.

The results show that forward movements are safer in flat heels. In wide heels the EFH group have more problems moving forward and sideways. For the EWH and ETH groups, the more experienced they are, the worse sideway postural control in flat heel is present. Reaction time and sway amplitude are related with the time spent wearing wide high heeled shoes. (the more the time, the greatest the reaction time and sway amplitude). The ETH group reduced anterior-posterior displacements when wearing wide high-heeled shoes.

We may conclude in our study that with experience the risk of falling at gait ending increases (higher velocity and end sway) when wearing heels different in comparison to those one is used to. Using flat-heeled shoes, gait steps are wider in order to compensate an increase of the reaction time in the lateral direction. In conclusion, it may be stated that implementing specific training programmes may be improve the performance of lateral movements, especially in women wearing high heels. Furthermore, the use of sports footwear with higher heels may also be recommended as a means to prevent foot and ankle injuries in this habitual population.

PHYSICAL ACTIVITY OF THE FEMALE STUDENTS OF THE UNIVERSITY OF THE THIRD AGE (U3A) AT WROCLAW UNIVERSITY AND SELECTED PARAMETERS OF THE BODY COMPOSITION

Ignasiak, Z., Żurek, G., Dąbrowska, G., Wnuk, W.

University School of Physical Education, U3A at the Wroclaw University, Poland

Introduction. The progress in many fields of science and improving medical care result in the growing number of elderly people. At the same time, it is important that living in their Third Age seniors enjoy full physical fitness. Hence the emphasis in scientific literature, on the significance of physical activity of the Third Age people.

The aim of the work was to measure the amount of physical activity of seniors – students at the U3A in Wroclaw according to BMI.

Material and methods. 116 people were researched all together, of whom the results of 101 women (= 75,6 old) were used. The body height and weight was measured, and on this base BMI was counted. With the help of an apparatus for measuring the body composition (FUTREX) a percentage content of the fatty tissue and the lean body mass (LBM) was determined. An interview was conducted to obtain the information concerning the level of the physical activity of subjects, i.e. inquiring about the frequency, intensity, and duration of their weekly physical exercise. The subjects were divided into two groups: one constituted by people whose BMI was lower than 25 and the other constituted by women of BMI higher than this value.

Results. The average values in both aforementioned groups differ significantly in all the somatic features compared as well as in body composition, however, no difference was observed in the level of physical activity. Subsequently, the measures of somatic development were correlated (Spearman correlation) with the level of physical activity.

The results show a stronger negative relationship between the amount of the fatty tissue and the declared level of physical activity in the group of higher BMI. In the group of subjects whose BMI was lower, the positive relationship was found between the lean body mass and the level of physical activity.

POSSIBILITIES OF THE EVALUATION OF THE QUALITATIVE STATUS OF MUSCLE TISSUE BY A MOLECULAR MODEL OF BODY COMPOSITION

Skorocká-Seflová, I., Bunc, V., Mahrová, A., Hráský, P., Balás, J., Cingálek, R.

Charles University Prague, Faculty of Physical Education and Sport, Czech Republic

Introduction: The monitoring of the body composition changes; particularly the monitoring of the percentage of body fat and lean body mass has become a frequent component of not only the clinical assessment of the health condition, but also of training practices. Besides the basic parameters of the body composition we can measure - by using the multi-frequency bioimpedance equipment - the extracellular mass (ECM) and the body cell mass (BCM). The proportion between ECM and BCM is clinically routinely used as one of the most sensitive indexes of the nutritional state, indicating e.g. malnutrition (Talluri et al., 1999). In our study we monitored the changes of ECM, BCM and its ratio in healthy men who attended regularly physical activities.

Methods: This study was carried out on 1938 healthy male' participants (age 5-60 years, mean age 22.0 ± 9.05 years, body mass 23.0 - 96.3 kg, mean values 72.3 ± 12.7 kg, body height 1.24 – 1.97 cm, mean values 178.6 ± 9.8 cm). They attended regularly physical activities at least 3 times in a week. We divided the participants into 7 age groups (Infants I. – 6 – 11 years, n = 30; Infants II. – 11 – 15 years, n = 149; Juveniles – 15 – 18 years, n = 572; Adults – till 30 years, n = 962; Matures I. - till 45 years, n = 197; Matures II. - till 60 years, n = 28). In the groups we estimated ECM, BCM and its ratio, body fat, lean body mass and total body water derived from whole–body bioimpedance measurement at different frequencies – 1, 5, 50 and 100 kHz (B.I.A. 2000M, Data Input, Germany).

Results: In the groups of participants we measured these results: Infants I. – BCM 15.7 ± 3.2, ECM 15.2 ± 3.2, ECM/BCM 0.97 ± 0.09; Infants II. –, BCM 27.5 ± 6.5, ECM 23.0 ± 4.3, ECM/BCM 0.85 ± 0.11; Juveniles – BCM 34.9 ± 4.6, ECM 26.3 ± 3.2, ECM/BCM 0.76 ± 0.09; Adults – BCM 38.5 ± 4.8, ECM 27.5 ± 3.4, ECM/BCM 0.72 ± 0.09; Matures I. - BCM 38.2 ± 6.5, ECM 27.9 ± 4.6, ECM/BCM 0.73 ± 0.08; Matures II. - BCM 33.7 ± 6.0, ECM 28.1 ± 4.7, ECM/BCM 0.82 ± 0.11.

Discussion and Conclusion: The results of the ECM/BCM ratio show in all age categories lower values in the physical actives than in the normal population (B.I.A. 2000M).

We observed the lowering of values ECM/BCM from the infants to adults. The lowest values of ECM/BCM were measured in the categories adults and mature I. These changes are significantly different ($p<0.01$) and are accompanied by characteristic changes of ECM.

EVALUATION OF SENIOR SPORT OFFERS IN SWITZERLAND: A PILOT STUDY

Wanner, M., Martin, B., Wyss, T., Schneider, A.

Swiss Federal Office of Sports, Switzerland

Background: In Switzerland several different organisations offer a wide range of physical activity and sport courses for seniors. These are well known in the Swiss population. However, the variety of sport offers for seniors has not yet been systematically evaluated.

Objective: In this pilot study the feasibility of evaluating senior sport offers was investigated and preliminary data were collected on the participant's profile.

Methods: In structures volunteering for this study, seven open-end courses (gymnastic clubs, N=112, no refusals), two 10-week courses (aqua gymnastics, N=17, response rate 85%) and one 1-week course (different sports, N=71, response rate 92%) participated in the questionnaire survey. Data were obtained on course satisfaction, expectations, level of physical activity and characteristics of the participants. Different aspects of overall course satisfaction were assessed such as organisation, competence of the instructor, atmosphere among the participants, motivation to be physically active outside the course.

Results: The mean age was 67.2 years in the open-end courses, 57.0 years in the 10-week courses and 68.2 years in the 1-week course. The proportion of women was 96.1%, 100% and 66.2% in the open-end courses, the 10-week courses and the 1-week course, respectively. 48.4% of participants in the open-end courses and 60.5% of participants in the 1-week course were sufficiently active according to the physical activity recommendations in Switzerland compared to 35.9% in the general Swiss population (1). None of the participants were classified as completely inactive, compared to 19.4% in the general Swiss population (1).

In the three types of courses, between 73.2% and 100% of the participants were very satisfied with the course, 99% were at least rather satisfied. The proportion of individuals at least rather satisfied ranged from 88% to 100% for organisation, competence, atmosphere and motivation. In both the 10-week courses and the 1-week course, the participant's expectations were met or exceeded (as assessed in the beginning and at the end of the course).

Conclusions: A questionnaire survey appears to be a feasible and well accepted method to obtain data from participants of senior sport offers in Switzerland. Preliminary data suggest that very active elderly people are currently reached by senior sport courses. The results have to be confirmed in larger samples. It remains a challenge to reach other segments of the senior population while maintaining the excellent satisfaction of participants.

RELATIONSHIP BETWEEN MEASURES OF BODY FATNESS AND AEROBIC POWER IN CHILDREN

Stavrinou, P., Theos, A., Papaspyrou, A., Bogdanis, G.C., Maridaki, M.

University of Athens, Greece

Introduction

Child obesity is associated with several risk factors for chronic diseases, particularly when obesity is combined with inactivity. The purpose of the present study was to examine the relationship between obesity estimated by body mass index (BMI), percent body fat (%BF) and aerobic fitness.

Methods

Seventy seven children (38 boys and 39 girls, age: 11.3 ± 0.8 years, height: 147 ± 1 cm, weight: 43.3 ± 1.2 kg, mean±SE) were tested in this study. Aerobic power (VO2max) was estimated from a 1000 m running test (Klissouras, 1973), while %BF was estimated according to the equations of Slaughter et al. (1988). The running test was performed twice and the best time was recorded. Body mass index (BMI; weight/height2) was converted to percentiles (adjusted for sex and age) according to the LMS method (Cole et al., 2000). Values between the 85th and the 95th percentile were taken to indicate risk of overweight, while values greater than 95th percentile were considered to indicate obesity.

Results

There was no significant difference between boys and girls in height (147 ± 1 vs. 148 ± 1 cm), body mass (45.0 ± 1.7 vs. 41.7 ± 1.6 kg) and VO2max relative to body mass (51.2 ± 1.4 vs. 48.9 ± 1.3 ml/kg/min). BMI and %BF were also higher in boys compared to girls (20.6 ± 0.5 vs. 18.8 ± 0.5 kg/m², $p<0.05$ and 23.3 ± 1.4 vs. 19.5 ± 1.1 %, $p<0.05$ respectively). The percentage of the children being at risk of overweight was 10% for the boys and 5% for the girls. The %BF was negatively correlated with VO2max ($r = -0.40$, $p<0.01$, $n=77$), and positively correlated with BMI ($r = 0.83$, $p<0.01$).

Discussion

The results of this study suggest that BMI is a reliable indicator and can be used as a measure of fatness in children. Furthermore the negative relationship between %BF and VO2max indicates that child obesity may be accompanied by decreased aerobic fitness.

EFFECT OF NUTRITION, PSYCHOLOGY, AND DAILY LIFESTYLE ON ATHLETIC PERFORMANCE

Michiko, M., Haruo, S.

Nara Woman's University, Japan

The best assessments for improving of athletic performance, is to include that the results of psychology, dietetics and medicine.

This study was intended to clarify factor that contribute to conditioning and performance for athletes.

Methods

The subjects were soccer players (89 boys, 15-17years old) in Japanese high school. The athletic level is national convention participation school for 2004 years.

The measurement: nutritional states are carbohydrate, protein, V.B1, V.B2, niacin, Ca, iron. Psychological conditions are depression, conclusion, angry, tension and vigor (POMS-test). And life states are appetite, fatigue, and physical condition. In addition, the performance evaluations of the subjects from coaches were checked for the test reliability. A multivariate analysis was used as statistics (spss 11.0 J for Windows).

Results and discussion

1) The subjects categorized a regular player and an irregular player. The results based on discriminant analysis to examine a difference of a performance.

Results were extracted in order of protein, carbohydrates, calcium, V.B2, niacin, V. B1, depression, as nutrition factors.

Protein and carbohydrate are nutrient of an energy source of supply. Calcium is the nutrient, which is necessary for contraction of the muscle of exercise. And V.B1, V.B2 and niacin are the nutrient which are important for energy metabolism1) .

Depression is regarded as an important factor related to psychological self-control, and it is thought that a psychology skill to maintain mental stability is important for the better athletic performance2).

2) As results of statistically analysis of depression by using multiple regression, depression measure was the positive correlation with physical condition and negative correlation with carbohydrate statistically showed. It was thought that feelings and a change of emotion influenced athletic performances. As carbohydrate was energy source of exercise, an intake of carbohydrates promoted secretion of a hormone, it reduces tension and anxiety3).

In this study, the importance of carbohydrate intake was accepted as to reduce, in which depression was dependent variable.

3) The performance scores evaluated by coaches were statistically different with high-depressed group and low-depressed group. That is high-depressed group was showed some feelings of heavy body movement and fatigue by coaches.

IMPROVING PHYSICAL ACTIVITY AMONG PATIENTS IN TREATMENT FOR PSYCHOGENIC OBESITY AND BINGE EATING DISORDER

Carraro, A., Schiavone, P., Fiorellini, A.

University of Padua and Casa di Cura Parco dei Tigli, Italy

Obesity is a chronic multifactorial condition in which excess body fat may expose the individual to serious health risk (e.g. diabetes mellitus, hypertension, heart disease, etc.) and to severe alteration of the psychosocial functioning and quality of life. Moreover it can be associated with disordered eating, as overeating or binge eating disorder, depression, low self-esteem and impulsivity. This coexistent psychopathology may worsen the treatment outcome and produce early relapse.

Basic treatment of overweight and obese patients requires a comprehensive approach involving diet, regular physical exercise and cognitive and behavioural changes, with an emphasis on long-term weight management rather than short-term excessive weight reduction. The intrinsic motivation is one of the most important factors supporting the compliance with patients in treatment, in particular, the motivation to physical activity and the change in the attitude of patients towards physical experience are determining elements of the weight control treatment success (Berger, 2004; Dietz, 2004).

In a clinical psychiatric setting, we have been running a program of adapted physical activity (APA) for overweight and obese in-patients with psychiatric symptomatology. We have developed a specific multidimensional program for these patients including an energy-restrict diet, individualized physical activity daily program, nutritional education, together with individual and group cognitive-behavioural psychotherapy. The chief aims of our obesity APA program are: ameliorate the physical conditions, improving the exercise capability, the readiness to the physical activity, self-esteem, and increasing social relationships.

Our sample consisted of 35 inpatients (5 male e 30 female) with a mean age of 37,5 years (SD=14,4). The most frequent psychiatric diagnosis were Binge eating disorders and Borderline PD. On the basis of the BMI estimate 5 patients presented an overweight, 9 were in obesity class I, 7 were in class II and 14 were in class III; the mean BMI was of 39.23 kg/m2 (SD=8.5). Results have been evaluated with several tools, including: bio-medical parameters, improving BMI, psychometric scales (SCL-90, University of Rhode Island Change Assessment Scale, Dieter's Temptations of Eating Inventory, Body Image Avoidance Questionnaire, SF-36, Borg scale), physical measurement, recording of fitness performance, and specific observation for physical activity patterns. The results obtained so far are compatible

with the recommendations of the international guidelines for the cure of obesity(NHI, 1988): the mean weight loss was 5.9 kg corresponding to 5.5% of the initial weight.
Our findings lead us to support that a specific interview to support the motivation and the regular participation to physical activity could be an important functional element within a multidimensional therapy program aimed at the treatment of obesity with psychiatric comorbidity.

SEDENTARY BEHAVIOUR, PHYSICAL ACTIVITY AND THE METABOLIC SYNDROME AMONG FLEMISH ADULTS

Philippaerts, R.M , Wijndaele, K., Duvigneaud, N., Matton, L., Thomis, M., Duquet, W., Lefevre, J.

Ghent University, Belgium

The metabolic syndrome (MS) is considered to be an important public health problem, but until now less studies investigated relationship between MS and physical (in)activity. Purpose: We examined the association between sedentary behavior, physical activity and the prevalence of MS in Flemish adults. Methods: This study involved 1570 Flemish adults aged 18 to 75, including three study cohorts of the Policy Research Centre Sport, Physical Activity and Health (902 men, 668 women). MS was defined according to the 2005 International Diabetes Federation Definition. The Flemish Physical Activity Computerized Questionnaire was used to assess time spent in moderate to vigorous leisure time physical activity (MVLPA) and watching television/video and computer games (SB). Cut offs for MVLPA were 0, <3, and ≥3 h/week. Cut offs for SB were <14, 14 to 21, and ≥21 h/week. Subjects performing at least 3 h/week of MVLPA (age-specific MET-values) or watching less than 14 h/week were considered as reference groups. Binary logistic regression was used to calculate odds ratios (OR) and 95% confidence intervals. Results: Age-adjusted analysis showed that men who did not engage in MVLPA had almost twice the odds of having MS [OR, 1.83; 95% CI, 1.13-2.97]. Multiple adjustments (age, cohort, education, smoking, alcohol, height, SB) revealed the same results [1.86; 95% CI, 1.13-3.04]. Men engaged in less than 3 h/week had no significant OR for age and multiple adjustment respectively. In women, the same age-adjusted association between MVLPA and MS was found with OR for the three groups respectively [1.0] (referent), [1.03; 95% CI 0.59-1.82], and [1.98; 95% CI 1.09-3.60]. OR after multiple adjustments were similar. In men, age-adjusted OR for SB were [1.0] (referent), [0.66; 95% CI 0.42-1.02], and [1.09; 95% CI 0.72-1.65]. Additional multiple adjustment minimally affected the OR. In women, age-adjusted OR were [1.0] (referent), [1.65; 95% CI 0.92-2.99] for 14 to 21 h/week, and [2.66; 95% CI 1.44-4.94] for ≥21 h/week. Multiple adjustment resulted in the following OR, [1.0] (referent), [1.61; 95% CI 0.87-2.95] for 14 to 21 h/week, and [2.17; 95% CI 1.13-4.17] for ≥21 h/week. Conclusion: MVLPA and SB are independently associated with the prevalence of MS. Efforts to lessen the amount of time spent on watching television or using computer, and promoting a more active lifestyle could result in a substantial decrease in the risk of having the metabolic syndrome.

COMPARISON OF EXERCISE AND DIETARY INTERVENTION ON HEALTH MARKERS IN PHYSICALLY INACTIVE POST-MENOPAUSAL WOMEN

Kimura, Y., Ohki, K., Nakagawa, N., Sato, T.

Saga University, Japan

Introduction

According to the WHO Report 2002, cardiovascular diseases are the most common cause of death in postmenopausal women in the western countries. The hormonal and metabolic changes during and after the menopause have a negative impact on various cardiovascular risk factors, including the lipid metabolism, thus promoting the development of the metabolic syndrome. Nutrition and physical activity are among the most important self-care behaviors that contribute to health and quality of life. Strength training (ST) is a specific physical activity for the neuromuscular system, but health effects of ST in women, especially in aging women, are less well known. Therefore, this study was designed to evaluate the effects of an individualized, combined exercise and dietary intervention on health markers in physical inactive postmenopausal women.

Methods

35 postmenopausal women (age: 62.1±5.5 years) with body mass: 60.6±8.1 kg, BMI: 25.4±3.6 kg/m2, body fat %: 31.2±5.6 %, waist to hip ratio (WHR): 0.84±0.2, total cholesterol (TC): 238±29 mg/dl, HDL-C: 76±18 mg/dl, LDL-C: 125±45 mg/dl and blood pressure (BP): 130.9±19.1/90.4±10.5 mmHg were randomly divided in three groups: 1) ST and nutritional counseling (ST+N, n=12), 2) ST and no-nutritional counseling (ST+O, n=13) and 3) no-ST and no-nutritional counseling (CONN, n=10). Two-week instruction was given to guarantee sufficient energy and proper balance of nutrients. Moderate gymnastics and supervised progressive ST with loads of 45-75% of 1 RM were performed two times a week for 12 weeks. A bicycle ergometer test was performed to determine the physical performance (at 2 mmol/l lactate) and leg strength also measured. Bone health markers (osteocalcin: BGP, pyridinoline: PYR and deoxypyridinoline: DPD) also included. These measurements were examined at the beginning of the study, after six and after 12 weeks.

Results

Leg strength increased significantly ($p<0.01$) in ST+N and ST+O by 23.8±8.5%, 25.7±5.6%. Serum concentrations of TC decreased significantly ($p<0.01$) in ST+N and ST+O by 12.0±3.5%, 9.6±2.5%, HDL-C increased in ST+N and ST+O by 9.2±2.3%, 8.8±3.8%, and LDL-C decreased in ST+N and ST+O by 14.1±3.1%, 13.7±3.4%. In body composition variables, BMI decreased significantly ($p<0.05$) in only ST+O by 4.2±1.7 and body fat % decreased significantly ($p<0.05$) in ST+N and ST+O by 14.8±3.5%, 13.7±3.8%. Physical performance capacity (2.0 mmol/l lactate) was significantly ($p<0.01$) increased in ST+N and ST+O from 55±21 to 62±10 watts, from 58±18 to 67±21 watts. GBP/PYR increased significantly ($p<0.05$) in only ST+O from 0.31±0.09 to 0.34±0.07. CON had no significant influence on any parameters. The positive effects of a combined exercise and dietary intervention result in a significant and clinically considerable improvement of the total health markers.

Conclusion

In conclusion, ST favorably affected health markers, and nutritional counseling even contributed to these positive changes.

ASSOCIATIONS BETWEEN REGIONAL MUSCLE MASS, MUSCLE FUNCTION, AND BONE MINERAL DENSITY IN POST-MENOPAUSAL WOMEN

Sanada, K., Miyachi, M., McGrath, K.F., Tabata, I., Usui, C., Higuchi, M.

Institute for Biomedical Engineering, Japan

Although a number of studies have reported the relationship between muscle function (strength and/or power) and bone mineral density (BMD), there is little scientific information on the effect of increased regional skeletal muscle (SM) mass on these factors in postmenopausal women. The purpose of this study was to investigate the relationships between SM mass, muscle function and BMD in postmenopausal women, and to determine the predictors of regional BMD using SM mass, muscle function and a physical activity questionnaire. Healthy Japanese postmenopausal women (n=62) aged 48-76 yrs participated in the study. Leg extension power (LEP) and handgrip strength (HGS) were measured in all subjects. Muscle thickness (MTH) was determined by ultrasound spectroscopy, and total or regional SM mass (arm, trunk, and leg) was estimated based on the 9 sites of MTH. Total and regional lean soft tissue (LST), fat mass, BMD (total body, arms, legs, and lumbar spine) were measured using Dual-energy X-ray absorptiometry (DEXA). The NASA/JSC physical activity scale (PAR), a questionnaire method, was used to survey the subject's physical activity. Total LST was significantly correlated with the total or site-matched regional BMD (r=0.42-0.45, P<0.001), and the relationships between SM mass and the total or site-matched regional BMD (r=0.44-0.47, P<0.001) corresponding to LST. When MTHs were adjusted to the years since menopause, the anterior upper arm (r=0.50, P<0.001), abdominal (r=0.36, P<0.01) and posterior thigh MTH (r=0.31, P<0.05) were significantly correlated with the site-matched regional BMD. Both absolute HGS and normalized (for arm SM mass) values were significantly correlated with arm BMD. Absolute LEP (W) was significantly associated with the leg BMD. Lumbar spine BMD, but no other sites, was significantly correlated with PAR (r=0.44, P<0.001). Stepwise regression analysis on LEP and PAR for the prediction of lumber spine BMD (r = 0.59, SEE = 0.087, P < 0.001), and on total SM mass and normalized LEP (for leg SM mass) for the prediction of leg BMD (r = 0.59, SEE = 0.089, P < 0.001) produced significant findings. The associations between SM mass estimated by ultrasound and total or site-matched regional BMD were comparable to the lean soft tissue values measured by DEXA. LEP, PAR and SM mass are independent predictors of trunk and leg BMD in postmenopausal women.

EFFECT OF THE EXERCISE MODE ON THE OXYGEN UPTAKE KINETICS DURING HIGH INTENSITY EXERCISE IN CHILDREN

Machado, F., Guglielmo, L.G., Greco, C.C., Denadai, B.S.

Universidade Estadual Paulista - Unesp, Brazil

INTRODUCTION: The slow component (SC) of the oxygen uptake (VO2) is the additional oxygen cost presented in constant load exercises with intensities above the lactate threshold (LT). In adults, factors such as the aerobic training state and the exercise mode (running x cycling), can modify the SC. However, age effects on the SC are still conflicting. OBJECTIVE: To verify the effect of the exercise mode (treadmill running x exercise bike) over the time constant (Tau) and the SC of the VO2 in 11-12 year-old children who exercised in high intensity (75%r). METHOD: 20 looking healthy active boys (age = 11.48 ± 0.41 years old; body mass = 41.38 ± 10.45kg; height = 147.45 ± 6.56 cm), sexual maturation levels 1 and 2 (pubic hair) took part of this study. These children first took an incremental test on the running treadmill (RT) and on the exercise bike (EB) to determine the peak oxygen uptake (VO2peak) and the LT. To determine the VO2 kinetics two six minutes step-change were taken in each ergonometric in 75%r intensity [75%r = LT + 0.75 x (VO2peak – LT)]. RESULTS: The VO2peak (45.16 ± 5.98 x 42.93 ± 7.51 ml/kg/min) and the maximal heart rate (196.5 ± 6.98 x 187.3 ± 9.27 bpm) were slightly higher in the RT comparing to the EB, respectively. The VO2 expressed in relative values to the body mass (31.82 ± 10.09 x 25.19 ± 7.36 ml/kg/min) and the VO2peak (69.83 ± 16.63 x 58.96 ± 14.55%) and the heart rate (150.5 ± 17.75 x 131.3 ± 12.98 bpm) corresponding to the LT also were slightly higher in the RT comparing to the EB, respectively. The SC expressed in absolute values (165.79 ±139.93 x 95.86 ± 77.68 ml/min) and as the percentage contribution of the CL to the VO2 increment at the end of the exercise (12.0 ± 9.0 x 7.0 ± 5.0%) were slightly higher in the EB comparing to the RT, respectively. However no differences were observed related to Tau in both exercise mode (RT = 18.83 ± 4.36 x EB = 19.94 ± 7.57 sec). CONCLUSION: Just like what was observed in adults, the SC of the VO2 is dependent on the exercise mode (EB x RT) during high intensity exercise in children.

KEY-WORDS: slow component, children, running, cycling.

THE EFFECT OF 8 WEEKS MAXIMAL AND SUB MAXIMAL (INTERVAL AND CONTINUOUS) EXERCISE ON HEMATOLOGICAL PARAMETERS IN FOOTBALL PLAYERS ON YOUNG MALE 16-19 AGED

Jahani, G., Tarverdizadeh, B., Azarbaijani, M.A.

Islamic Azad University,Branch of Abhar, Iran

Some study were to investigate the effect of maximal or sub maximal (interval or continuous) exercise on hematology parameter in athletic, whereas, there are no many study about the effect of compound exercise on blood parameters in athletic .therefore, the purposes of this study were to investigate the effect of 8 weeks maximal and sub maximal (interval and continuous) exercise on hematological parameters in football players on young male 16-19 aged.

Materials and methods

Experimental design: cross sectional study to investigate the response of hematological parameters to the 8 weeks compound exercises in football players.

Participants: Twenty four healthy, physically active, football players Fajre club in Tehran.

Young male aged 16-19 years. In sub maximal (continuous) exercise they were allowed to continue the program with 60-70% VO2max, heart rate reached 120-170/min.

In maximal (interval) exercise were instructed to intensity exercise until exhaustion with 80-90% VO2 max. Heart reached over 170/min.

Blood sample were withdrawn from antecubital vein in to the E.D.T.A tubes immediately after resting fasted in the morning. Then participants trained at least 45-90/min /day for 8 weeks and antecubital vein blood sample were obtained after 24 hours rest and fasted in the morning.

Results

Analyzing of the data showed:

1. There was a significant difference in R.B.C, Hb, HCT, W.B.C, M.C.H and M.C.V response of football players to compound exercise.

2. There was no a significant difference in M.C.H.C and P.L.T response of football players to compound exercises.

3. there was a increase 5.39% in R.B.C, 4.52% in H.b , 2.97% in H.C.T , 7.99% in W.B.C ,2.03% in M.C.H and 91% in M.C.V after 8 weeks compound (interval and continuous) exercise in young football players .this increase was a significant difference in blood parameters .

4. There was a increase 4.41% in P.L.T and 21% in M.C.H.C after 8 weeks compound (interval and continuous) exercise in young football players .this increase was no significant difference in blood parameters.

Conclusions

The aim this work was to investigate the resting levels responses of hematological parameters e.g. red blood cell (R.B.C),hemoglobin(H.B) , hematocrite (H.C.T),white blood cell(W.B.C), mean corpuscular volume (M.C.V), mean corpuscular hemoglobin (M.C.H) , mean corpuscular hemoglobin concentration (M.C.H.C)and platelets (P.L.T), ratio to 8 weeks compound exercise .

A number of studies have demonstrated considerable hematological parameters changes during and after exposure to different environmental, physiological conditions and acute exercise or endurance training.

BIOCHEMICAL AND ANTROPOMETRICS VARIABLES AND THEIR ASSOCIATION WITH THE BLOOD PRESSURE IN MEN

Brito, C.J., Lima, W.A., Glaner, M.F.

Catholic University of Brasilia, Brazil

Elevated levels of body lipids are linked to the increase of serics concentrations of cholesterol, which can rise the systolic blood pressure (BP) and, consequently, develop a cardiovascular disease (Bonora et al., 2003). This study aimed to verify the influence of biochemical and anthropometrics variables on the BP. Were measured 123 men, age 35.8+/-10.4 years, body mass 73.4+/-11.4kg and %fat 20.9+/-8.6. The anthropometrics variables used as predictors were waist circumference (WC) and topography of fat (%Garms, %Glegs and %Gtrunk - dual energy X-ray absortometric). WC was measured on 2.5cm above the umbilical scar. The biochemical variables used as predictors were glucose (G) and seric cholesterol (SC), very low density lipoprotein (VLDL), low density lipoprotein (LDL), high density lipoprotein (HDL) and triglycerides (TG). These variables were dosed after fast of 12 hours by the enzymatic method with semiautomatic spectrophotometer. The adopted statistical treatment was the multiple linear regression by the stepwise method ($p < .05$). The values of the measured variables were: WC = 87.5+/-10.6cm, %Garms = 12.5+/-6.7, %Glegs = 20.4+/-8.2, %Gtrunks = 23.5+/-10.2, SC = 168.9+/-35.4mg/dL, G = 93.6+/-12.0mg/dL, VLDL = 34.9+/-32.4mg/dL, LDL = 99.2+/-32.1mg/dL, HDL = 39.4+/-10.4mg/dL, TG = 152.4+/-89.3mg/dL, BP = 132.4+/-18.4mmHg. Among the variables used as predictors of the BP, the WC by itself influenced in 27.5% ($p < .0005$), WC and SC, together, in 31% ($p < .015$) and WC, SC and %Garms, together, in 34.6% ($p < .011$). While WC and SC influenced directly, the %Garms influenced inversely. The other predictors variables did not influence, in a significant way, the BP ($p > .05$). As the WC and the SC increase and the %Garms decreases, the subjects appraised present higher BP. Therefore, in conclusion: the measure of WC is a good indicative of BP; the excessive accumulation of fat on the trunk must be controlled, with the intention of avoiding risk factors associated with cardiovascular diseases, like the BP.

R.O.M. IMPROVING EXERCISES IN PHYSICALLY INDEPENDENT ELDERLY WOMEN: STRETCHING VS DYNAMIC FLEXIBILITY

Lanza, M., Fracca, I.

University of Verona, Faculty of Exercise and Motor Science, Italy, Italy

Introduction

Flexibility is one of the most important health related physical activity for Older People (ACSM, 1998) but there are no detailed guidelines about dose and types of exercises needed to improve Range of Motion (ROM) (Cotton, 1998). Researches show static stretching as the elective method for improving the ROM (Briant, 2003) but dynamic exercises, that includes bending, extension, rotation and circumduction of the joint, are frequently adopted. Aims of the research is to compare the efficacy of Static Stretching (SS) and Dynamic Flexibility Exercises (DFE) in ROM improving.

Methods

ROM changes with SS and DFE were measured in 66 Physically Independent Elderly Women (Age=66.3y; 56y - 81y; d.s.=5.34). Two days a week they attended a-one-hour physical activity session. It included 15 minutes of SS and DFE for flexibility. Others activities of the training were endurance, local muscular endurance, coordination and balance. Flexibility was evaluated through the Standing-Sit-and-Reach (SSR) and Back Scratch tests (BS). Subjects were divided in two groups (gr.A – gr.B), homogeneous for number, age and performance in flexibility test (gr.A:n.32; Age:66.4y, d.s.:5.10; SSR:-8.3; BS:-4.5cm. – gr.B:n.34; Age:66.2y, d.s.:5.6; SSR :-7.1; BS:-5.4 cm.). In the first three weeks ("Run In" Phase) the two groups carried out an equal activity. In the second four-week-phase (Improvement), in order to improve flexibility, gr.A adopted static stretching alone (gr.A-SS) while the gr.B used dynamic flexibility exercises (gr.B-DFE). In the third four-week-phase (Maintenance) the groups exchanged the methods (gr.A-DFE; gr.B-SS). In the final three-week-phase both the groups stopped activity (Detraining).

Results

Flexibility showed a meaningful improvement (SSR=2.09cm; BS=2.05cm; $p<0.001$) and no difference in the two groups. In "Detraining" flexibility showed a reduction (SSR=-0.83cm; BS= -0.83cm; $p<0.001$) and no difference in the two groups.

CAN INACTIVE YOUNG PEOPLE BE REACHED THROUGH AN INTERNET PROGRAMME TO PROMOTE PHYSICAL ACTIVITY?

Padlina, O., Jimmy, G., Martin, B.

Swiss Federal Office of Sports, Switzerland

Introduction

Feelok is an online health promotion programme for young people aged 12-18 (www.feelok.ch). It has been available since 2002 and includes sections on the following topics: smoking, cannabis, stress, self-confidence, alcohol, nutrition, and sexuality.

An additional section to promote physical activity among inactive youth was added in 2005 with support of the Swiss Federal Office of Sports.

The aim of the current study was to determine whether inactive young people could be reached through the internet medium and if they showed an interest in engaging in the programme.

Method

Three different sources were used to answer the above question.

1) When the section on physical activity had not been added to feelok yet, all visitors of the general feelok programme were asked how many times per week they engaged in sports outside school hours.

2) Once the section on physical activity was launched, a programme running in the background of feelok recorded user numbers and duration of visits to this section.

3) feelok also offers a physical activity test based on a 7-day recall questionnaire. The number of test participants classified as inactive was determined being those who accumulated less than 1500 kcal through physical activities during a week.

Results

1) The question on sports outside school hours was answered by 545 youths aged 10 to 19 (54% female, response rate 14.2%) during a 2 week time period. Twenty-five percent reported engaging in sports less than once a week.

2) The feelok physical activity promotion programme was visited 208 times for at least 3 minutes during a time period of 8 weeks. An average visit lasted 14 minutes.

3) Out of 378 youths aged 10 to 19 (64% females) who completed the physical activity test, 12% were classified as inactive.

Conclusion

Seeing that a quarter of visitors of the general feelok programme were rarely active in sports, it can be concluded that this kind of programme is a good starting point to reach the group of inactive youths. The number of 104 visits per month for the physical activity promotion programme is comparable to the use of partial modules for other health dimensions of feelok and shows that this programme attracted the interest of the young people. Among those who completed the physical activity test, 12% were classified as inactive which indicates that this group can be reached. However, more active recruitment measures may lead to a higher participation rate of the inactive.

NEW OPPORTUNITIES IN TOURISM, SPORT & LEISURE

Reverter, J., Barbany, J.R.

Zaragoza University, Barcelona University, Spain

The present crisis of the tourism industry can be considered as a logical consequence of its created core destination strategies which have been established in the period of mass tourism (1960-1990), and which lacked both a conceptual and a customer focus. Big socio-demographic shifts, health awareness and changes in consumer behaviour and values have become important determinants and critical factors of success for what might be termed "new tourism". The transformed tourist demand calls for new innovative products (Hinch & Higham, 2004)*. New tourism clusters in the field of sports and health will in consequence constitute the only way to package and offer a complete and holistic range of wellness services. The aim of this work is to make an integrated proposal of new opportunities in tourism, sport & leisure.

BODY PUMP® INSTRUCTOR'S PEDAGOGICAL FEEDBACK – COMPARISON BETWEEN DIFFERENT EXPERIENCED LEVELS AND DIFFERENT ACADEMIC DEGREES

Simões, V., Franco, S.

Escola Superior de Desporto de Rio Maior, Portugal

Introduction

The propose of this study was to characterize the Body Pump® instructors pedagogical feedback and compare this behaviour type in instructors with different types of academics qualifications and with different levels of professional experience.

Two hypotheses were formulated:

There are significant differences among experienced and inexperienced Body Pump® instructors feedback.

There are significant differences among Body Pump® instructors feedback with superior degree and without superior degree in sport's area.

Methodology

The sample was constituted by 15 Body Pump® instructors: 10 experienced and 5 inexperienced; 5 licentiates and 10 non licentiates.

The feedback emitted by the instructors was observed through the record videos of the respective classes.

The pedagogical feedback observation systems (Piéron & Rodrigues, 1991, in Piéron, 1999; Sarmento et al. 1998; Schmidt & Lee, 1999) that were used had 7 dimensions with 24 categories. The recording tactic used was Event Recording.

Conclusions

In each dimension, the more frequently feedback types observed were: Verbal, Concurrent, Isolated, Positive Evaluation, to the Class (Inexperienced and Licensed Experienced) or Individual (Experienced Not Licensed), Positive Afectivity, and Feedback Followed by Observation.

It was verified that:

There aren't significant differences among Body Pump®'s Inexperienced instructors (inexperienced as Fitness instructors and Non Licentiates) and Body Pump®'s Experienced instructors (Non Licentiates), concerning the feedback type occurrence, except in the category Group, in that the Experienced instructors present larger frequency of feedbacks.

There are significant differences between the Non Licentiates Body Pump® instructors and the Licentiates (both Experienced), concerning the feedback type occurrence, in the following categories: Visual, Concurrent, Terminal Immediate, Isolated and Accumulated. Significant differences were not verified in the remaining categories. The Licentiates instructors emit more Visual, Immediate and Accumulated feedbacks and less Concurrent and Isolated, that the Non Licentiates.

PARTICIPANTS' PERCEPTION AND PREFERENCE ABOUT BODY PUMP® INSTRUCTORS' PEDAGOGICAL FEEDBACK

Franco, S., Simões, V.

Escola Superior de Desporto de Rio Maior, Portugal

Introduction

The purpose of this study was to characterize and to compare participants' perception and preference about instructors' pedagogical feedback in the resistance training program Body Pump®.

Methodology

Sample subjects were 184 Body Pump® program participants.

A questionnaire about pedagogical behaviour was develop and validated, in the perception and preferences versions, based on 7 dimensions, and 24 categories, of pedagogical feedback behaviour observation systems (Piéron & Rodrigues, 1991, in Piéron, 1999; Sarmento et al., 1998; Schmidt & Lee, 1999). A five-point Likert-type scale was used to measure the 24 feedback categories, ranging from least frequent (1=Never) to most frequent (5=Always).

The minimum, maximum, mean and standard deviation was used in the descriptive analyses. Wilcoxon test was used to compare the participants' perception and preference.

Conclusion

In all dimensions, the feedback category that the participants percept and prefer as more frequent in Body Pump® instructors were the same.

When we compare the participants' perception and preference, concerning Body Pump® instructors' feedback, we found there were significant differences in 18 of the 24 categories.

In most of the feedback categories participants preferred that the Body Pump® instructors provide it more frequently, like in Franco et al (2004) study' about fitness instructors' profile, what can mean that the participants want to receive feedbacks more frequently.

13 YEARS FOLLOW-UP OF PHYSICAL FITNESS IN FLEMISH NURSES AS MEASURED WITH THE EUROFIT TEST BATTERY

Zinzen, E., Watthy, C., Luyten, R., Vandevelde, P., Clarys, P.

Vrije Universiteit Brussel, Belgium

Introduction.

Low physical fitness is assumed to be one of the major factors contributing to an increased incidence of cardiovascular disease, diabetes mellitus, obesitas, musculoskeletal problems, …. There is evidence that increased physical activity increases physical fitness levels and decreases the risk for above mentioned diseases (Erikssen, 2001; Katzmarzyk et al., 2004). Burton et al. (2004) indicate in their European Guidelines for Prevention of Low Back Pain (LBP) that increasing physical fitness level is the most effective action in primary prevention for LBP. The nursing population is very sensitive for LBP.

The findings of Tsigilis et al. (2002) indicate that the Eurofit test (EUT) system yields reliable information for the determination of physical fitness.

Purpose.

The purpose of this study was to investigate – in a longitudinal way – the physical fitness level of nurses in a Flemish academic hospital. Do the scores on the EUT change over a period of 12 years, with no particular interventions in that field? Does back schooling, with an explicit accent on physical activity, improve the scores on the EUT after one year?

Methodology.

In 1992, 12 male and 25 female nurses of the academic hospital of the Vrije Universiteit Brussel volunteered to participate the EUT. In 2004, 158 males and 670 females volunteered. After one year of back school intervention (2005) 86 males and 483 female nurses still participated the study. The EUT consists out of 8 tests: Flamingo Balance (FLB), Plate tapping (PLT), Sit and Reach (SAR), Standing Broad Jump (SBJ), Sit Up (SUP), Bent Arm Hang (BAH), Handgrip (HGR) and a Shuttle Run (SHR).

Data were cleaned, checked for normal distribution, and the means were compared by a one-way ANOVA with the Scheffé post hoc test. Significance levels were set at 5%

Results.

The results of 1992 compared to 2004, for the male nurses, indicate a significant improvement in flexibility (SAR). The SHR on the other hand showed significant lower results. After one year with 3 sessions of back schooling only the SUP test improved significantly.

The female nurses in 2004 performed, in comparison with 1992, significantly worse for the FLB and the SHR and better for the SAR. After back schooling they scored significantly better on PLT, SUP, and BAH. Scores were significantly worse for FLB and SBJ after that year.

Discussion and conclusion.

The results after 12 years are – in exception for the worse SHR and the better SAR – not that different for male and female nurses considering the small sample size in 1992. It was noted by Zinzen et al.(1997) that the nurses scored on both items exceptionally in comparison with a reference group. The back school intervention had the most effect for the female nurses with the SUP improved for both sexes. With regard to prevention of low back problems, stronger abdominal muscles are considered as an important improvement.

EFFECTS OF TAI JI QUAN ON DYNAMIC POSTURAL STABILITY AND ANKLE JOINT MUSCULAR STRENGTH IN OLDER WOMAN

Guanglin, X., Kumagawa, D., Tanaka, S., Tsunoda, N.

Graduate school of Sports System, Kokushikan University, Japan., Japan

It is well known that condition body balance control with a one of the ability to maintain the postural equilibrium in human. Tai Ji Quan is a widely practiced one of the Chinese martial arts. The characteristics of Tai Ji Quan are slow and continuous movements with a lower centre of gravity. Generally, older people have decline lower limb muscle function due to aging. Several studies reported that Tai Ji Quan practice improved balance ability in older people. However, there are no findings for dynamic postural control ability effect of Tai Ji Quan practice on older people. Therefore, the purpose of this study was to clarify the effects of Tai Ji Quan on dynamic postural stability and ankle joint muscular strength in older woman.

The subjects were fifteen female long-term Tai Ji Quan practitioner group (TG) and fifteen healthy non-practical female as a control group (CG). Dynamic balance control ability with opened-eyes during 20 seconds was tested by dynamic balance test of the Stability System (Biodex, USA) in all the subjects. The subjects were tested under three standing conditions of normal standing with both legs (BS), right leg standing (RS) and left leg standing (LS). The indexes of dynamic postural stability were evaluated amount of sway in the overall directions (OSI), anterior/posterior directions (A/PSI) and medial/lateral directions (M/LSI). The lower index values are showing higher dynamic balance ability. The relative dynamic postural stabilize time of ratio (%) in the center of target (A-zone) of each condition was evaluated. And also, the force of isometric plantar flexion was measured by dynamometer (Biodex System 3, USA).

In OSI, TG was shown significantly lower value than CG ($p<0.01$). In all standing conditions. And also A/PSI and M/LSI was obtained same tendency. The relative ratio of stabilizes time at A-zone on TG showed significantly higher values in all standing conditions ($p<0.01$). Plantar forces on TG were significantly higher than CG in right and left ankle. In a single leg standing condition of TG, significant negative correlation coefficients were obtained between plantar force and OSI with right and left (RS：r = 0.635，LS: r = 0.692. $p<0.05$). However, it was not significant correlated between plantar force and OSI in CG. Significant correlation coefficient between plantar force and A/PSI (RS: r = 0.655，LS : r = 0.702), and M/LSI (RS : r = 0.578，LS : r = 0.542) were obtained in all the subjects. And also plantar force related to ratio of stabilize time at A-zone with right (TG: r = 0.630, CG: r = 0.798) and left ankles (TG: r = 0.557, CG: r = 0.631).

From these results, it was considered that Tai Ji Quan exercise may effect on muscle force of ankle and dynamic posture stabilizes ability in older woman.

OBESITY INTERVENTION WITH THE M.O.B.I.L.I.S. PROGRAMME

Laqué, M.K., Berg, A., Frey, I., König, D., Lagerstroem, D., Predel, H.-G.

Institute of Cardiology and Sports Medicine, Germany

Obesity is one of the greatest public health challenges of the 21st century. Sustainability in terms of body weight reduction as well as stabilisation are demonstrably achieved by a combination of diet and physical activity interventions. Hereby M.O.B.I.L.I.S. (multicentre organised movement oriented initiative for lifestyle modification in personal responsibility) aims at a lasting modification of the activity level towards a balanced lifestyle and a simultaneous improvement of health competency via a 12-month movement oriented therapy intervention. The documentation of the therapy progress as an evidence-based medicine is aspired for 4.000-5.000 adults with a BMI between 30 and 40 kg/m2. Meanwhile one year results exist for three model groups following a standardised concept.

40 adults (age: 47,4±11,6, weight: 107±16 kg, BMI: 35,2±2,9 kg/m2, waist circumference: 112±11 cm, hip circumference: 121±9 cm, overweight: 40,8±11,8 %, LDL-C: 140±34 mg/dl, HDL-C:54±13 mg/dl, TG: 139±52 mg/dl) took part in the one year programme. Trained interdisciplinary teams impart content from the areas of movement/sport, psychology/pedagogy, nutrition and medicine/health in 20 theoretical and 35 practical sessions. Hereby different phases and time segments are provided: a 6-week start phase, 18-week body weight reduction phase and 6-month stabilisation phase. In order to optimise the individual therapy a permanent information exchange takes place within the teams.

Of the 52 participants 40 completed the one year programme (drop out rate 23%). The reduction of bodyweight (-10,9 kg), of BMI (-3,6 kg/m2) and in particular of the waist circumference (-8,4 cm) point to a significant reduction of abdominal-visceral fat mass ($p<0,001$). Furthermore, the hip measurement was reduced (-9 cm) as well as overweight (-14,4 %) ($p<0,001$). The atherogenic and inflammatory risk factors acted accordingly: LDL-C -6,4 mg/dl, TG -18 mg/dl ($p<0,05$), HDL-C +8,2 mg/dl, hs-CRP -0,16 mg/dl ($p<0,01$). The parameters of heart circulation regulation and load capacity (watt/kg body weight, heart rate variability, heart frequency, BP systolic and BP diastolic at rest and during load) also improved with $p<0,001$.

A one year instruction programme comprising the basic module movement in combination with diet- as well as behaviour modification and medical supervision constitutes a highly effective therapy option for obese adults.

Complete teams (PE teachers/sport scientists, psychologists/pedagogues, dietetics specialists, MD) are educated by the leaders of the four M.O.B.I.L.I.S. competency areas at special M.O.B.I.L.I.S courses since December 2004 and subsequently they take charge of M.O.B.I.L.I.S groups. Currently 37 groups of 15 participants each are professionally supervised.

SELF REPORTS: A NEW POSSIBILITY TO REPORT ADVERSE EVENTS AMONG CONSUMERS OF ILLICIT HORMONE PHARMACEUTICALS INDICATES A SPECIFIC PATTERN OF DOPING ABUSE

Thurelius, A.M., Garevik, N., Rane, A.

Karolinska University Hospital, Sweden

Background:

The Anti Doping Hot-Line works to prevent, discover, reduce, counteract and eliminate the misuse of doping and its consequences in Sweden. The most common reported adverse events (AE) of illicit hormone pharmaceuticals- mostly anabolic androgenic steroids (AAS), are: acne, plasma lipids alterations, hypertension, psychiatric and behavioural disorders, potency disorders, testicle atrophy and gynecomastia in males, and to some degree reduced fertility. Other AE include masculinization in women. In 2004 an interactive website was created with a possibility for the consumers to report AE. We investigated the different characterizations with respect to age among consumers of AAS, closely related substances and dietary supplements containing for example ephedrine.

Objective:

To understand the pattern of the abuse of illicit hormone pharmaceuticals and related compounds and develop preventive strategies to identify and describe physiological, social and psychiatric adverse events.

Methods:

An anonymous self-report questionnaire on the Anti Doping Hotlines website with questions concerning AE, substances misused and effects on quality of life. The form was filled in by a total of 97 anonymous consumers to the Anti Doping Hotline (including 10 (9.7%) females at age 19-32, 44 (42.7%) males at age 16-23, 43 (41%) males at age 24-44). The two different male groups were compared and analyzed with unpaired t-tests.

Results:

The consumers of solely AAS was significantly higher among the males at age 16-23 ($p<0.001$), the consumers of mixed drugs (AAS and other related hormone pharmeuticals) was significantly higher among males at age 24-44 ($p<0.001$). Having a positive experience of the abuse was significantly higher among males at age 24-44 ($p<0.001$), in this group 12 individuals also reported no AE. Clenbuterol, a beta-2 adrenergic agonist, was only abused among the group of males at age 24-44. The most common AE among males in total were psychiatric symptoms as anxiety and aggressiveness. No significantly differences were found between the males concerning AE. The proportion of females was low (only 10).

Conclusion:

Our data verify a different pattern of the abuse of illicit hormone pharmaceuticals and related compounds with respect to age among males. Among the older males a mixed abuse with different hormone pharmaceuticals involved was more common. Some of these pharmaceuticals were consumed in the belief that they prevent AE. However, there were no significant difference concerning age and AE, (despite the amount of abusers reporting no AE at all and having only a positive experience in the older group). This might be a sign of no expected effect of these hormone pharmaceuticals. Clenbuterol did not exist as an abuse among the younger males, which could indicate that they are less advanced in their abuse. This oral presentation will include current figures and statistics from the Anti Doping Hot-Line.

THE PHYSICAL AND PSYCHOLOGICAL EFFECTS OF A LONG-TERM EXERCISE PROGRAM IN ELDERLY PEOPLE

Sasaki, H., Takahashi, M.

Asai Gakuen University, Japan

Introduction: As the population of elderly people continues to grow in advanced nations, there is interest not only longevity, but also in the quality of life (QOL). QOL is defined by the World Health Organzation (WHO) as an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns (General Guidelines for Methodologies on Research and Evaluation of Traditional Medicine WHO, WHO MD; 2000). The QOL for elderly people has two aspects; physical health and mental health.

Exercise maintains and promotes physical and mental function. Exercise is also one of the main stated factors that influences the improvement of QOL. Furthermore, as the physical and psychological effects of these exercises have explained in recent years, exercises for elderly people have widely in the prevention of nursing care Furthermore, as the physical and psychological effects of these exercises have explained in recent years, exercises for elderly people have widely in the prevention of nursing care.

Objective: The purpose of this study was to examine the physical and psychological effects of long-term exercise in elderly people and assesses the program's effect on QOL.

Subject & Method: Subjects in this study were 23 elderly people with a mean age of 64.1±6.0. They participated in a senior fitness class for about 9 months. Physical and psychological measurements were taken.

Those measurements were performed about once every about four months. The physical measurements were anthropometric indexes. These were; height, body weight, body fat, systolic and diastolic pressure, chest girth, abdominal girth, hip girth, left and right thigh girth, left and right lower leg girth, and fitness tests including grip strength, sit-ups, sitting trunk flexion, foot-balance with eyes opened, 10m obstacle walking, up and down step test. The psychological measurement used a 30-item General Health Questionnaire (GHQ30) and QOL was measured at the same time by WHO/QOL26.

Result: In the physical measurements, left and right thigh girth, grip strength and 10m obstacle walking improved. GHQ30 and QOL26 did not significantly changed. In each factor on the GHQ30, the ratio of the person with a high score (3-5point) of insomnia was about 30 percent. It was higher than in the other factors.

Discussion: From these results, it was supposed that the physical indices changed earlier than the psychological index in elderly people. The psychological index did not significantly change, but from the ratio of the persons with the highest scores in the factor of the GHQ30, it was suggested that one in three or four persons experienced a sleeping disorder. Continuous measurement is necessary to assess the change of psychological index.

INJURIES IN GERMAN PROFESSIONAL FOOTBALL - EPIDEMIOLOGY AND PREVENTION

Henke, T., Schulz, D., Platen, P.

Ruhr-Universität Bochum, Germany

Problem: Although football is of high social importance, in professional football economical factors are dominating. The total turnover has increased to over 1 billion euro in the 1st national football league alone which means a decupling since 1990. It is therefore plausible that the clubs have to take care for their player's health not only from the ethical but also from an economical point of view. In this context, the question arises what injury prevention in professional football should focuse on. The study presented was funded by the insurance of the german professional athletes (VBG).

Methods: For statistical analysis the following datasets of the season 2004/2005 were surveyed:

- Personal, sports specific and sociodemographic data of the 1953 professional football players from the 1st, 2nd und 3rd german professional football leagues. These players present the population.
- Type, severity and costs of 5361 sports injuries sustained by the german football professional players.
- Mechanisms, situations and circumstances of 448 out of the 5361 injuries were recorded in a special survey.

Results: Each professional football player sustains an average of 2 injuries per season, one of these resulting in an absence from sports and the other causing only medical costs. There is no player who sustains not at least one injury per season. About 13.5% of the players are constantly sidelined due to injuries. The costs (medical costs and salaries paid for injured players) of the injuries in professional football summarise up to 90 Mio. per season. Knee injuries are by far the most serious injuries in german professional football. They cause costs of about to 33 Mio. per season, which is equivalent to 37% of all injury costs. Ankle injuries (14 Mio.) and injuries of the thigh (10 Mio.) also create high costs. Injuries of the lower extremities cause 2/3 of all injury costs. About 25% of the knee injuries are non-contact injuries.

Conclusions: The situation presented is not acceptable, neither from the sporting nor from the economic point of view. Many clubs face with financial problems which are likely to increase due to changes concerning the television broadcasting rights. And even performance enhancement and success in championships and cup competitions will only be possible, if the teams important players stay uninjured. Against this background this study provides information, about how the problem of injuries in professional football can be approached and which preventive measures may be successful especially concerning the serious problem of knee injuries. With respect to other studies and own experiences proprioceptive and coordinative exercises seem to be most promising in this area. But these measures will only be accepted in professional football, if they are adapted especially for elite football and if it is communicated that they are not primarily preventive but also performance-enhancing.

THE IMPACT OF PHYSICAL TRAINING ON SICK LEAVE, CARDIO-RESPIRATORY PHYSICAL FITNESS, LEISURE PHYSICAL ACTIVITY, LIFE SATISFACTION AND MUSCULOSKELETAL COMPLAINTS OF EMPLOYEES IN NURSING HOMES

Gundersen, K.T., Bratteberg, M.P.

North-Troendelag University College, Norway

Abstract

Title: The Impact of Physical training on Sick Leave, Cardio-Respiratory Physical Fitness, Leisure Physical Activity, Life satisfaction, Musculoskeletal Complaints of Employees in Swedish and Norwegian Nursing Homes

Magnhild Bratteberg1, Kjell Terje Gundersen1

North-Troendelag University College, Faculty of Education, Engineering and Nursing, Levanger, Norway

Employees working at nursing homes are mentally stressed because of duty on rotation basis. They are working physically hard and have a high level of sick leave (Ihlebæck&Læhrum, 2004). Physical fitness and physical training should be of great importance to avoid developing health complaints. However there is limited knowledge based on research about the effects of physical activity and exercise on employees in health and care sectors and (Goverud&Hvamstad, 1999; Roness&Matthisen, 2002).

The study focus on employees in three nursing homes in Sweden and Norway and the effects of an intervention program with physical exercise in a social and pleasant setting. Objectives are the effect on sick leave, self-reported cardio respiratory physical fitness, leisure time physical activity, life satisfaction (LISAT) and functional musculoskeletal complaints (MSQ).

The intervention project included physical training of employees partly during working hours at the nursing homes and partly after finishing work.

Questionnaires were used to collect data from pre- and post-tests. Differences between Swedish and Norwegian results were assessed by bivariate analyses and analyses of variance (ANCOVAs).

The effects of the program reflect significant differences on cardio respiratory physical fitness, subjective well being and functional musculoskeletal complaints.

Key-words: nursing homes, intervention, sick leave, leisure physical activity, physical fitness, well being, functional muscle complaints

PHYSICAL PERFORMANCE, FITNESS AND GENE POLYMORPHISMS

Dondukovskaya, R., Ahmetov, I., Topanova, A., Mozhayskaya, I.

St Petersburg Research Institute of Physical Culture, Russia

Severe disease and peak physical performance can be viewed as the two extremes of a continuum of human fitness. There are individuals who fall close to one extreme (i.e. unfit and obese individuals) or the other (elite athletes). Fitness participants are generally considered as people with body weight and health problems, who wish to be fitter and healthier. Strong evidence for genetic influences on health condition, anthropometric characteristics and athletic performance has accumulated over the last years. The knowledge of genotype data of young athletes as well as fitness participants is supposed to help in individualization of training processes and optimizing their diet to achieve better fitness level and to prevent metabolic diseases such as obesity, type II diabetes and cardiovascular diseases. The aim of the present study was to compare the frequencies of endurance-related alleles of PGC1A, PPARA, UCP2 and UCP3 genes between endurance-oriented female athletes and unfit women, participants of fitness club and to search the association between genotype data and several physiologic and anthropometric characteristics of unfit females.

One hundred and fifty four Russian endurance-oriented female athletes (cross-country skiers, road cyclists, biathletes, triathletes and rowers, BMI 21.8±0.2) and eight unfit women (participants of fitness club; BMI 27.1±2.3 kg/m2) were studied. PGC1A Gly/Ser, PPARA intron

7 G/C, UCP2 Ala/Val and UCP3 -55C/T polymorphisms were determined by PCR and restriction enzyme digestion. Several physiological tests were performed to assess aerobic and anaerobic characteristics of the unfit women.

Mean BMI was significantly higher in unfit women than in female athletes (P=0.02). We found that the frequencies of endurance-related alleles - G (PPARA) and Gly (PGC1A) were significantly higher in athletes than in unfit women (G: 86.7% vs 68.7%, P=0.045; Gly: 59.4% против 25.0%, P=0.01). Furthermore, in unfit women, BMI and fat mass was slightly bigger in SS PGC1A and CT UCP3 (associated with high risk of development of metabolic diseases) genotypes carriers, but these differences were non-significant. In considering physiological data, we found that PPARA GG homozygotes exhibited the highest value of endurance performance (111±13 W vs 84±10 W (heterozygotes), P<0.05; estimated by PWC-170 test), and UCP3 CC genotype carriers showed the best values of handgrip dynamometry (29.4±1.4 vs 23.3±2.6 (heterozygotes); P<0.01). In conclusion, PPARA, PGC1A and UCP3 gene variants were associated with physical performance and fitness level of female endurance-oriented athletes and unfit women.

PREDICTING BODY FAT FROM BODY MASS INDEX IN HEALTHY INDIVIDUALS

Stavropoulos-Kalinoglou, A., Metsios, G.S., Koutedakis, Y., Nevill, A.M., Douglas, K.M., Jamurtas, A.Z., Kitas, G.D.

Univesity of Wolverhampton, United Kingdom

Excess body fat (BF) is a prominent health hazard significantly contributing to the development of cardiovascular disease (CVD). Assessments for body fatness include the calculation of body mass index (BMI - in kg/m2) and more accurate estimations of relative adiposity (i.e. BF percentage).

However, as BMI does not distinguish between lean-body mass and fat mass, in a way that people of similar stature and weight, but unequal muscle content, will have the same BMI but different BF levels, several authors have questioned its validity. Age and gender are among the factors that can affect the proportion of lean to fat mass. Assessments of BF percentage, even though more accurate than BMI, require specialised personnel and expensive equipment. Thus, the aim of this study was to develop an accurate and practical method to predict fat content in healthy individuals.

A total of 82 (39 males, 43 females) healthy, middle-aged (mean age: 46; sd: 12.3) individuals volunteered for the study. Their BMI (kg/m2) and BF percentage (using the "Tanita BC-418 MA Segmental Body Composition Analyser"; Tanita Corporation, Tokyo, Japan) were assessed. Mean (sd) BMI was 25.5 (4.5) [males: 25.7 (3); females: 25.4 (5.5)] and mean (sd) BF, 25.9 (9.5) [males: 19.2 (5.2); females 32.1 (8.2)].

According to BMI, 50% of our participants were classified as normal-weight, whereas, according to BF 62%. Age was significantly correlated with both BMI (r=0.234, p<0.05) and BF (r=0.337, p<0.01). One-way ANOVA revealed significant differences between genders for BF (p<0.01) but not for BMI (p>0.05). Linear regression analysis produced a predictive equation for BF (R2=0.769, p<0.01), deriving from BMI, age and gender (BF= 1.059 x BMI + 0.108 x Age + Gender - 0.719; where gender is: male= -11.294, female= 0).

In our sample, BMI over-predicted fat content. Both BMI and BF were increased with age but only BF differed among genders. Our data are supported by the current literature on the subject, as the validity of BMI is being questioned, especially in females who, normally, exhibit increased levels of body fat compared to males. Since BF percentage is a more accurate estimate of fat content, given that cut-off-points are age and gender specific, the equation presented herein can be used to more accurately predict fat content in healthy individuals.

THE EFFECT OF AGING ON THE REGENERATIVE CAPACITY OF SKELETAL MUSCLE

Ponsot, E., Lexell, J., Kadi, F.

Department of Clinical Medicine, Sweden

Introduction

It is well known that aging is associated with a progressive loss of skeletal muscle mass due to the atrophy of individual muscle fibres. This is accompanied by a decrease in the capacity to generate force and power, leading to a progressive weakness. However, it remains a matter of debate whether there is an age-related decrease in the capacity of skeletal muscle to repair minor or lethal injuries that occur at the level of muscle fibres in response to daily physical activity. The regenerative potential of skeletal muscle is partly dependent upon the regenerative history represented by the telomere length. The aim of the study was to determine the effects of aging on muscle DNA telomere length on muscle biopsies obtained from healthy active elderly women and men.

Methods

Fourteen healthy active elderly women and men (age range, 70-83 years) were compared to 15 healthy young women and men (age range, 20-32 years). All individuals participated regularly in recreational sports such as aerobics, jogging, cycling, and ball games. Muscle biopsies were obtained from the tibialis anterior muscle of the dominant leg. Total DNA extraction is achieved by incubation in proteinase K digestion buffer. The genomic DNA is then digested with a restriction enzyme to generate a smear of DNA fragments containing telomeres with different lengths of the TTAGGG repeat sequence. Telomeres were detected using southern blot analysis. The telomeres are detected by hybridization to a 32P-labelled (TTAGGG)4 probe, followed by exposure to x-ray film. The signals are analysed using Scion software and average and minimal telomere lengths were determined.

Results

The signal obtained provides a distribution profile of telomeric lengths of all myonuclei and satellite cells present in the tissue. Average telomere length indicates the most frequent DNA telomeric lengths of the tissue whereas the minimal telomere length indicates the shortest DNA telomeric lengths found in the tissue. The elderly group had a mean telomere length of 10.7 ± 1 kbp and a minimal length of 4.7 ± 0.6 kbp. In young, the mean length was 10.7 ± 0.9 kbp and the minimal was 5 ± 0.6 kbp. There were no significant differences in both mean and minimal telomeric length between young and elderly.

Conclusion

Contrary to what is described in-vitro and in-vivo in several tissues, it seems that healthy elderly and young men and women have similar skeletal muscle telomeric length. This result implies that we have to further improve our knowledge on the mechanisms allowing the stabilisation of telomere length in human skeletal muscle.

CLASSIFICATION OF PHYSICAL ACTIVITY BY HEART RATE AND ACCELEROMTERY DATA, RECORDED SIMULTANEOUSLY

Mäder, U., Ruch, N., Rumo, M., Martin, B.W.

Federal Office of Sports, Switzerland

INTRODUCTION: The extraordinary importance of habitual physical activity and exercise for disease prevention and health promotion is widely recognized. However, physical activity remains difficult to be measured accurately and the available measurement techniques have inherent limitations. The simultaneous use of heart-rate monitoring and accelerometry may be useful to overcome some limitations of those two methods, commonly used separately. The purpose of this study was to elicit, whether physical activities might be classified by heart rate and accelerometry data.

METHOD: Heart rate and accelerometry (biaxial) data were collected simultaneously by a chest mounted device (ikcal, Teltronic AG, Biberist, Switzerland) every 10 sec during walking (flat, uphill, downhill at 3 different velocities), during biking and arm cranking with two intensities each, sitting and standing. 6 of the volunteers were women (30.5 ± 11.6 y, BMI = 22.8 ± 5.0, 10 were men (37.2 y, BMI = 26.6 ± 3.3). Data of walking at 3 velocities on the flat and sitting were used to normalise all measured values before scanning for activity specific data patterns and defining 8 activity classes (walking (W), uphill (UH), downhill (DH), leg activity (LA), arm activity (AA), inactivity (IA), and not assigned (NA)). The established data patterns were used to classify measured activities among 12 subjects (6 females, 41.5 ± 14 y, BMI = 21.4 ± 2.6; 6 males, 39.3 ± 16.3 y, BMI = 22.3 ± 1.0) during 30 min of walking (treadmill, flat), biking (ergometer), stepping, and playing (joggling, diabolo, hit a target). Before the measurement, volunteers performed the calibration procedure described above.

RESULTS: During 30 min of walking 42.3 ± 37.0 % were classified correctly. Other classes were significantly less often selected ($p < 0.05$), except DH (16.7 ± 27.7 %) and NA (28.0 ± 28.6 %). 48.7 ± 29.7 % during 30 min biking were assigned to LA. The other classes were less represented ($p < 0.05$), except AA (30.6 ± 20.7 %). During 30 min of stepping 30.7 ± 37.7 % and 25.1 ± 31.7 % were recognised as UH and DH, respectively. 30.3 ± 25.3 % were NA. Only IA was significantly less represented than DH (0.3 ± 0.7 %, $p < 0.05$) during stepping. The 30 min of playing consisted of 39.7 ± 16.7 % min NA, 30.7 ± 17.0 % LA, 9.3 ± 11 % AA, 8.0 ± 8.7 % IA, 6.7 ± 22.3 % UH, and 6.3 ± 7.0 % W.

DISCUSSION: The results indicate, that values, averaged over 10 sec, for hear rate and accelerometry might be used to classify physical activity. The simple algorithms used for the classification process in this study have been applied to minimise the required computing level for a wearable device that record physical activity. However, it would be desirable to improve the validity of the classification process so it can be used in advanced research on physical activity behaviour.

TRACKING PHYSICAL FITNESS OF PRIMARY SCHOOL CHILDREN AT VIANA DO CASTELO, PORTUGAL

Rodrigues, L., Bezerra, P., Saraiva, L.

Instituto Politécnico Viana do Castelo & LIBEC/Un. Minho, Portugal

There is little knowledge regarding children's physical fitness behavior during primary school years (1st to 4th grade). To understand this phenomenon better there is a need to track for individual trajectories across repeated measures of time.

To investigate physical fitness trajectories and stability we took a sample of 358 children (184 girls, 174 boys) which we followed for three consecutive years (mean ages 7.5, 8.5, and 9.5 years-of-age) in the "Estudo Morfofuncional da Crianca Vianense", Portugal. Physical fitness was assessed by seven different tests: 60 sec sit-ups (SU), flexed arm hang (FAH), standing long jump (SLJ), 50 meters dash (50M), 10 meters shuttle run (SHR), 20 meters pacer run (PR), and sit-and-reach (SR). Repeated measures ANOVA tests were used to inquire into the behavior of each fitness variable along the three time waves. Results showed a general positive effect of AGE for SU, 50M, SHR, and PR for both genders; a negative effect for SR on boys only; and no effect for FAH. A structural equation modeling approach was then used to look for the whole multidimensional trait of physical fitness across time. Two autoregressive models were used, with all tests loading on a general physical fitness factor, repeated across three time waves with autocorrelated errors, to fit both gender data. The models presented a good fit to the data (NFI,CFI, GFI and RMSEA were respectively .96, .98, .86, .07, and .96, .99, .88, .05 for girls and boys). Structural coefficients for stability between the three moments were very high (beta21=.96 for girls and boys; beta32=.95 for girls and .94 for boys), explaining 93% and 90% of the variance of the girls trajectories, and 92% to 88% for boys. Disattenuated autocorrelation coefficients between the three latent physical fitness factors ranged from .96 to .91 for girls; and from .96 to .90 for boys.

These results showed that (a) almost all PF components were improving each year, meaning that children were getting fitter from 8 to 10 years-of-age; (b) PF as a whole was very stable across these pre-puberty years, although stability coefficients were decreasing more rapidly on boys than girls. A thorough explanation of the results asks for a contextual interpretation. A high tracking of individual PF was probably expected given the proximity of the evaluation moments (one year apart). But, from a developmental and educational perspective, primary school years should account for a major increment on organized physical activity and motor stimulation (in and out of school).This fact intuitively lead us to think that different trajectories should diverge between children (depending on the stimulation) and, if so, stability would diminish.

EFFECT OF PHYSICAL AND MENTAL FACTORS BY COMBINED TRAINING IN MIDDLE-AGED WOMEN WITH DIFFERENCES OF TRAIT ANXIETY

Maeda, Y., Yokoyama, N., Kuno, S.

University of Tsukuba, Japan

 Trait Anxiety is mentioned as an individual personality showing the tendency to perceive and react to the situation of giving a threat. Many studies have reported that the exercise brings not only physical effects but mental effects. However there are few studies in Japan about physical and mental effects by exercise with differences of trait anxiety. The purpose of this study was to investigate the physical and mental effects by combined training in middle-aged women with differences of trait anxiety.

 Participants were 28 middle-aged women(57.0±4.4 years).Training session was 10 weeks period, twice per a week at training room in university and 3 times per a week at home, resistance training and aerobic training. The investigation about trait anxiety was conducted with State-Trait Anxiety Inventory JYZ(STAI) in pre-post training session. There were measured Body Weight(BW), Body Mass Index(BMI),Waist-Hip Ratio(WHR), Body Fat Ratio(BFR) by Bioelectrical Impedance(BI) methods, the cross-sectional area(CSA) of thigh group and psoas major by magnetic resonance imaging(MRI), the estimated VO2max by submaximal exercise test , serum high-density lipoprotein cholesterol(HDLC), low-density lipoprotein cholesterol(LDLC), total cholesterol(TC), and triglycerides(TG) as physical factors, and General Health Questionnaire28(GHQ28) as mental factors in pre-post training session. Moreover there were measured the number of training and walking steps per a week in training session. Then participants were classified into two groups, Low Group(LG) having 20～39 score and High Group(HG) having 40～62 score, from the result of trait anxiety by STAI.

 There were no significant differences of physical factors, the number of the training and walking steps of training session by both groups in pre training session. As for GHQ28 about mental factors, the low rank scale was classified into four elements, Somatic Symptoms, Anxiety and Insomnia, Social Dysfunction and Severe Depression. There was significant higher score about Social Dysfunction in HG than LG (p＜0.05), although there were no significant differences about other elements in pre training session. As physical factors, the interaction was accepted by HDLC and TG in the comparison between LG and HG (p＜0.05), and TG was more significant decrease in post training session than pre it (p＜0.05). As mental factors the interaction was accepted by Social Dysfunction of GHQ28 in the comparison between LG and HG (p＜ 0.05) and there was the significant decrease of it's score in post training session than pre it. Moreover the interaction was accepted by trait anxiety in the comparison between LG and HG (p＜0.05), and it was more significant decrease in post training session than pre it (p＜0.001).These results suggest that the training session in this study improves not only trait anxiety but activities in society and serum lipid levels as for lifestyle-related disease in middle-aged women with differences of trait anxiety.

EFFECTS OF SAME INTENSITY WALKING AND WEIGHT TRAINING ON THE PHYSICAL FITMESS OF KOREA MIDDLE-AGE WOMEN

Choi, D.H., Choi, H.N., So, W.Y.

Sogang University, Korea, South

The purpose of this study was to finding out 2 type training which is walking and weight training with the same intensity have an effect on body composition, cardiorespiratory function, physical fitness and blood profiles. Subjects of this study were 42 women who had never exercise experience, started exercised at fitness center for inhabitants. They divided by three group(Walking, WT, and Control group). Fitness test were performed at pre, post 8weeks such as VO2max test with Bruce protocol, muscular strength, flexibility, muscular enduranc, power, agility and balance. The results are as follows: First, there was a statistic significant difference on the systolic blood pressure(p=.000) and normal heart rate(p=.008) while diastolic blood pressure(p=.07) tended to be decreased. Secondly, as for fitness test, there was no statistic significant diffence of cardiorespiratory endurance, flexibility, muscular endurance, power, agility and balance among groups, whereas muscular strength showed significant difference(p=.033). Third, as for blood profiles, there was no statistic significant difference of triglyceride among groups, whereas glucose(p=.019). total cholesterol(p=.045) showed significant difference. In conclusion, same intensity exercise for 8 weeks improved cardiorespiratory function and blood profiles such as blood pressure, heart rate, glucose and total cholesterol.

STUDENT'S PERCEPTIONS OF SCHOOLBAG LOADING AND PAIN SYMPTOMS IN GREEK ELEMENTARY SCHOOL STUDENTS

Emmanoulidou, M., Arampatzi, F., Kellis, E.

Aristotle University of Thessaloniki, Greece

Introduction

The prevalence of non-specific back pain increases dramatically during adolescence from less than 10% in pre-ten-year olds up to 50% in 15-16-year olds (Sheir-Neiss et al. 2003). There is a widespread concern that heavy schoolbags carried by students may be associated with some potential health problems, including muscular aches, back strain, altered posture and eventual up and low back pain (Whittfield et al. 2005). The purpose of the study was to investigate the prevalence of pain symptoms (PS) in upper body and the student's subjective perception (SSP) of the schoolbag load in elementary Greek school. Furthermore, we examined whether PS have an association with SSP of the schoolbag load and the percentage of body weight (% of BW) represented by school bags.

Methods

A total of 183 (105 boys, 84 girls) students aged between 6 and 11 years old (M=8.7, SD=±1.6) volunteered to participate in this study. The body weight of students was measured, as was the weight of their schoolbags. Information about the prevalence of PS caused by carrying schoolbags and the SSP of the schoolbag load was obtained from a self-administrered questionnaire (Negrini et al 2001, Whittfield et al 2005). Pearson correlation statistical method was used to establish if PS have an association with SSP of the schoolbag load and % of BW of schoolbags.

Results

The mean schoolbag weight for students was 5.3 ±1.08 kg (range from 3 to 8.5) and the % of BW represented by school bags was 15.10% (range for 6.49% to 28.29%). Sixty-one percent of students experienced MS whilst carrying a schoolbag. The prevalence of symptoms according to location were as follows: neck (14.7%), shoulders (33.9%), upper back (25.2%), lower back (8.6%), elbow (3.4%). Females reported the highest prevalence of symptoms (neck 26.9%, shoulders 44.2%, upper back 28.8%, lower back 17.3%) than males (4.8%, 27%, 22.3%, 1.6%, respectively) (p<.01). The student's subjective perception of heavy schoolbag was observed by 47% of students and fatigue experience whilst carrying a schoolbag by 32.8%. PS were correlated with fatigue whilst carrying a schoolbag (r=.534), the feeling that the schoolbag was heavy (r=484) and % of BW (r=.499) (p<.001).

Discussion/Conclusion

The student's subjective perception of the schoolbag load and the % of their BW were found to be associated with PS in the upper body. Students with PS were more likely to be females. Future work is required to confirm these results. Reduction of the schoolbag load borne by students is recommended.

SCHOOLBAG WEIGHT IN 385 PRIMARY AND SECONDARY EDUCATION STUDENTS EXCEEDS SAFETY LIMITS

Emmanoulidou, M., Kouvelioti, V., Kellis, E.

Aristotle University of Thessaloniki, Greece

Introduction: Carrying schoolbags constitutes a daily activity for children aged from 6 to 18 years old. In recent years there has been a widespread concern over the role of school bags in the occurrence of back pain during childhood and adolescence (Puckree et al. 2004). Previous studies in USA (Goodgold, et al 2004), Italy (Negrini et al. 1999) and N. Zealand (Whittfield et al. 2001) showed that the school bags weight represented 17.2%, 22% and 11.7%, of the body weight of the students respectively. The purpose of the study was to determine the weight of the school bags, and the percentage of body weight (% of BW) represented by school bags.

Methods

A total of 385 (210 boys, 175 girls) students between the ages of 6 and 14 years (M=9.7, SD=±2.2) from a city in Northern Greece, volunteered to participate in this study. Body weight was measured to an accuracy of 0.5 kg using electronic scales and the same scales were used to determinate the weight of the school bags. Data were collected on an unscheduled day so that students could not alter their schoolbag weight.

Results

The mean body weight of elementary students was 37.28 ±11.0 kg and for high school students was 55.15 ±11.9 kg. The mean schoolbag weight for all student was 5.18 ±1.2 kg (range for 2.5 to 9). This value for elementary students was 5.6±1.1 kg and for high school students 5±1.4 kg. Percentage of BW by grade was as follows: elementary school: 1st=15.5%, 2nd=16.6%, 3rd=14.1%, 4th=14.3%, 5th =14.4%, 6th =12.4%, and high school: 1st =11.7%, 2nd =9.3%, 3rd =9%. Forty-seven percent of elementary students carried schoolbags that weighed from10% to 15% of their BW and thirty-nine percent more than 15% (ranging from 15% to 28.8 %) of their BW. Concerning high school, thirty-three percent of students carried schoolbags that weighed from 10% to 15% of their BW and thirteen percent more than 15% (ranging from 15% to 21.21%) of their BW. The most commonly reported type of schoolbags for the whole sample was back bags without a frame (92.6%).

Discussion/Conclusion

Schoolbags loads represent a significant percentantage of BW of this sample and younger students carried proportionally heavier loads. Similar findings have also been obtained in the previous studies. The National Back Pain Association suggest that ideally a schoolbags should weigh no more than 10% of a student's BW and this weight should be supported on both shoulders in a backpack style schoolbag.

INTERNATIONAL PHYSICAL ACTIVITY QUESTIONNAIRE: SHORT OR LONG VERSION?

Delgado-Guerra, S., Serrano-Sanchez, J.A., Olmedillas, H., Guadalupe, A., Perez-Gomez, J., Vicente-Rodríguez, G., Bernales, O., Navarro, E., Calbet, J.A., Dorado, C.

University of Las Palmas de Gran Canaria, Spain

Introduction

The long version was designed to assess physical activity undertaken across a comprehensive set of domains: leisure time physical activity, domestic and gardening (yard) activities, work-related physical activity, and transport-related physical activity. The items in the shorter version are walking, moderate-intensity and vigorous-intensity activities. The purpose of the present study was to determine the validity by direct comparison of the measurements obtained by the administration of the IPAQ with a direct assessment of the main components of physical fitness and body composition.

Methods

A sample of 168 males (age= 31±6.9 yr; mean ± SD) were studied. Data collected with IPAQ were total METs per week in all domains and levels of physical activity as Low, Moderate or High active. Body composition and percent body fat (%Fat) were measured by DXA. The maximal leg extension isometric force in the squat position with knees bent at 90º and the mean power, peak power, and height jumped during vertical squat and countermovement jumps were assessed with a force plate. Additionally, 30-m and 300-m running tests were used to determine maximal running speed and to estimate the anaerobic capacity. Maximal aerobic power was estimated using the 20 m shuttle-run test.

Results

Thirty-six, 83 and 49 subjects were classified as Low, Moderate and High levels of physical activity with the short IPAQ, respectively. The corresponding numbers for the long IPAQ were 31, 91, 46, respectively. Weekly energy expenditure was related to several variables. However, no significant correlation was obtained between the three IPAQ physical activity categories and the physical fitness variables. Total domestic and garden MET-minutes/week derived from the long IPAQ correlated negatively with several physical fitness variables: body mass index, thorax and waist circumference, and %Fat (r= -0.35-0.16, $p<0.01$). Total leisure-time MET-minutes/week was correlated with waist, hip circumference, and %Fat (r=-0.36-0.34, $p<0.01$). Total moderate and vigorous MET-minutes/week correlated with maximal aerobic power (r=-0.15-0.16), and %Fat with Total vigorous MET-minutes/week (r=-0.23, $p<0.01$). In the short form, walking and moderate MET-minutes/week was related to waist and hip circumference, and maximal aerobic power (r=-0.22-0.31, $p<0.01$). The %Fat correlated also with walking, moderate, and vigorous MET-minutes/week (r=-0.19-0.21, $p<0.01$).

Conclusions

Correlations between physical fitness and body composition in one side and the estimation of weekly energy expenditure are low implying a scarce validity of the IPAQ as a tool to asses either physical fitness in males. However, the total energy expended during leisure time, assessed by the long version of the IPAQ appears have higher validity than other outcome variables assessing physical activity in this version of the IPAQ.

SURVEY ON BODY COMPOSITION, PHYSIOLOGICAL AND ANTHROPOMETRICAL PROFILE OF IRANIAN ELITE INDOOR SOCCER(FUTSAL) PLAYERS

Parnow, A., Salehi, S., Ghrakhanlou, R., Rastegar, M., Agha Alinejad, H.,Tofighi, A., Eneyattabar, M.

Tarbiat Modares University, Iran

The purpose of this study was to describe the body composition, physiological and anthropometrical profile of Iranian elite indoor soccer players and the relationship between some of measured parameters. A number of 44 indoor soccer players(25.7± 4.37 age), including members of Iranian national team attended in Asian Indoor soccer Games (Makauo, 2004) and indoor soccer players present in Iranian premier- league of indoor soccer, were tested. For body composition profile, height, weight, body fat percentage, BMI, and for anthropometrical profile thigh circumference and length, calf circumference and length, sitting height and lower body length were measured. Physiological profile was composed of aerobic (20m shuttle run test) and anaerobic (sarjent jump) power, speed (10 &20m run), agility (Illinois), and flexibility (sit & reach). There was a significant reverse relation between aerobic and anaerobic power($r = -0.307$, $P<0.05$) of subjects. Similarly, aerobic power was reversely related to body fat percentage($r = -0.301$, $P<0.05$), indicating that increased body fat percentage will result in disturbance of aerobic performance. The changes in body fat percentage were directly related to those of anaerobic power($r = 0.516$, $P<0.001$), indicating that body fat percentage shouldn't be considered as a limiting factor for aerobic power. A significant direct relationship of agility with 10m($r = 0.391$, $P<0.001$). Speed, but not with 20m($r = 0.139$, $P>0.05$), is reported. There was also a reverse, but statistically insignificant, relationship of BMI with 10m($r = -0.045$, $P>0.05$). As well as 20m Speed($r = -0.26$, $P>0.0$). BMI was also reversely related to agility ($r = -0.081$, $P>0.05$). Findings showed that Iranian elite indoor soccer players were round the average in terms of height as well as weight.

Key words: Indoor soccer, Aerobic Power, Anaerobic power, Speed, Agility, Flexibility, BMI, Body Fat Percentage, Anthropometrical, Body Composition.

SAFETY MEASURES IN GOLF --THE ACTUAL SITUATION CONCERNING ACCIDENTS (INJURIES AND DAMAGES) AS REVEALED BY A QUESTIONNAIRE SURVEY OF GOLF COURSES A POSSIBLE MEASURES TO PREVENT THEM--

Yoshihara, S., Aoyama, H., Miura, M., Miura, K., Noguchi, K., Akita, K., Nishida, K., Katoh, Z., Nakashima, Y., Yamamoto, T., Ree Kyoug, O.K., Ogura, M.

St. Marianna University, Japan

[Objective] We have identified the actual situation concerning accidents and emergency medical services in golf course in the last time through questionnaire surveys we sent to more than 2,200 Japanese golf courses during the 20 years. This time, in order to survey the safety situation in Kanto district golf courses, we distributed questionnaires to 780 golf courses in Kanto district, Japan.

[Method] The survey period was one year, between April 2003 and March 2004. Six questions posed were as follows: 1) Frequency of ambulances dispatched to the golf courses in a year (subdivided into the number of emergency calls per month), 2) Main reasons for calling an ambulance, 3) Established cooperative arrangement with neighboring hospitals (general and private hospitals), 4) Distance to recommended hospital departments, and travel time, 5) Emergency medical care available at the golf course and crisis control system (designated person in charge, emergency training, qualified first aid persons, emergency equipment, fixtures, etc.), 6),Annual incidence or accidents among golfers (surgical accidents, deaths, etc).

[Results] 1) Ambulance calls: Out of 781golf courses, 198 replied. The response rate was 25.3%. With respect to the month, there were 3 requests in January (2.7%), 4 in February (3.7%), 16 in March (14.9%), 9 in April (8.4%), 22 in May (20.5%), 16 in June (14.9%), 26 in July (24.2%), 39 in August (36.4%), 11 in September (10.2%), 20 in October (18.6%), 18 in November (16.8%), and 10 in December (9.3%),respectively. These results indicated that ambulance calls were most frequent in July and August in all regions. 2) Emergency medical care system: Concerning emergency medical care procedures at golf courses, 65 golf courses (32.8%) said that "cooperative arrangements with a given medical institution are in place", while 133 courses (67.1%) replied that they had "no fixed cooperative arrangements". About half of the golf courses did not have an established system for cooperating with a given medical institution in case of an emergency. Looking at practical emergency care procedures in the case of an emergency on the golf courses, 118 golf courses (59.5%), the majority, had a designated member of staff who would be expected to take charge. 80 courses (40.4%) held training courses for their staff in emergency care, but 134 courses (67.6%), the majority, provided no emergency training. 3) Accidents to golfers: Accidents to golfers involving golf balls and clubs had been experienced at 86 golf courses (43.3%) and had not experienced at 112 (56.5%). The total number of accidents was 170. 107golf courses (54%) had experienced accidents due to falls and slips, while 91 (45.9%) had not. The total number of accidents was 233. There were 11 accidents resulting in death at 13 golf courses last year. Since the golf courses had been in operation, there had been 104 fatal accidents in total, 2 of them due to being struck by a thunderbolt (at 3 different courses).

FEMALE ATHLETE TRIAD IN DIFFERENT BRASILIAN SPORT MODALITY

Oliveira, F.P., Perini, T.A., Oliveira, G.L., Ornellas, J.

Federal University of Rio de Janeiro, Brazil

INTRODUCÇÃO: The American College of Sports Science (1992) published in a consensus conference that eating disease and partial syndromes had been understood as the Female Athlete Triad component. This syndrome is characterized for the coexistence of eating disease, premature amenorrhea and osteoporosis in woman athlete. It occurs with higher frequency in athletes who participate in sports that emphasize leanness.

OBJECTIVE: To examine the prevalence of the Female Athlete Triad in some Brazilian sports modalities.

METHODS: A transversal and descriptive study with 101 female athletes (age between 15 and 20 years) was developed. Sporting modalities: Rhythmic gymnastics (n=29; 15,0 ±2,8 years); Endurance runners (n=17; 15,0 ±1,8 years); Rowers (n=16; 19,0 ±2,7 years); Synchronized swimmers-juniors athletes (n=19, 15,6 ±0,8 years); Synchronized swimmers-seniors athletes (n=8; 19,0 ±1,ános) and University athletes (n=12; 20,4 ±1,6 years). For effect of comparison with the athletes 32 no-athletes had been evaluated (15,0 ±1,6 years). Four questionnaires had been used: 1°-Anamnese; 2°-Eating Attitudes Test, 3°-Bulimic Investigatory Test Edinburgh and 4°-Body Shape Ques-

tionnaire. The anthropometric measurements were done in all of the volunteers according to standardization of the International Society for Advancement in Kinanthropometry - ISAK. The data analyses were done in the Statistical for Windows 6.0.

RESULTS: The athlete's body fat were in healthy level and proper for the athletic performance. Synchronized swimmers-juniors (15,8%); Rowers: (12,5%) and Rhythmic gymnastics (6,9%) presented expressive total of athletes classified "at risk" to develop Eating Disorders (positive result in the 03 adopted questionnaires). It was observed that the occurrence of bone injuries, in the last two, years was expressive; however, only two athletes of rower had osteoporosis diagnosis. The frequency of dysmenorrhoea and oligomenorrhoea was accented in the Synchronized Swimmers-juniors (36.8% and 57.9%) and Endurance runners (29.4% and 41.2%). Secondary Amenorrhoea had greater frequency in Synchronized Swimmers-juniors (10.5%) and Synchronized Swimmers-seniors (12.5%).

CONCLUSIONS: It was verified more prevalence of inadequate alimentary practices and pathological attitudes (weight-control) associated with the dissatisfaction with the body image in sports which leanness or a specific weight was important. Only one athlete presents the Female Athlete Triad and four athletes are at risk of present it.

Keys words: Exercise, Eating disease, Amenorrhea, Osteoporosis.

References: Sundgot-Borgen J.(2004) Clinical Journal of Sport Medicine,14(1):25-32; Drinkwater B (2000). Women in sport. Australia: Blackwell science; American College of Sport Medicine.(1997),1(5):I-IV.

THE ACCUMULATION OF PERSONAL BARRIERS REDUCES WHILE THE ACCUMULATION OF SOCIAL SUPPORT INCREASES THE LIKELIHOOD FOR A PHYSICALLY ACTIVE BEHAVIOUR

Serrano-Sanchez, J.A., Sanchis-Moysi, J., Dorado-García, C., Ara-Royo, I., Vicente-Rodríguez, G., Calbet, J.A.

University of Las Palmas, Spain

Background. Personal barriers (PB) and social support (SS) influence physical activity (PA). Different types of PB (for example, lack of time) and SS (for example, having a friend to exercise) have been associated with PA (1-2). However, the effect of the accumulation of PB and SS on PA are less known. Methods. A representative sample of the general population of Gran Canaria composed by 3000 adults (18-75 years-old) was interviewed at home. Participants were asked about their PA using the Minnesota Leisure Time Physical Activity Questionnaire. Thirteen types of PB; 4 types of SS and a set of personal characteristics were measured. Two groups of PA according to public recommendations were established (sufficiently vs. insufficiently active). In addition, participants were classified in two groups as active (≥ 1 day/week) vs. inactive (< 1 day/week). PB were grouped in two categories: strong barrier (when the answer was: "often" or "very often") and weak barrier (when the answer was "sometimes" or "rarely" or "never"). Similarly, SS was grouped in two categories, existence of SS (when the answer was: "agree" or "strongly agree") and absence of SS (when the answer was: "disagree" or "strongly disagree"). The number of strong PB and the number of SS answers was obtained for each participant. Logistic regression with PA as dependent variable adjusted by age, gender, education, occupational activity, health status and BMI was applied. Results. Most PB predicted better inactivity than insufficient PA. Nine strong PB were associated with inactive status (p<0.001), with adjusted ORs ranging from 3.57 (95% CI. 2.50,5.08) for "I do not like exercise" to 1.49 (95% CI. 1.22,1.81) for "I do not have time". The accumulation of three strong PB enhanced the predictive value (OR= 4.66 for being inactive; OR= 3.57 for being insufficiently active). The four SS were associated similarly with both status of PA (active and sufficiently active). The adjusted OR for active status ranging from 1.92 (95% CI. 1.58,2.33) for "I have a friend to exercise" to 1.56 (95% CI. 1.29,1.88) for "I have a relative to exercise". The accumulation of three or more SS were more strongly associated with PA (OR= 2.37 to be active; OR= 2.20 to be sufficiently active) than each SS individually. Conclusions. To enhance the amount of PA of the population is convenient to reduce the number of personal barriers and increase the number of social support. The accumulation of personal barriers reduces while the accumulation of social support positive answers increases the likelihood for an active behaviour. The number of barrier or social support positive answers appears to be more important than any particular barrier or social support.

PAST SPORTS EXPERIENCES DETERMINE EXERCISE HABITS IN JAPANESE YOUTH: EXAMINATION OF "FROM WHEN" AND "HOW MUCH"

Suzuki, K., Nishijima, T.

University of East Asia, Japan

Introduction: Lifestyle-related diseases and a decline in youth physical fitness are widely acknowledged as serious problems in Japan. Previous studies demonstrated that exercise habits improve physical fitness. Suzuki & Nishijima (2006) took one further step and demonstrated that past sports experiences affected current exercise habits. However, it is not clear exactly what sports experiences are necessary to establish exercise habits in youth. The purpose of this study was to seek the criteria related to past sports experiences for establishing exercise habits in Japanese youth.

Methods: The subjects were 2,725 (male: 58.0%) high school students in Japan. Survey items included current exercise habits (frequency, duration), and past sports experiences (number of sports events: NSE, commencing time of sports: CTS, time spent per event: TS/E). An exercise habit was defined as implementation of exercise three or more days/wk and one or more hrs/day, according to the recommended level of physical activity for youth in previous studies. Classification and regression trees (CART) and logistic regression (LR) analysis were performed between exercise habits (yes or no) as an independent variable and past sports experiences as dependent variables. For checking replicability of these solutions, the data were randomly split into sample A and B halves.

Results and Discussion: 46.9% of the subjects was included in the exercise habit group. From the result of CART analysis for sample A, a classification tree with misclassification cost of 0.35 was produced. The rule of the highest ratio of exercise habit group (72.9%) was NSE > 2 events, & TS/E > 6.9 hrs. When variable importance index of NSE was considered to be 100, the relative value of TS/E was 50.4. From the result of CART analysis for sample B, a classification tree with misclassification cost of 0.34 was produced. The rule of the highest ratio of exercise habit group (76.3%) was NSE > 2 events, & TS/E > 8.3 hrs. Variable importance index of TS/E was 43.7. Split variables, split sequences, and magnitude relations of variable importance in CART analyses indicated the same results (NSE > TS/E > CTS) between the samples. The results of LR analysis using each sample indicated that only two variables, NSE and TS/E, were statistically significant in both samples (P < 0.01). Odds ratios of NSE and TS/E were 1.78 and 1.10 among sample A, 1.65 and 1.07 among sample B. The results showed that magnitude relation of odds ratio was equal (NSE > TS/E) between the samples. Magnitudes of variable importance and odds ratio

also indicated equal relations. Therefore, replicability of the results of CART and LR analysis by this data was confirmed. It was concluded that a requirement for establishing exercise habits in youth was as follows: 1) NSE > 2 events, and 2) TS/E > 6.9-8.3 hr before the end of high school.

THE RELATIONSHIP BETWEEN PHYSICAL FITNESS, PHYSICAL ACTIVITY AND JOB SATISFACTION IN MALE AND FEMALE OFFICE WORKERS

Hunter, A., Dibsall, K., Manson, N.

University of Stirling, United Kingdom

Introduction

It has been previously shown that there is a relationship between work performance and physical activity and cardiorespiratory fitness (Pronk et al., 2004). However in this study cardiorespiratory fitness was estimated from a self reported questionnaire and job performance was self rated by the participants. Both of these variables can be limited by misinterpretation and validity to the actual values. Accordingly, we examined employee Job Satisfaction Index (JDI)(Faragher et al., 2005), Scottish Physical Activity Questionnaire (SPAQ) (Lowther et al., 1999) and a selection of physiological fitness tests to see if these relationships exist.

Methods

102 healthy, moderately active, office workers (68 females and 34 males) with a mean age of 40 + 11.2 (range 20 - 66) participated in a selection of physical health and fitness tests and questionnaires. The health and fitness tests included resting heart rate and blood pressure, anthropometry, submaximal predicted VO2max, maximum number of sit ups achieved in 1 minute, sit and reach test, vertical jump and grip strength. The questionnaires involved completing both the standardised JDI and SPAQ.

Results

A significant relationship ($p<0.05$) was only shown for the males when correlating JDI with VO2max (job satisfaction r2 0.15, job in general r2 0.18, relationship with co-workers r2 0.23) and blood pressure (r2 -0.23). No significant relationships were shown when correlating the JDI with the other fitness tests. All participants showed significant ($p<0.05$) relationships when correlating VO2max with both age (males r2 0.33 females r2 0.12) and blood pressure (male r2 -0.14 female r2 -0.11), but none was shown between SPAQ and any other variable.

Discussion/conclusion

This study suggests that in male office workers there is a positive relationship between job satisfaction and aerobic capacity and a negative relationship with blood pressure, neither of which was observed in the females. Also, there is no relationship between aerobic capacity and self reported physical activity for both genders. Future studies should examine the differences in gender for these relationships and the validity of SPAQ to aerobic capacity.

STANDARDIZATION OF ANTHROPOMETRICS INDEXES AND THE AMOUNT OF PHYSICAL ACTIVITY AND STUDY THEIR RELATIONSHIP WITH CORONARY HEART RISK-FACTORS AMONG TEHRANIAN MEN AGING FROM 30 TO 55

Tofighi, A., Agha Ali Nejad, H., Salehi, S.

Tarbiat Modares University, Iran

Standardization of Anthropometrics Indexes and the amount of Physical Activity and study their relationship with Coronary Heart Risk-Factors among Tehranian men aging from 30to55.

Asghar Tofighi; Tarbiat Modares University(IRI)

Hamid Agha Alinejad; Tarbiat Modares University(IRI)

Saadat Salehi; Islamic Azad University of Arak(IRI)

This research was carried out to standardize the Anthropometrics Indexes including WHR, BMI, WC, Body Fat Percentage and the amount of Physical Activity and to study their relationship with Coronary Heart Risk-Factors which includes densities of Tchol,TG,Low Density Cholesterol Lipo-Protein ,Ratio Of LDL-C/HDL-C or Risk Factor and the Density of High Density Cholesterol Lipo-Protein among tehranian men aging from 30to55.The subjects involved in this study were 450 men from Tehran . In order to evaluate the relationship between anthropometrics indexes and coronary heart risk-factors , we took 46 blood samples of this research population Based on the results of this research the subjects norms was as following:

WHR: (0.95±0.57), WC: (93.77±10.22 cm), BMI :(25.8±3.65 kg/m2), PHYSICAL ACTIVITY (7.29±1.5). Moreover significant relationships between these factors were found: [WHR and TG ($r=0.536, p<0.01$)] , [WHR and Chloe ($r=0.49, p<0.01$)] ,

[WHR and HDL-C ($r= -0.541, p<0.01$)] , [WHR and RF ($r= 0.532, p<0.01$)]. Data analysis showed that there were significant relationships between these factors:

[BMI and TG ($r= 0.389, p<0.01$)] , [BMI and Chloe ($r= 0.37, p<0.05$)] ,

[BMI and HDL-C ($r= -0.415, p<0.01$)] , [BMI and RF ($r= 0.394, p<0.01$)] .

[%BF and TG ($r= 0.48, p<0.01$)] , [%BF and Chloe ($r= 0.4, p<0.01$)] ,

[%BF and HDL-C ($r=- 0.464, p<0.01$)] , [%BF and RF ($r= 0.45, p<0.01$)] .

[PHYSICAL ACTIVITY and HDL-C($r=0.58, p<0.01$)] ,

[PHYSICAL ACTIVITY and LDL-C($r=-0.429, p<0.01$)] ,

[PHYSICAL ACTIVITY and RF ($r= -0.526, p<0.01$)] .

We can conclude based on the results of the study that asWHR,BMI,WC,BODY FAT PERCENTAGE and a decrease in PHYSICAL ACTIVITY increase, the probability of subjects catching coronary heart diseases increases too.

Keywords: WHR, BMI, WC, Body Fat Percentage, the amount of Physical Activity, Coronary Heart Risk-Factors.

MOTOR COMPETENCE AND LEISURE TIME PHYSICAL ACTIVITY IN AN INTERNET BASED INTERVENTION

Loftesnes, J.M., Motterud, G., Veka, B., Myklebust, M.B.

Sogn og Fjordane University College, Sogndal, Norway

Introduction

An internet based intervention promoting physical activity was carried out involving 923 Norwegian school classes. The goal of the intervention was; participants should be as active as possible during a three week period in a nation wide competition. The pupils had to do a virtual walk around Norway. 10 minutes of physical activity was converted to 2 km on the map. Our goal was to detect whether inactive and little active children could benefit from this net-based campaign carried out by Trivsel.net (The Norwegian Olympic Committee and Confederation of Sports).

Methods

The subjects, 69 in all, aged 11.2 ±1.2 years old (Mean ±SD), were tested on the Movement Assessment Battery for Children, age band 4 (Henderson & Sugden, 1992). This assessment consists of 8 sub-tests in three groups. Permission was given by parents, children and the school, and the study took place in quiet settings so that the children could be anonymous. A questionnaire, consisting of five questions was administered: 1. To what extent it was fun to participate?, 2. To what degree do you feel you have been more physically active?, 3. Would you like to participate again?, 4. What kind of organised activity do you participate in and how many times in a week?, and 5. What kind of unorganised activity do you participate in and how many times during a week?

Results

There was a significant association between physical activity level in the Trivsel.net and motor competence (p= .047). Participants reported having had great fun, but only some of the very active children found it only a bit fun, while no subjects answered 'boring'. In total, 84 % answered that they were more active during the intervention period, with the remaining 16 % being in the very active group. Likewise, 87 % would like to participate again. However, the remaining 13 % belonged to the low active group. A strong Trivsel.net level of activity/organised leisure time activity association was present (Mann-Whitney U, p= .001). There was also a strong association between the physical activity level in Trivsel .net and unorganised leisure time activity (Mann-Witney U, p= .002).

Discussion

This study identified a close relationship between levels of physical activity and skilled performance, and confirmed that children with poor motor skill are less active both in organised activities and unorganised leisure time activities. The children in the low active group all confirmed the intervention as being great fun, and that they would like to participate in such an activity again. Since the children less motor skilled is the least active it seems that in order to get these inactive children in better physical shape, one must focus on teaching these children better motor skills.

ABDOMINAL SKELETAL MUSCLE AND ADIPOSE TISSUE CROSS-SECTIONAL AREA MEASURED BY MAGNETIC RESONANCE IMAGING IN OLDER FEMALE SWIMMER

Kazuya, Y., Kiyoshi, S., Chiyoko, U., Izumi, T., Mitsuru, H.

Nippon Sport Science University, Japan

Introduction

To protect against the increase of fat mass and loss of skeletal muscle (SM) mass with advancing age is important for older individuals to maintain a high level quality of life. Swimming reduces the mechanical stress on the joints because of lower impact in water. Therefore, many elderly females have participated in this exercise to advance their health and fitness. Although swimming improves cardiovascular fitness such as peak oxygen uptake (VO2peak), there is little evidence to support whether regular swimming exercise prevents the increase of fat mass or loss of skeletal muscle (SM) mass, especially the SM supporting abdominal region. The aim of this study was to investigate the abdominal SM and adipose tissue cross-sectional area (CSA) measured by magnetic resonance imaging in postmenopausal women who regularly perform swimming exercises.

Methods

A total of 73 older women participated in this study, and they were divided into two groups (42 Swimmers and 31 Untrained). Percentage of body fat was measured by air displacement plethysmograph using BOD POD System. The VO2peak during running was measured by incremental treadmill testing. The CSA of the abdominal profiles were measured by Magnetic Resonance Imaging (MRI). MRI images were segmented into the three components, i.e., SM, fat, and bone areas, and we divided the subcutaneous fat, visceral fat, flexor muscles and extensor muscles. Moreover their images were traced on the outline of the tissue, and their CSAs were analysed by NIH Image software (Ver 1.63).

Results

Swimmers had lower percentage of body fat and larger the VO2peak than untrained subjects (percentage of body fat; 27.4 ± 3.8 vs. 31.0 ± 5.0 %, VO2peak; 1.67 ± 0.21 vs. 1.46 ± 0.17 L/min in Swimmer and untraiend). There were significant differences with fat free mass (38.3 ± 3.3 vs. 35.4 ± 3.5 kg) and the CSA of the trunk SM (extensor muscle CSA; 43.2 ± 7.5 vs. 37.6 ± 4.8 cm2, flexor muscle CSA; 45.2 ± 8.5 vs. 41.5 ± 9.7 cm2) between swimmers and untrained subjects. There were no significant differences found regarding the waist circumference, (89.3 ± 6.9 vs. 90.5 ± 6.9 cm), subcutaneous fat CSA (117.1± 41.1 vs. 116.3 ± 40.1 cm2), and visceral fat CSA (46.4 ± 17.5 vs. 48.3 ± 17.6 cm2,) in this study.

Discussion/Conclusion

These results suggest that swimming exercise induce higher cardiovascular fitness in older women, and maintain the trunk muscle sizes in both the extensor and flexor muscles.

ASSOCIATION BETWEEN OVERWEIGHT, OBESITY AND LEVELS OF PHYSICAL ACTIVITY IN STUDENTS FROM JOÃO PESSOA, PARAÍBA – BRAZIL

Silva, F., Silva, K., Martins, C.

Catholic University of Brasília, Federal University of Santa Catarina, Faculty of Sports- Porto , Brazil

Introduction: Overweight and lack of physical activity have been promoting great impact in public health, an increasing problem in different populations. The diagnosis of risk factors contributes to an effective intervention. The aim of the present study was to associate overweight, obesity and physical activity levels of students from João Pessoa - Brazil. Method: The sample comprised 1091 children (573 boys and 518 girls), aged 9-12 years (10±0,1 year) of public and private schools from João Pessoa. All students answered a questionnaire about leisure time physical activities; distance and means of transport used to go to school and intensity and frequency of their physical activities practice. BMI was calculated from the ratio of weight / height2 and determined overweight and obesity according to criteria proposed by Glues et al. (2000). The scores obtained in the activities determined the levels of physical activity according to quartis. Statistical descriptive analysis, binary logistic and multivariate regression were made to observe associations isolated and/or combined among the variables. Results: Data showed 14,5% (n=155) of overweight; 3,6% (n=38) of obesity; 25% (n=263) of physical inactivity and 47,4% (n=501) indicated viewing TV in leisure time. No differences were observed between sexes nor association of overweight and obesity with quartis of physical activity. However, it tends to increase four times for those that spend more time dedicated to TV or leisure activities instead of those who practice sports or help in domestic tasks. Children of private schools presented risk for overweight and obesity three times larger than children of public schools. Conclusion: Overweight showed significant association with low activities and school segment. Intervention strategies for reduce risk for obesity should be stimulated at school.

EFFECTS OF THE TRAINING FREQUENCY UNDER A HAYPOBARIC HYPOXIA ON CARDIOVASCULAR FUNCTIONS

Ogita, F., Nishiwaki, M., Kawakami, R., Wagatsuma, A., Tamaki, H., Tanaka, T., Saito, K.

National Institute of fitness and Sports, Japan

Introduction

It has been well accepted that both exercise and hypoxia can be a great stimulus to increase vascular endotherial growth factor (VEGF), which is an important mediator of angiogenesis (Hoppeler 1999, Richardson et al. 1999). The developed capillary network by angiogenesis would elicit a favorable cardiovascular adaptation to satisfy the elevated tissue demands and to reduce peripheral resistance. Also this skeletal muscle adaptation to exercise would be influenced by training frequency. Therefore, the present study aimed to examine the effects of the training frequency under a hypobaric hypoxic condition on cardiovascular functions.

Methods

Twelve healthy adults (26±7 yrs) were assigned to two groups matching for physical fitness level. Both groups had aquatic exercise training in the hypobaric condition corresponded to 2000m above sea level, and were exposed to the condition for 2.5 hours/session. The exercise training was done in swimming pool located in a chamber where atmospheric pressure could be regulated. Also the training was performed at the intensity of around 50%VO2max level for 30 minutes/training session, 3 (3DG) or 4 (4DG) days/week, for 4 weeks. Before and after the training period, VO2max and cardiovascular responses such as heart rate (HR), stroke volume (SV), cardiac output (CO), and systolic (SBP), diastolic (DBP) and mean blood pressure (MBP) during cycling exercise at the intensity of 50%VO2max were determined.

Results

After the 4 weeks of training, VO2max did not change significantly in both groups. In cardiovascular responses during the exercise at 50%VO2max, no significant changes were observed in 3DG, except for MBP. On the other hand, a significant increase was observed in SV (pre: 115±19, post: 132±25 ml) and CO (pre: 14.7±2.8, post: 16.3±2.5 l?min-1) in 4DG ($P<0.05$). Furthermore, DBP (pre: 68±8, post: 55±4 mmHg) and MBP (pre: 98.4±5.2, post: 91.9±4.4 mmHg) in 4DG were significantly decreased ($P<0.05$).

Discussion/Conclusion

The findings of this study and our previous studies suggest that the exercise training in hypobaric hypoxic condition would induce the favorable cardiovascular changes which increases easily SV and CO reducing total peripheral resistance and that to obtain such cardiovascular adaptations in young healthy adults, it is required to do exercise training more than 4 days a week.

THE SQUAT: ISO-INERTIAL RESISTANCE EXERCISE PROMOTES GREATER QUADRICEPS MUSCLE USE THAN THE BARBELL EXERCISE

Norrbrand, L., Tous Fajardo, J., Tesch, P.

Karolinska Institutet, Sweden

Knee extensor and adductor muscle use in the Squat exercise carried out with either iso-inertial resistance or barbell, was assessed by means of functional Magnetic Resonance Imaging (MRI). Thus, exercise-induced contrast shifts of images were determined in an effort to grade and compare individual muscle use (1) in the Squat employing these two loading modes. On two separate days, five trained men

(age; 33±2 yrs, height; 179±10 cm, body mass; 88±17kg, barbell half-squat 10RM; 146±18 kg) performed the Squat (5 sets of 10 reps @ 10RM) using either free weights (barbell half-squat; BS) or an exercise device (2), which uses the inertia of rotating flywheels (flywheel squat; FS) to provide resistance. MRI spin-echo scans (double echo sequence, proton density with TR/TE: 1500/30 msec, T2 weighted with TR/TE: 1500/60 msec) of the thighs were performed prior to and immediately after completing any exercise session. From each stack of images of both limbs, five images were analyzed by measuring signal intensity (SI) and calculating T2 of mm. rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), vastus intermedius (VI), adductor magnus (AdM), biceps femoris (BF) and gracilis (Gr). SI and T2 of subcutaneous fat, bone and bone marrow were also analyzed to assure reliable measurements across scans. A two-way repeated measures ANOVA was employed to compare measurements. T2 of all individual quadriceps muscles and AdM was enhanced after both exercises ($p<0.05$). T2 of Gr and BF, subcutaneous fat, bone and bone marrow was unchanged ($p>0.05$). T2, averaged across the four quadriceps muscles, showed greater ($p<0.05$) use with FS compared with BS. Among individual muscles, RF showed greater ($p<0.05$) use with FS. Though both exercise modes provoked enhanced T2 of quadriceps and AdM muscles, it appeared the overall response was more marked for FS compared with BS. In contrast to weight training, iso-inertial resistance allows for the execution of maximal, voluntary concentric actions through the entire range of motion and across repetitions of a full set. This may explain the greater response shown after FS and suggest that quadriceps muscle use in the Squat exercise, employing iso-inertial resistance, is boosted compared with traditional barbell resistance exercise. Hence, this technology could serve as an alternative for athletes who are concerned about performing the classical barbell Squat with near maximal loads.

THE TREATMENT OF SHOULDER PAIN: CURRENT TRENDS IN CHIROPRACTIC MANAGEMENT

Pribicevic, M., Pollard, H.

Macquarie University, Australia

Background: Shoulder pain is a common problem encountered in clinical practice and represents a very challenging area for the therapist due to its structure and strong biomechanical and anatomical relationship with adjacent areas. The chiropractic literature contains no standardized approach to the management of shoulder pain, and is supported by low-grade evidence based upon published case reports. The common denominator of chiropractic management is the use of a multi modal treatment approach incorporating soft tissue therapy, electrotherapeutics, manipulation and exercises. Other accepted and standard forms of conservative treatment for shoulder disorders include the use of oral non-steroidal anti-inflammatory drugs, corticosteroids oral and injections, manipulation under anaesthesia, and physiotherapy approaches including exercise, mobilization, taping and electrotherapeutics. Aim: To describe the clinical management of shoulder pain as described in the literature. Methodology: Included recent publications derived from medline, cinahl, ovid and science direct databases. Also included were searches from the Cochrane Musculoskeletal Group trials register and Cochrane Controlled Trials Register. Manual searches of relevant textbook and journal bibliographies were utilized with a main focus on recent chiropractic and physiotherapy publications, 1985-present. Results: The papers presented in this review largely utilised a multimodal approach. All subjects demonstrated a positive outcome in terms of reduction of pain , improvement in range of motion, and the normalisation of orthopaedic tests after a course of treatment, with the restoration of normal daily and sporting activities. Conclusion: The chiropractic literature supports a multimodal management approach of shoulder disorders based upon low-grade case report publications. No quality research has been undertaken within the profession to substantiate a particular approach in the form of a controlled trial.

A RANDOMIZED CONTROLLED CLINICAL TRIAL OF MANUAL THERAPY TREATMENT FOR SHOULDER PAIN

Pribicevic, M., Pollard, H.

Macquarie University, Australia

A RANDOMIZED CONTROLLED CLINICAL TRIAL OF MANUAL THERAPY TREATMENT FOR SHOULDER PAIN Pribicevic M, Pollard HP Macquarie Injury Management Group, Macquarie University, NSW 2109, Australia Background: Shoulder pain has a high prevalence in clinical practise, with very little research being dedicated to this complex clinical entity from a manual therapy perspective. Aim: The purpose of this study is to describe a clinical trial and treatment rendered on a randomised pool of subjects utilising 2 different manual therapy treatment methods. Methodology: Forty-two subjects participated in the trial, who were individually randomised into 3 different groups: a control group (n=12), a manipulation group (n=15), and a multimodal treatment group (n=15). Each subject after randomisation and the initial assessment was treated for a total of 8 visits over a 4-week period. Reassessment of subjects occurred at the end of the 4-week treatment. The treatments rendered included: A detuned ultrasound set at a zero setting for the control group, manipulation of the cervical or thoracic spines, and or gleno-humeral joint for the manipulation group, and a multimodal approach combining soft tissue methods, manipulation of the cervical, thoracic spines, or glenohumeral joint and rehabilitation exercises. The outcome measures for the trial included: patient perception of pain, VAS, and key orthopaedic tests (Hawkins, Neer's, and Jobe's and painful arc).Results: The data was statistically analysed with descriptive statistical and inferential methods using a standard significance level (alpha) of 0.05. Both treatment groups showed a marked reduction in mean pain levels pre and post treatment for both pain outcome measures. The multi modal group demonstrated a change from pre-treatment levels of pain for both outcome measures of 6.7/6.2 respectively to post treatment levels at 1.8/1.36. The manipulation group for both outcome measures demonstrated changes from the pre treatment levels of 5.2/4.8 to post treatment levels of 2.8/2.2. The control group showed no statistically detectable change with t-test analysis. For both pain outcome measures the demonstrated pre treatment values were 5.1/4.3 with post treatment levels being 4.8/3.7. The subjects randomised to the multimodal treatment group demonstrated a greater mean pain level change for both outcome measures. Conclusion: This report of preliminary findings demonstrates the potential benefit of a multimodal manipulation protocol and "straight" manipulation protocol in managing pain syndromes associated with dysfunction of synovial structures of the shoulder and or shoulder girdle.

GENDER DIFFERENCES IN SENSORY AND MOTOR THRESHOLDS DURING ELECTRICAL STIMULATION OF THE QUADRICEPS FEMORIS MUSCLE

Maffiuletti, N.A., Herrero, A., Jubeau, M., Bizzini, M., Dvorak, J.

Schulthess Clinic, Switzerland

Electrical stimulation (ES) therapy is largely used in rehabilitation-orthopaedic medicine (Snyder-Mackler et al. 1995) and in sports medicine (Lake 1992), with the general objectives to (1) minimize the effects of prolonged disuse on skeletal muscle structure and function, and (2) improve neuromuscular function parameters (e.g., as a resistance training and/or as a recovery modality). One hypothesis for the well known gender differences in body composition is that males and females respond to ES differently, and would therefore require different current intensities to optimize treatment effectiveness. Aim of the present study was to examine gender differences in sensory and motor thresholds during ES of the quadriceps femoris muscle at both high (75 Hz) and low (10 Hz) frequency modulation.

Forty healthy subjects (20 males and 20 females) were stimulated via surface electrodes placed over the vastus lateralis muscle and a portable ES unit. The two experimental frequencies (10 and 75 Hz) were randomly presented. Stimulation intensity (in mA) was increased progressively and the following thresholds were determined: sensory (ST), i.e., initial perception of stimulus sensation; motor (MT), i.e., minimal visible muscle contraction; maximal motor (MMT), i.e., full knee extension. Then, maximal voluntary contraction (MVC) torque of the quadriceps muscle was measured, and the subject was stimulated to evoke 10% of the MVC torque (10%T). Skinfold thickness was measured under the stimulating electrode and quadriceps cross-sectional area was estimated according to Housh et al. (1995). A two-way ANOVA (gender, frequency) was performed.

A significant frequency effect was consistently found; ES thresholds were significantly lower at 75 Hz compared with 10 Hz ($p < 0.001$). ST and 10%T were significantly lower in females than in males (ST: 3.1 vs. 5.4 mA, $p < 0.001$; 10%T: 46.8 vs. 57.0 mA, $p = 0.01$), while MT was significantly higher in females as compared to males (13.5 vs. 11.3 mA, $p = 0.042$). Interestingly, ST was significantly correlated to both skinfold thickness ($r = -0.71$, $p < 0.001$), and cross-sectional area ($r = 0.65$, $p < 0.001$). Significantly higher pain scores (VAS) were found in the female group and at low frequency (data not presented).

It is concluded that, during surface ES of the quadriceps femoris muscle, females need different doses of current to activate both sensory and motor nerve fibers as compared to their male counterparts. Gender differences in skin nerve fiber density (Goransson et al. 2004, Mowlavi et al. 2005), subcutaneous fat layer and quadriceps muscle mass mainly account for these results. Our findings are valuable in terms of the gender-specific response to acute and chronic application of ES.

ASSESSMENT OF CARDIORESPIRATORY FITNESS BY A CYCLE ERGOMETER TEST AND THE REFERENCE VALUES FOR A GENERAL POPULATION OF FINNISH ADOLESCENTS

Tammelin, T., Remes, J., Oksa, J., Näyhä, S., Zitting, P., Kujala, V.

Finnish Institute of Occupational Health , Finland

Poor cardiorespiratory fitness is associated with increased risk of several cardiovascular and metabolic diseases. The weakened results of repeated fitness tests performed in Finnish schools and defence forces indicate that the level of cardiorespiratory fitness has declined among young Finnish people. However, cardiorespiratory fitness has not been evaluated in health surveys of young people in Finland and the reference values of maximal oxygen uptake for large unselected population of adolescents have not been available. This study evaluated the accuracy of a submaximal cycle ergometer test to assess cardiorespiratory fitness in adolescents and provided population based reference values. In a health study of Northern Finland birth cohort 1986, cardiorespiratory fitness of 5375 boys and girls aged 15 to 16 years was measured by a submaximal cycle ergometer test by using a two-stage exercise protocol designed for this survey. A total of 4903 subjects performed two work stages, and maximal workload and peak oxygen consumption (VO2peak) were calculated on the basis of heart rate responses by extrapolation method (WHO). An additional 472 subjects were able to finish only one work stage. For them, VO2peak was calculated by Åstrand nomogram (ÅN). To evaluate the accuracy of submaximal testing, a validation sample of 90 subjects performed both a submaximal test and a maximal cycle ergometer test with direct measurement of VO2peak. The WHO method proved to estimate VO2peak with a reasonable accuracy. The ÅN method overestimated VO2peak considerably, and therefore a new single-stage regression method (SSR) was applied to calculate VO2peak on the basis of heart rate and perceived exertion rate during single work stage. The reference values of cardiorespiratory fitness were provided for methods WHO and SSR for a general population of Finnish boys and girls aged 15 to 16 years. Mean VO2peak was 49 ml/kg/min in males (N=2635) and 35 ml/kg/min females (N=2268) by method WHO. The developed test protocol and the reference values provided will be an aid in the population surveys measuring cardiorespiratory fitness among the youth. The methodology and the reference values presented would also be useful in fitness testing and in any efforts to enhance physical activity, cardiorespiratory fitness and health among young people.

EFFECTS OF BATHING AND POST-EXERCISE BATHING ON AUTONOMIC CARDIOVASCULAR REGULATION IN MIDDLE-AGED AND OLDER MEN

Matsui, T., Miyachi, M., Kawano, H., Nishimura, M., Amaoka, H., Senoo, N., Kosaka, T., Ono, K., Onodera, S.

Nihon Fukushi University, Japan

It has been reported that baroreflex sensitivity during head-out water immersion in middle-aged and older people is weaker than that in young people. Due to this reduction, middle-aged and older individuals have an inadequate ability to regulate increased central blood volume caused by immersion. Therefore, middle-aged and older people show greater fluctuations in blood pressure, and are at higher risk for cardiovascular events than young people. Especially when bathing in water at 40 degrees C or higher, central blood volume is affected by both immersion and warmth, and the risk of event might be greater. Speedy and adequate autonomic cardiovascular regulation is needed during bathing in hot water. Users of Kurhouse (hot spring spa with sports facilities) perform exercise, then get into a bath shortly there after. In this situation, effects of exercise are added to the effects of bathing in hot water. However, there have been few studies of the effects of post-exercise bathing.

We investigated the characteristics of autonomic cardiovascular regulation in response to bathing and post-exercise bathing (40 degrees C, 20min) in healthy middle-aged and older men (MO, 55 +/- 10 years, range: 40-71 years) compared with young men (Y, 22 +/- 3 years). During bathing, heart rate (HR) of MO and Y were similarly increased, and were parallel to the decreases of heart rate variability (logHF, vagal modulation) and spontaneous cardiac baroreflex sensitivity (logSBRS). Systolic blood pressure (SBP) in MO temporarily increased at the beginning of bathing, then significantly decreased in the last phase of bathing similar to that in Y. The MO also showed a significant decrease in SBP and diastolic blood pressure (DBP) at the beginning of the recovery phase after post-exercise bathing. In both group, stroke volume (SV) and cardiac output (CO) significantly increased, and total peripheral resistance (TPR) significantly decreased in both bathing trials. But the TPR of MO was greater, and extension of the carotid artery diameter (systolic – diastolic) was smaller than that of Y. Based on these results, it was suggested that bathing attenuates spontaneous cardiac baroreflex sensitivity, and affects the regulation of fluctuation in blood pressure response in MO. Further, greater attenuation of sensitivity observed during post-exercise bathing in MO seemed to affect blood pressure regulation during the recovery phase after leaving the bath.

CASE STUDY, POTENTIAL 'PIT FALLS' IMAGING HAMSTRING INJURY

Rogers, R., Allen, G., Witvrow, E.

University of Wolverhampton , United Kingdom

Hamstring injuries are among the most common muscle injuries in athletes. Recurrence rates for hamstring strains also tend to be high despite concentrated rehabilitation efforts. The high rate of re-injury and of persistent complaints after return to athletic activities can pose difficult problems for Sports Medicine Clinicians as well as Trainers. The factors dealing with the main causes of the injury are numerous, and no unanimous conclusion has been drawn. Several biomechanical and morphological aetiologies have been proposed, with a multifactorial basis to hamstring injury most likely. The imaging basis of strain to the hamstring muscle relies on demonstrating the features of myofibrillar disruption. Currently MRI and Ultrasound imaging are employed as the mainstay of radiological assessment. Evaluating the location, extent and severity of hamstring injury can provide supplemental information to the clinical assessment and may potentially assist in defining the prognosis and guide rehabilitation. Such information is also crucial in the professional sporting context, given the pressure to return rapidly to competition. Often however imaging does not correlate with clinical impressions. This presentation will provide four case studies where clinical and functional assessments did not correlate with imaging. In addition we will discuss some of the potential "pit falls" in relying solely on imaging studies for prognosis and return to play.

THE EPIDEMIOLOGY OF GOLF-RELATED INJURIES IN AUSTRALIAN AMATEUR GOLFERS: A MULTIVARIATE ANALYSIS

McHardy, A., Pollard, H., Luo, K.

Macqaurie University, Australia

Introduction: Golf is a popular sport played worldwide by people of all ages and skill levels. Part of the appeal of golf is that there are no gender, skill or age limits to participation. Golf participation rates vary across all age ranges and are high in the older age groups. This is partly due to the fact that: older persons have more leisure time to pursue activities and golf is a low impact sport with a general aerobic component, which makes it a perfect recommendation for practitioners wanting their patients to exercise. Although they are uncommon, injuries do occur whilst playing golf. Considering the popularity of golf, both in participation and spectator rates, it is surprising that there have been only a small number of small studies on golf injury. Indeed, most studies on injury rates in golfers were produced ten to twenty-five years ago1,2,3.

Objective: To perform an epidemiologic study of amateur golfers to determine the golf-related injury rates in amateur golfers across Australia. To determine the common injury mechanisms in golf and to determine if factors such as age, gender, warm up and conditioning habits, equipment and skill level affect injury rates.

Method: a one-year retrospective design was used to study golf injuries associated with golfers of randomly selected Australian golf clubs. Risk factors of golf-related injury (age, gender, warm up and conditioning habits, equipment and skill level) were further examined together by univariate and multivariate analysis using logistic regression.

Results: there were 1634 golfers included in the present study. Of them, 288 reported having had one or more golf-related injuries in the previous year. The most common injury location was the lower back (25.3%), followed by the elbow (15.3%) and the shoulder (9.4%). The most common injury mechanism occurred due to the golf swing (44.8%). Significant difference between injured and non-injured golfers was identified when assessing age, warm-up status and conditioning habits, and participation in other sports / activities. Equipment use such as type of golf club shaft used, and type of shoes used were found not to be statistically significant.

Conclusion: the most injured site identified in this study was the low back, the elbow and the shoulder respectively. Age, warm-up status and conditioning habits, and participation in other sports / activities were identified as risk factors associated with injury. This study provides timely and new information on the location and factors associated with injury in amateur golffers in Australia.

ONE-YEAR PROSPECTIVE STUDY ON GOLF INJURIES IN AUSTRALIAN AMATEUR GOLFERS

McHardy, A., Pollard, H., Luo, K.

Macqaurie University, Australia

Introduction: Golf is a popular activity, particularly in the older population as it provides an opportunity for those with available time to exercise in the outdoors playing a game they enjoy. From a health perspective golf, as a form of exercise, is popular as it provides a low level of physical exertion over an extended period, without the physical contact and high intensity of many other sports. Despite this ,popularity only one previous study has prospectively investigated golf injuries, a study that was conducted on low back injuries in beginner golfers by Burdorf and co-workers1. All other golf injury epidemiology studies have been retrospective in nature, raising the possibility of recall bias in their findings. Additionally, due to a lack of prospective studies, the true incidence rate of golf injuries has been unable to be accurately determined.

Objectives: To undertake a detailed, epidemiological study of golf injuries sustained by golfers in order to define their incidence, nature, severity, and causes.

Methods: A one-year prospective design was used to study golf injuries associated with 588 golfers at 8 Australian golf clubs. Golfers self-reported injuries sustained during golf participation and provided details of the location, onset, and mechanism (phase of the golf swing). Additionally, information was sought on any treatment sought for each injury was recorded.

Results: The overall incidence of injury was 15.8 injuries/100 golfers. Recurrent injuries were most common, while injuries were more likely to occur over time. The lower back was the most common injury site (18.3%), closely followed by the elbow. Incorrect swing mechanics accounted for 46.2% of injuries, while in the golf swing injury was most likely to occur at impact (23.7%), followed by the follow through phase of the swing. When assessing for risk factors for injury, multivariate analysis produced significance in the amount of game play and time of last change of clubs ($P < 0.05$) Factors such as age, gender, handicap, practice habits and warm-up habits were not identified as risk factors for injury, despite earlier research of a retrospective nature that suggested the opposite (unpublished data)2.

Conclusions: On average, nearly 16% of golfers may expect to sustain a golf-related injury in the next 12 months and that injury would be most likely be sustained in the lower back region as a result of faulty swing mechanics. Based on statistical analysis, only the amount of game play and recent change of golf clubs seem to be significantly associated with risk of injury after adjusting for other risk factors ($P < 0.05$).

FORCE CONTROL DURING SUBMAXIMAL ISOMETRIC CONTRACTIONS OF THE KNEE EXTENSOR MUSCLES IN INDIVIDUALS WITH MENTAL RETARDATION

Periklis, V., Hadjixenofontos, M., Tsimaras, V., Charitonidis, K., Michailidis, C., Kotzamanidis, C.

Aristotle University of Thessaloniki, Greece

Relevant studies have shown that people suffering from mental retardation (MR) present diminished efficiency in motor performance (Agelopoulou et al 1999) regarding people without mental retardation(NMR). More over there is lack of information related with their variability during motor task execution (Latash & Corcos 1991) and specifically during strength effort. For this reason the purpose of this study was the comparison of the force variability between successive and increasing isometric contractions of the knee extensor muscles between people with mental and without mental retardation. The sample consisted by 10 adults, 5 subjects with MR (age: 24,3±2,5 and height: 168,4±5,9 cm) and 5 subjects without MR (age: 25,6 ± 1,3 and height:171,9 ± 2,6). They voluntarily participated in the experimental procedure and they did not have systematic athletic training. The levels of submaximal isometric contractions were fixed in the 6%, 12%, 24%, 36%, 48% and 60% (Smits-Engelsman, 2005), of maximal isometric contraction (MIC). The variability of force was estimated using two variables, standard deviation (SD) and coefficient of variance (CV). After MIC estimation the subjects performed 5 efforts in the 6%, 12%, 24%, 36%, 48% and 60% of the MIC. Simultaneously vastus lateralis, vastus medialis (agonist) and biceps femoris (antagonist) activity were recorded. The neuronal activation of the agonist muscle was normalised as the ratio of aEMG vs maximal value while antagonist activity as the ratio of antagonist activity vs the maximal activation of the same muscle acting as antagonist. For the measurements CYBEX NORM. dynamometer and the BTS EMG device were used. For the statistical analysis the level of significance was $p<0.05$. The obtained results indicated that there was not statistically significant differences in the level of agonist activation between groups while antagonist activity was higher in MR. The CV remained constant in all selected intensities in the NMR group while it was continuously increased in MR group. People with MR presented higher CV in all cases combared with NMR group. More over the antagonist activity increased in parallel with contraction intensity in both groups and in all cases was higher in people with MR. The individuals with NY present developmental delay, thus they have delay in the beginning of basic kinetic skills as the posture and gait. The above results can partial be explained by low perception in motor ability, decreased attention, hyper mobility, aggressiveness and negativism (Agelopoulou, 2004).

MORPHOLOGY OF TRICEPS BRACHIALIS MUSCLE IN ELITE TENNIS PLAYERS

Guadalupe-Grau, A., Bernales, O., Delgado-Guerra, S., Olmedillas, H., Dorado, C., Calbet, J.A., Sanchis-Moysi, J.

University of Las Palmas de Gran Canaria, Spain

INTRODUCTION: Tennis is an excellent exercise model to study muscle plasticity in response to chronic exercise. Tennis players submit their dominant-arm to a huge amount of physical activity compared to their contralateral arm. In consequence, the muscle mass is about 20% higher in the dominant compared to the non-dominant arm (Calbet et al. 1998). However, the effect of tennis participation on arm muscle morphology remains unknown. Moreover, only scarce data is available on triceps morphology in athletes (Mizuno et al. 1990; Parsons et al. 1993; Mygind, 1995; Terzis et al. 2006) and there is, in general, a paucity of data on the effects of exercise on arm muscles.

PURPOSE: The aim of this study was to assess the effect of tennis participation on the morphology of the triceps brachialis muscle of the dominant compared to the non-dominant arm.

METHODS: Four elite tennis players (23.0 ± 1.0 yr, mean ± SEM) accepted to participate in this study. Muscle biopsies were taken from lateral aspect of the triceps brachialis of both arms and processed for histochemical fiber typing and determination of fiber cross sectional areas. In addition, the muscle mass of the dominant and non-dominant arm was also determined using dual-energy x-ray absorptiometry (DXA). Side-to-side comparisons were carried out using a one-tailed Student's t-test.

RESULTS: The muscle mass of the dominant arm was 14% greater than that of the contralateral arm. Compared to the non-dominant the type 1, 2a and 2x muscle fiber were hypertrophied in the dominant arm by 36% (4018 ± 457 and 5472 ± 556 μm2), 31% (6185 ± 1015 and 8109 ± 1542 μm2) and 39% (5333 ± 1389 and 7430 ± 1370 μm2), respectively. The mean area of all muscle fibers was 33% higher in the dominant than in the non-dominant arm ($P<0.05$). The percentage of type 1, 2a and 2x fibers was similar in both arms, i.e., 29 ± 8 and 32 ± 7%, 39 ± 4 and 42 ± 2, and 21 ± 10 and 20 ± 6%, in the non-dominant and dominant arm, respectively.

CONCLUSION: Long term tennis participation is associated with marked hypertrophy of all fiber types in the lateral portion of the muscle triceps brachialis, without any significant effect in the fiber type distribution. The inter-arm difference in muscle mass was smaller than the difference in cross sectional area of the triceps brachialis, emphasizing the relative importance of this muscle in tennis players.

INCREMENTAL TREADMILL TESTS TO DETERMINE ENERGY COST OF RUNNING

Fusi, S., Salvadego, D., di Prampero, P.E.
University of Udine, Italy

During incremental exercise tests, the intensity is increased by a constant amount at regular short intervals, so that the O2 consumption (VO2) keeps increasing without ever attaining a steady state. The energy cost of running (Cr = energy spent to transport the subject's body over one unit of distance) is traditionally determined from steady state VO2 at constant speed. We show here that Cr can be obtained also during incremental running as follows. Assume that the speed is increased by a constant amount ?v at regular intervals of duration T, while VO2 is measured on a breath by breath basis. Within each step below the anaerobic threshold VO2 increases exponentially towards the steady state:

$$VO2n,t = (VO2n,s - VO2n-1,T) (1 – e-(t/?)) + VO2n-1,T \quad 1)$$

where the values at time t within the nth step and at the end of the immediately preceding one are denoted by VO2n,t and VO2n-1,T and where VO2n,s is the steady state value, were T long enough to attain it. If VO2n,t is averaged over homologous times (a, b, c …) within each period, and neglecting the initial ones, the VO2 difference between the corresponding time values becomes constant and equal to the difference between the appropriate steady states:

$$VO2n,a - VO2n-1,a = VO2n,b - VO2n-1,b = \ldots\ldots = VO2n,s - VO2n-1,s \quad 2)$$

Thus, Cr is given by:

$$(VO2n,a - VO2n-1,a)/ ?v = (VO2n,b - VO2n-1,b)/ ?v = \ldots$$

$$\ldots = (VO2n,s - VO2n-1,s)/ ?v = Cr \quad 3)$$

We determined Cr above resting on 7 well trained runners as follows. After 4-5 minutes walking, the treadmill speed was increased by 0.5 km h-1 every 30 seconds. Single breath VO2 was measured and the averages from 0 to 10 (a), 10 to 20 (b) and 20 to 30 (c) seconds calculated for each period. Cr was obtained from the ratio of the difference between the VO2 averages for any two homologous times within subsequent periods to the corresponding speed difference (?v) (equation 3). Between the walking to running transition and the anaerobic threshold, Cr on the treadmill is independent of the speed. Therefore, and since ?v and the T (30 sec) were constant, the relationship between VO2 and speed (S) is described by straight lines of the form:

$$VO2a = A + BS; \quad VO2b = A' + BS; \quad VO2c = A'' + BS$$

The intercepts (A, A', A") depend on the time within the step over which VO2 was averaged, and the slope B = ? VO2a/ ?S = ? VO2b/ ?S = ? VO2c/ ?S yields the mean individual Cr above resting. On 7 subjects, the so obtained values of Cr (ml O2/ (kg m)) amounted to 0.182 ± 0.007 (n = 6) for a (0 to 10 sec) 0.175 ± 0.012 (n = 6) for b (10 to 20 sec) and to 0.175 ± 0.012 (n = 7) for c (20 to 30 sec). These values are essentially equal to those that can be expected from the ratio of VO2s to speed (0.185 ml O2/ (kg m)), so confirming the validity of the incremental approach for assessing the energy cost of running.

FREQUENCY OF DIABETES TYPE 2 AND CVD RISK FACTORS IN OBESE CHILDREN AND ADOLESCENTS

Matzenbacher dos Santos, J., Gaya, A.R., Cardoso, M., Mansilha, H., Mota, J.
Faculty of Sports- Porto University, Portugal

Background: The prevalence of obesity and overweight has dramatic increased in youth along with different diseases, which were specific of adult population, namely the diabetes type II [1-2]. Thus, the aims of this study were (1) to analyse the frequency of diabetes type II in at risk of obesity children, and (2) identify the association with cardiovascular disease factors.

Methods- 87 children and adolescents obese from Maria Pia Pediatric Hospital (Porto -Portugal) age: 12.1±2.4 years-old; weight: 75.2±21.7 kg; height: 156.3±12.8 cm; BMI: 30.7±3, Kg/m2 participated in the study. The calculation of Homeostasis Model Assessment (Homa), using plasmatic insulin and glucose value, were used to estimate insulin resistance [3]. Children's and adolescent's Homa over 2.24 were classified as risk to development diabetes type 2 [4].

Results: 68.4% of children and adolescent at risk of obesity were classified as a risk to development of diabetes type 2. Logistic regression showed that BMI, triglycerides and physical activity were predictors ($p<0.05$) of diabetes type II in obese youth. No significant results were found for waist circumference, HDL, LDL, systolic blood pressure, diastolic blood pressure and birth weight

Conclusions: BMI, triglyceride and physical activity was found to be associated with risk to development of diabetes type 2 in youth at risk of obesity.

GLUCOSAMINE ADMINISTRATION IN ATHLETES: EFFECTS ON RECOVERY OF ACUTE KNEE INJURY

Ostojic, S., Arsicm, N., Prodanovic, S., Vukovic, J., Dikic, N.
Sports Academy, Serbia and Montenegro

The main aim of the present study was to examine the effects of four weeks of glucosamine administration on the functional ability and the degree of pain intensity in competitive male athletes after acute knee injury. Randomized, double-blind parallel trial of glucosamine

(1500 mg per day) or a placebo for 28 days. Hundred and six patients with acute sports injury of knee evaluated at the beginning of the study and at 7, 14, 21 and 28 days after starting treatment. Evaluation included pain intensity at rest and while walking with a visual analog scale, passive knee flexibility (flexion and extension) of the injured limb and degree of knee swelling. No statistical difference was found between glucosamine and placebo group in mean pain intensity scores for resting and walking, and degree of knee swelling at the 7-day, 14-day, 21-day and 28-day assessment ($p > 0.05$). There was no statistical difference found between passive knee flexibility at the 7-day, 14-day and 21-day assessment ($p > 0.05$). After 28 days of treatment the patients from glucosamine group demonstrated significant improvement in knee flexion and extension as compared to placebo group ($p < 0.05$). The findings of the present study indicate that administration with glucosamine does not significantly alter recovery after acute sports injury of knee. Yet, glucosamine supplementation appears to be suitable as a flexibility improvement strategy in athletes after 4 weeks of treatment.

RELATIONSHIP BETWEEN SOME ANTHROPOMETRIC CHARACTERISTICS AND FINAL RANK STANDING IN THE GREEK HANDBALL CHAMPIONSHIP

Bayios, I., Noutsos, K.

National & Kapodistrian University of Athens, Greece

Introduction. The success of top level handball players depends on many factors, including morphological, physiological, psychological, technical and tactical characteristics. The aim of this study was to investigate the relationship between selected anthropometric characteristics and the final team ranking in the Greek handball championship.

Methods. Female handball players (n=101) of the first Greek National League participated in the present study (age 23.2±5.3 yrs, training age 10.9 ±2.2 yrs, body mass 66.6±9.3 kg, body height 167.2±7.4 cm). Anthropometric measurements involved height, body mass, four skinfolds and selected measurements used for somatotype estimation. Fat mass (FM), fat free mass (FFM) and percent body fat (%BF) were calculated for all subjects from the sum of skinfolds, using a standard equation (Siri, 1956). Somatotype assessment was performed according to Heath & Carter's (1990) anthropometric technique and different component calculation was based in the equations proposed by Heyward & Stolarczyk (1996). Ranking was reported as the final points of the teams in the Greek handball championship during 2002-2003 competition season. Relationships between anthropometry and ranking were studied with Spearman correlation coefficient ($p<.05$).

Results. Body mass index was calculated 23.8 ±2.7 kg/m², percentage body fat 25.6±3.4, fat mass 17.2±4.1 kg, fat free mass 49.3±6.2 kg, endomorphy 4.0±1.0, mesomorphy 4.1±1.2, ectomorphy 1.8±1.0. The results showed significant correlation between final team ranking and chronological age ($r=0.478$, $p<.001$), training age ($r=0.382$, $p<0.001$), body height ($r=0.385$ $p<0.001$), fat free mass ($r=0.255$, $p<0.01$), mesomorphy ($r=-0.214$, $p<0.05$) and ectomorphy ($r=0.211$, $p<0.05$). No significant correlations were found between final team ranking and body weight, body mass index, endomorphy, percentage body fat, fat mass and somatotype attitudinal mean.

Discussion. It seems that both chronological and training age favorably affect team ranking. In addition, elevated body height and high fat mass were positively associated with final team ranking in these female handball players. Finally, team ranking also seems to be affected by somatotype (mesomorphy and ectomorphy) of the players as previously suggested (Carter & Heath, 1990).

ACTIVATION OF COAGULATION AFTER A DOWNHILL MARATHON RUN (TYROLEAN SPEED MARATHON)

Schobersberger, W., Greie, S., Fries, D., Mittermayr, M., Falkensammer, G., Griesmacher, A., Sumann, G.

University for Health Sciences, Medical Informatics and Technology, Hall/Tyrol, Austria, Austria

Introduction: Prolonged exercise can be associated with multiple changes in blood hemostasis. Eccentric muscle activation (e.g. downhill running) induces micro-traumata of skeletal muscle thus inducing an inflammatory response. Since in several diseases there is link between inflammation and coagulation we speculated that downhill running may activate the coagulation system.

Material and Methods: 13 volunteers (12 males, 1 female) participated at the Tyrolen Speed Marathon (42,195 km downhill race, 795 m vertical displacement; range of running time 3.12 hrs to 4.26 hrs). Blood from antecubital veins was collected 3 days (T1) and 3 hrs (T2) before the run, within 30 min after finishing (T3) and one day thereafter (T4). Measured parameters: Creatine kinase (CK), myoglobin, PT, aPTT, platelet count, thrombin-antithrombin-complex (TAT), prothrombin fragment F1+2 (F1+2), D-dimer, plasmin-alpha2-antiplasmin (PAP), Thrombelastography with RoTEM®: intrinsic pathway: InTEM-CT (clotting time), InTEM-CFT (clot formation time), InTEM-MCF (maximum clot firmness), InTEM-alpha (alpha angle). All parameters were corrected for plasma volume changes according to van Beaumont (1981). Statistics: Friedman ANOVA follwed by Wilcoxon test; level of significance $p < 0.05$.

Results: CK and myoglobin were elevated at T3 and were further increased at T4 (mean CK and myoglobin values at T4: 4879 U/L and 1409 ng/ml) We found a significant shortening in PT and aPTT and an increase in platelet count after the race. TAT, F1+2, D-dimer and PAP were significantly increased at T3; F1+2 and PAP remained elevated until T4. ROTEM analysis exhibited a shortening of InTEM-CT and InTEM-CFT after the marathon and an increase in InTEM-MCF and InTEM-alpha.

Conclusions: We could demonstrate that a 42km downhill marathon induces coagulation activation, as measured by specific parameters for coagulation and RoTEM. These changes were accompanied by pronounced increases in markers for micro-damage of skeletal muscle.

REDUCTION IN ECCENTRIC HAMSTRING STRENGTH AFTER A DOWNHILL MARATHON RUN (TYROLEAN SPEED MARATHON)

Greie, S., Koller, A., Hoertnagl, H., Sumann, G., Griesmacher, A., Falkensammer, G., Schobersberger, W.

University for Health Sciences, Medical Informatics and Technology, Hall, Austria, Austria

Introduction: Marathon running can be associated with some hazards, e.g. musculoskeletal injuries. It is a common suggestion stating that lower extremity fatigue is a risk factor in musculoskeletal injuries arising from participation in marathons, although little is known about muscle fatigue in marathon participants. We performed the present study to investigate the effects of a downhill marathon-specific fatigue on concentric and eccentric quadriceps and hamstring strength.

Material and Methods: We selected the Tyrolean Speed Marathon as model for a competition with a high eccentric muscle effort (42,195 m; downhill vertical distance 795 m). Peak concentric and eccentric quadriceps and hamstring torques of both legs were measured in 13 marathoners (12 males, 1 female; range of running time 3.12hrs to 4.26hrs) at an isokinetic testing speed of 60°s-1. These measures were obtained at rest (T1) and 12 hours after the marathon (T2). In addition, serum total creatinkinase (CK) and myoglobin (Myo) were analysed. Level of significance $p < 0.05$. Data are given as mean values ± 1SD.

Results: Whilst there was a significant decrease in eccentric hamstring strength ([left leg] T1: 145.3±31.7 Nm, T2: 120.1±33.1 Nm, $p = 0.012$; [right leg] T1: 133.8±22.2 Nm, T2: 119.7±25.1 Nm, $p = 0.024$), there was no significant decline in concentric ([left leg] T1: 150.8±30.1 Nm, T2: 133.7±43.5 Nm, $p = 0.064$; [right leg] T1: 148.3±40.8 Nm, T2: 130.8±49.5 Nm, $p = 0.083$) and eccentric ([left leg] T1: 194.1±40.2 Nm, T2: 174.8±67.9 Nm, $p = 0.124$; [right leg] T1: 193.6±43.1 Nm, T2: 179.8±63.8 Nm, $p = 0.148$) quadriceps strengths, and concentric hamsting strength ([left leg] T1: 110.7±27.0 Nm, T2: 104.2±30.8 Nm, $p = 0.176$; [right leg] T1: 109.3±26.9 Nm; T2: 102.7±29.9 Nm, $p = 0.102$). CK and Myo were increased at T2 by + 3781 U/l and by 967 ng/ml, respectively.

Conclusions: Downhill marathon running was shown to induce a significant deterioration in eccentric hamstring strength which was associated with pronounced increases in total creatinkinase and myoglobin.

THE EFFECT OF EXERCISE PLUS METFORMIN ON THE NON ALCOHOLIC FATTY LIVER DISEASE

Tock, L., Prado, W.L., Caranti, D.A., Piano, A., Cristofalo, D.M., Lederman, H., Siqueira, K.O., Stella, S.G., Tufik, S., Mello, M.T., Dâmaso, A.

São Paulo Federal University, Brazil

Despite the increasing prevalence of non-alcoholic fatty liver disease (NAFLD), its pathogenesis and clinical significance remain poorly defined and there is no better treatment. Although there is no accepted pharmacological treatment that can reverse fatty liver disease, all patients should be given a low fat diet, insulin resistance-lowering agents and encouraged to practice exercise. The purpose of this study was to assess the short-term (12 weeks) changes on the NAFLD prevalence and insulin resistance in obese adolescents. The inclusion criteria were severe primary obesity (IMC>30 wt/ht2), insulin resistance and/or NAFLD diagnostic. 21 obese adolescents were submitted a multidisciplinary lifestyle intervention (aerobic exercise and nutrition) plus metformin (500mg twice daily). The visceral/subcutaneous adiposity and NAFLD were measured at pre and post-intervention by ultrasonography. Fasting blood samples were collected to measured glucose and insulin. The differences between times were assessed by Test T for dependent samples. The metformin treatment associated to exercise and nutritional intervention promotes a significant decrease in the prevalence of the NAFLD (50% to 25%) and insulin resistance (90% to 76%), accompanied by a significant decrease in HOMA (5.01+1.63 to 4.45+4.06), visceral (3,99+1.01 to 3.46+1.53) and subcutaneous (3.22+0.60 to 2.97+0.87) adipose tissue. It's suggest that long-term therapy can be a better treatment to improve and prevent NAFLD and insulin resistance associated to obesity in adolescents.

NO SIGNIFICANT DIFFERENCES IN 24 HOUR ECG AND BLOOD PRESSURE RECORDINGS IN OVERTRAINED ATHLETES COMPARED TO CONTROL ATHLETES

Uusitalo, A., Vanninen, E.

Kuopio University Hospital, Helsinki University Central Hospital, Finland

Palpitation, arrhythmia's and blood pressure changes are symptomes and signs hypothesized to be related to excessive physical training and overtraining (Kuipers and Keizer 1988, Swanson 2006), and patho-physiology of those could be related to changes in autonomic function and/or inflammatory reasons (Lehmann et al. 1998, Swanson 2006). On the other hand, athletes may have several changes in their ECG related to athletes heart (Holly et al. 1998). There are no controlled studies of long-term ECG and blood pressure changes in overtrained athletes. Our aim was to study overtraining related changes in 24-hour ECG and blood pressure.

Methods Twelve otherwise healthy severely overtrained athletes (OA): age 25±7 (SD) yr; 6 women and 6 men; 9 endurance athletes and 3 ice hockey players; body mass index (BMI) 23±2 kg/m2; maximal oxygen consumption (V O2max) 49±9 ml/min/kg, and 11 control athletes (CA): 26±6 (20-39) yr; 6 women and 5 men; 10 endurance athletes and one sprinter; BMI 22±2 kg/m2; VO2max 55±6 ml/min/kg took part in the study. Overtrained athletes 1) had suffered from an unexplained decrement in physical performance and fatigue for several weeks to many months and continued to have equal symp-toms even after a recovery time of weeks to months, 2) had been examined to be otherwise healthy and 3) had a suitable training history for overtraining (increase in volume and/or intensity of training or training monotony). 24-hour ECG and blood pressure and resting ECG were recorded at the overtraining state (BL) and after one to two years of recovery (RE). Heart rate (HR), ventricular and supraventricular arrhythmia's, pauses over 2 seconds, takycardia (HR>120 bpm), bradycardia (HR<40 bpm), and PR-, QRS-, and QTc-times were studied from the ECG recordings. In addition, systolic, diastolic, and mean blood pressures during night and daytime were measured from 24-blood pressure recordings. Results There were group differences only in sleeping time at the RE ($p < 0.05$, mean±SD: OA 8.7 ±0.6 h, CA 7.5±1.1 h). Changes from BL to RE were found in QRS-time (from 94±11 ms to 92±12 ms, $p<0.05$) and sleeping time (from 7.7±1.4 h to 8.7±0.7 h, $p<0.05$) in the OA. However, some OA's had many supraventicular beats (mean 39, range 0-324) and pauses (21, 0-238) which CA's tended to have less (5, 0-12 and 5, 0-28, respectively). Blood pressures did not differ between the groups or did not change during the recovery. Conclusion Arrhythmia's, ECG changes and blood pressure changes did not significantly take place during overtraining state but this does not rule out individual changes in these parameters. Sleeping time reacts to overtraining state and recovery.

Granted by Finnish Ministry of Education, and Research Fund of Kuopio University Hospital.

BODY COMPOSITION AND PERFORMANCE DURING THE COMPETITION: A STUDY ON ITALIAN ELITE SOCCER PLAYERS

Corradini, G., Bertoldo, F., Dalle Carbonare, L., De Vita, F., Lo Cascio, V., Giordani, G., Masiero, M., Ferrari, M.

University of Verona, Italy

The aim of this study was to examine body composition in elite soccer players and its relationship with physical performance. Twenty seven soccer players (age 25.8±4.2, height 180.8±4.9 cm; body mass 78.4±5.3 Kg), divided into four groups (goal keepers, defenders, centrals, forwards) were studied. All of them underwent dual energy X-ray absorptionmetry scans (DXA), expressing the results as the ratio between, body fat mass, body lean mass, body mineral content (kg) and height (cm2). Total meters covered during competition at a speed >23 km/hour (fast running, FR), 15-19 km/hour (running, R) and 8-15 km/hour (slow running SR) were calcutated by means of a computerized analysis of video recording (Digital.Stadio, Sics, Vicenza, Italy) of four matches of the first division Italian championship.

Total body fat resulted not dependent on the role, whereas body lean mass was higher in forwards (20,6±1,03) in respect to other categories (goal keepers (19,1±0,65), centrals (19,1±0,85), defenders (19,3±0,67)) (p=0.01). Body mineral content tended to be higher in forwards (1,08±0,086) and in goal keepers (1,09±0,03), than in centrals (1,03±0,09) and defenders (1,05±0,08), even though the difference was not statistically significant.

A significant positive relationship was found between total bone mineral content and FR (r=0.78, p<0.001), and between SR and body lean mass (r=0.79, p< 0.001). On the contrary, body lean mass was negatively associated with R (r=-0.45, p=0.02).

Our data suggest that in elite soccer players the type of physical exercise associated to the role influences the body composition, particularly total lean mass; in turn, body composition is associated with a different physical performance during competition.

EFFECTS OF TRAINING LOADS ON SERUM HORMONES IN PROFESSIONAL BASKETBALL PLAY

Slowinska-Lisowska, M., Jozkow, P., Medras, M.

University of Physical Education , Poland

Interpretation of various reports on hormonal changes accompanying training cycle is difficult. Due to differences in training load it is often impossible to compare obtained results (Lehmann 1993, Urhausen 1995).

There is little data on changes of endocrine parameters in elite sportsmen undergoing long-term and high-intensity training.

Our aim was to investigate serum concentrations of gonadal and adrenal steroids in three consecutive training mezocycles. Hormones (total testosterone, DHEA-S, cortisole), and SHBG level were evaluated before and after each of the mezocycles.

Twelve professional basketball players were recruited for the study. They were preparing for the play-off round of the national championship.

The first mezocycle comprised a significant increase of the training load. When compared with baseline values, total testosterone, DHEA-S and FAI decreased, while cortisole and SHBG did not change.

In the second mezocycle the exercise load was reduced. When compared with the first mezocycle, concentrations of total testosterone, cortisole and FAI increased, when DHEA-S and SHBG did not change.

In the third mezocycle training's load and intensity were increased. This time total testosterone, DHEA-S and cortisole decreased when compared with the second mezocycle.

Overall, after three months of training: total testosterone decreased by 35%, DHEA-S by 39% and FAI by 19% when compared with baseline values.

We conclude that professional training significantly affects endocrine status of elite athletes. Hormonal measurements may be of use in monitoring training's load.

THE INFLUENCE OF RAPID WEIGHT REDUCTION ON IMMUNE RESPONSE IN MALE JUDO ATHLETES

Shimizu, K., Aizawa, K., Kimura, F., Suzuki, N., Mesaki, N., Kono, I.

Tsukuba University, Japan

Purpose: Judo athletes must reduce their body weight in a few weeks before competition. It is generally thought that athletes are susceptible to infectious disease, primary upper respiratory tract infection due to chronic immunesuppression. The purpose of this study was to examine the effects of rapid weight reduction on immune function in judo athletes. Methods: Seven male competitive college judo athletes (20.3 ± 0.4 years) from the University of Tsukuba, completed weight reduction program during 2 weeks before competition. They conducted dietary restriction, 30 min cycle ergometr exercise in the dry room, and sauna during 2 weeks. Saliva and blood samples were obtained at 40 (baseline; BL) and 3 (weight reduction; WR) days before, and at 1 and 3 days after the competition. Secretory immunoglobulin A (SIgA) concentration was measured by enzyme-linked immunosorbent assay (ELISA) and the SIgA secretion rate were calculated (SIgA concentration multiplied by saliva flow per minute). The number of T, Th (T-helper), Tc (T-cytotoxic), NK (Natural Killer), CD28+Th, CD28+Tc and CD14+TLR-4 (Toll-like-receptor-4) + cells were measured by flow cytometry. Results: Subjects exhibited significant decreases in body weight (2.8% average loss at WR) compared with BL ($p < 0.05$). At 3 days after the competition, their body weights returned to baseline-value. Percents of body fat were significantly lower at WR than that at BL ($p < 0.05$). SIgA secretion rates tended to decrease at WR, compared with BL ($p = 0.09$), and returned to BL at 3 days after the competition. This result suggested that rapid weight reduction had an adverse affect on mucosal immune function in judo athletes. The number of T cells significantly decreased at WR compared with BL ($p < 0.05$), and then returned to the baseline-value by 1 day after competition. Compared with BL, the number of Th, Tc, CD28+ Th and CD28+ Tc cells did not change significantly at WR. The number of NK cells did not show significant change. The number of CD14+TLR-4+ cells significantly decreased at WR, and then returned to baseline-value after the competition. These results suggested that rapid weight reduction decreased acquired and natural immunity in judo athletes. Conclusion: These results suggested that rapid weight reduction before the competition could decrease immune function, leading to decline of condition in judo athletes.

THE EFFECT OF FAR INFRARED IRRADIATION ON SKIN MICROCIRCULATION

Natsui, H., Nagai, S., Takemura, M., Ohshima, N., Kono, I.

Tokyo Women's College of Physical Education, Japan

The effects of far infrared have been known as increase of temperature and blood flow, or decrease of pain. Thermotherapy is indicated several times in sports rehabilitation, far infrared apparatus is compact and portable, so it will be used beside the sports field. In this study, we intended to evaluate the effect of far infrared irradiation on skin microcirculation using laser Doppler blood flow meter.

12 male adult (age 20 +/- 1) was used. 6 male was irradiated far infrared on their right upper back for 20 minutes (irradiation group), other 6 male was held switch-off apparatus 30 cm aloft (control group). Right upper back skin blood flow velocity and flow rate was measured during far infrared irradiation using laser Doppler flow meter (ADVANCE ALF21N, Tokyo). Skin temperature and comfort score was measured before and after irradiation using thermography (NEC San-ei TH9100, Tokyo) and visual analogue scale.

Skin temperature was increased 3.2 +/- 0.8 degrees centigrade on intra-irradiation area, and also increased 3.3 +/- 1.0 degrees centigrade on extra-irradiation area. Post irradiated skin blood flow velocity was increased 1.5 times compared with pre irradiation. Blood flow rate was also increased 2.3 times. Comfort score of irradiation group was higher than control group.

Far infrared has thermal effect on skin. Skin blood flow velocity and flow rate were increased by far infrared irradiation. Blood flow rate was calculated by blood flow velocity and blood flow mass. So, irradiation of far infrared might affect both increase of blood flow velocity and increase of blood flow mass.

A TWO-YEAR PROSPECTIVE STUDY OF SOCCER RELATED INJURIES IN THE CLUB ATLÉTICO BOCA JUNIORS PROFESSIONAL TEAM

Ortega Gallo, P., Garcia, L., Argemi, R., Batista, J., Liotta, G.

Club Atletico Boca Juniors, Argentina

Objectives: Soccer is known to be associated with a relatively high injury rate but there is no epidemiologic data in South American soccer where a different injury pattern was apparent.

Purpose: Analysis of injury incidence in the professional soccer team of the Club Atlético Boca Juniors over two competitive seasons.

Study Design: Prospective survey.

Methods: An injury report system was kept by the club's medical staff for all training sessions and matches.

Results: A total of 391 injuries per year were documented, with an average of 9.53 injuries per player per season. The mean (SD) number of days absent per injury producing some kind of training or match participation limitation was 9 (SD 15). Every week 10% of the team (4 players) was not able to train or play due to injury. The majority of injuries (87%) where slight or minor. A total of 1442 days and 354 matches were missed. Competition injuries represented 31% of those reported.

Conclusions: Professional soccer players are exposed to a high risk of injury, with 10% of our professional players unable to play every week due to injury. Injuries produce considerable economical and performance losses for a soccer team and probably long lasting consequences for the health and sport carrier of a soccer player. It was concluded that the majority of injuries were sustained during training in comparison to competitive matches. These results contrast when compared to findings within European soccer.

INCOMPLETE MUSCLE STRENGTH RECOVERY IN INJURED PROFESSIONAL FOOTBALL PLAYERS

Croisier, J.L., Ganteaume, S., Genty, M., Binet, J., Ferret, J.M.

University of Liege, CHU Sart Tilman, Belgium

Purpose: The injury risk in professional football is high and regularly entails absence from competitive participation for the wounded player. The decision as to when a player is considered fully rehabilitated after injury remains classically subjective. The recovery of normal strength and balance between agonist / antagonist muscles could potentially condition the performance on the field as well as the risk of relapse. The aim of the study was to assess the knee muscle strength performances in players who have returned to play after a major injury.

Methods: In total, 617 soccer players from professional teams in France, Belgium and Brazil were screened in that study. An injury report form was applied for determining the amount of players with a past history of major injury on the knee joint structures (bone, ligament, muscle, tendon). All players benefited from knee flexors and extensors isokinetic testing, following a standardized protocol consisting in concentric and eccentric exercises. A context of lingering muscle disorder was defined using statistically selected cutoffs for bilateral differences and Flexors / Quadriceps (Fl / Q) ratios (including a mixed Flexorseccentric/Quadricepsconcentric ratio).

Results: The isokinetic testing was performed in preseason and all involved players were considered at that moment as fit for training and matches by their respective medical staff. 413/617 players (67%) were identified as having sustained in the past a major injury on the predefined knee structures. Of these 413 players, 268 subjects still showed significant bilateral asymmetries and/or Fl/Q imbalances through the isokinetic assessment. These results mean that, after an injury, 65% of professional football players return to play in spite of serious muscle strength disorders.

Discussion and Conclusion: Our findings highlight the lack in standard return to play criteria as well as questionable options in professional football player treatment and rehabilitation after injury. Interestingly, a previous study dealing with hamstring strain [1] showed that persistence of muscle weakness and imbalance may give rise to recurrent muscle injuries. Furthermore, correction of preseason muscle imbalance allows for a significant reduction in the risk of subsequent muscle strain [2]. Therefore, we emphasize the role of an isokinetic intervention for muscle performance assessment before return to play after a major knee injury.

THE EFFECTS OF SERIAL FATIGUING TASKS AND ACUTE RECOVERY ON INDICES OF NEUROMUSCULAR AND SENSORIMOTOR PERFORMANCE OF THE KNEE FLEXORS IN FEMALES

Walters-Edwards, M., Minshull, C.M., Gleeson, N.P., Bailey, A., Nordvall, M., Rees, D.

Marymount University, United States

There is accumulating evidence of a link between fatigue and acute muscle strain injuries (Heiser, et al., 1984; Hawkins, et al., 2001). Females may be more influenced by fatigue and also show poorer proprioceptive capabilities compared to males (Huston and Wojtys, 1996). No previous research has investigated the effects of a fatigue intervention on neuromuscular and dynamic sensorimotor performance of the knee flexor musculature in females.

Maximal volitional peak force (PF) of the knee flexors and the error (constant; variable) arising from two types of sensorimotor performance (SMP) assessment were evaluated in females (n=20, 22.0 ± 2.8 years; 165.7 ± 0.04 m; 66 ± 6.5 kg [mean ± SD]). The SMP tasks involved the matching of a blind target force (50 % of PF) learned previously (SMP-TR [time-regulated force production at ~1000 N.s –1] and SMP-SR [self-regulated force production at ~200 N.s –1]). SMP response was reported as an over (+) or underestimation (-) of the target force. Assessments were undertaken prior to and immediately following two treatment conditions: (i) a control condition consisting of no exercise; (ii) a fatiguing intervention condition consisting of 4 bouts of 35 seconds maximal isometric exercise. Recovery measures were obtained at 1, 3 and 6 minutes. The SMP-TR and SMP-SR tasks were performed on separate days to minimise any the carry-over effects of fatigue. The fatigue intervention elicited a significant group mean decrease in peak volitional force of the knee flexors of up to 20.5%. This recovered to 94%-96% ± 2% (95% confidence limits) of pre-exercise values following 6-minutes of rest for both SMP-TR and SMP-SR assessment sessions, respectively ($p<0.05$).

Error of sensorimotor performance (constant error) was significantly increased (-2 ± 9% vs. 0 ± 12 % and -6 ± 11 % vs. -4 ± 12%) by the fatigue intervention during both SMP-TR and SMP-SR, respectively ($p< 0.002$) and remained at an increased level throughout recovery ($p<0.001$). Pre fatigue sensorimotor values were not re-established until 3 minutes following the final fatigue bout (94-96% of pre PFv values ± 2% [95% confidence limits]). Consistency of force response (variable error) was not significantly altered as a result of the fatigue intervention for both types of SMP. It is plausible that the disruption to the accuracy of force replication could be attributed to a failure of the force 're-scaling' mechanism during fatigue, where the under-shooting of the target force could be due to a failure by the afferent (muscle spindles) and efferent feedback systems.

The loss of proprioceptive performance of up to 6% (SMP-SR) and concomitant reduction in strength capability (20.5%) for up to 3 minutes following the cessation of the fatigue task suggests a substantial threat to dynamic joint stability during this period in females.

INCIDENCE OF EXERCISE-INDUCED HYPOXEMIA ON SUSCEPTIBILITY TO ACUTE MOUNTAIN SICKNESS IN SKI-MOUNTAINEERS

Durand, F., Bayonne, A., Ceugniet, F., Desplan, J.

Laboratoire Sport Santé Altitude, France

Introduction

Acute mountain sickness (AMS) occurs in those that go too high, too fast and is independent of endurance training. Ski-mountaineers could be affect by AMS all the more because it was exacerbated by exercise in the early hours of altitude exposure. In another way, it is commonly accepted that some endurance-trained athletes develop exercise-induced hypoxemia (EIH) at sea-level. Because many physiological events which were implicated in EIH have been well documented in the pathophysiology of AMS (Durand et al., 2000), we suggest that ski-mountaineers exhibiting EIH who exercise regularly at moderate altitude could be particularly susceptible to AMS as they exhibit EIH.

Methods

Nine male ski-mountaineering athletes (aged 34  1.8 yr) participated. They performed i) incremental exercise test to assess the maximal oxygen uptake (VO2max) and mesure EIH and ii) hypoxic test to assess the susceptibility to AMS (Rathat et al., 1992). Ventilation (VE), heart rate (HR), breathing frequency (f) and O2 saturation (SpO2) were measured and permitted us to calculate cardiac (CR) and ventilatory (VR) responses to exercise in hypoxia assessed by the following equations : CR = -HREH – HREN/SpEH-SpEN and VR = [VEEH-VEEN/SpEH-SpEN]/weigh (kg) x 100. Others parameters like resting desaturation (SpR = SpRN-SpRH), exercise desaturation (SpE = SpEN-SpEH) and f measured during exercise in hypoxia (fEH) were compared to normal values.

Results

All athletes exhibit EIH (SpO2 fall equals 13.1 ± 1.4%) which is significant from 40% VO2max. Negative correlation between the fall in SpO2 and SpE ($r=-0.84$, $p<0.05$) and fEH and VE measured at 40% VO2max during exercise test ($r=-0.7$, $p<0.05$) were observed. A tendency toward a significant correlation occured between the fall in SpO2 and RC ($r=0.6$, $p=0.08$). 5 ski-mountaineers were susceptible to AMS as at least two of the four parameters like CR, VR, SpR, SpE and fEH are out of normal values. These athletes report the greater degree of EIH. Nevertheless if all athletes had previously experienced altitude, no one had reported AMS.

Conclusion

At 40% VO2max which is the intensity of hypoxic test, EIH is explained by relative hypoventilation. This hypoventilation could influence the response to hypoxic test and particularly induce the increase in frEH. It is well known that moderate altitude increase arterial desaturation during exercise in athletes. Like this, greater is EIH exhibited by ski-mountaineers and greater is SpE. In conclusion, this study clearly suggest that EIH influence the responses to hypoxic test predicting susceptibility to AMS as no subjects had experienced AMS in previous altitude stage. EIH induced false positive response and ski-mountaineers which are athletes training and exercising in altitude have to interpret cautiously the results of hypoxic test.

ASSESMENT IN KINETIC REHABILITATION PROGRAMME OF ANKLE INSTABILITY AFTER AHILLIAN-CALCANEO-PLANTAR DISORDERS

Rusu, L., Vasilescu, M., Paun, E., Ortanescu, D., Ciocanescu, D., Dragomir, M., Diaconescu, D.

University of Craiova, Romania

Disorders of muscletendinos size like ahillian-calcaneo-plantar region(ACP), involve instability of ankle and this is the reason for that kinetic rehabilitation using kinetic method for rehabilitation is very important. The aim of this study is to present the efficency of kinetic rehabilitation programme that we used at a lot of athlets for recovery and return at soon at possibile to sport performance, after injuries of foot and ankle.

Material and method: We studied 15 subjects(volleybalist player), with mean age 20 years. The injuries of foot and ankle including disorders of muscletendinos jonction, disorders of Ahillian tendon, disorders of aponeurotique structure of foot. After all these disorders we observed ankle instability and perturbation of gait. Assesment of subjects including asseement of pain(scale of clinic pain assesment 0-4), and EVA score, specific evaluation like stability test, clinical assesment including palpation of region, stretching test, muscle force,jumping test(scale 0-2), mobility, flexibility, pain point, functional assesment use VISA scale(maxim score 100 with 8items) and echographic evaluation for assesment change of structure. Rehabilitation programme has the next goals: decrease pain and stifness, increase mobility and flexibility, increase muscle force, motor control, stability, coordination and balances during gait and jumping. For that we used kinetic method like FNP technique(Kabat, hold relax, passive and isometric stretching, proprioception training) and exercises in closed kinetic chain.The study has been made during one month, the number of kinetic programme during week was 5/week, 1hour.Return to sport training when the pain was out, stability and muscle force are normal.

Results: Before treatment at clinical assesment score was 1for 60% from subjects, 2for 40%. After rehabilitation programme score was 0 for 80% from subjects and 1 for 20%. Functional assesement has been 30points at the begining and after one month total score(in VISA scale) was 91 points for 30% from subjects, 96points for 60% from subjects and 100points for 10%.

Conclusions: Complet and seriously assesment before and during kinetic rehabilitation programme for ACP disorders help the athlets to return quikly at sport activity, because if we use objectiv scale for assesment clinical and functional aspects we can build an efficient programme for rehabilitation, how we seen in our study because after only one month our subjects can begin the training. Because our rehabilitation programme improvment stability and by proprioceptive method can involve an increase of muscle balance at ankle and foot.

WAIST CIRCUMFERENCE AND GLUCOSE METABOLISM AMONG PEOPLE OVER 65 YEARS OLD

Martins, R., Neves, A.P., Teixeira-Veríssimo, M., Teixeira, A.M.

Faculty of Sport Sciences and Physical Education, University of Coimbra, Portugal

According to the International Diabetes Federation definition, central obesity based on waist circumference (WC), should be defined as a value higher or equal to 94 centimetres, for the European men and as a value higher or equal to 80 centimetres for women. This definition addresses the new importance of the waist circumference values, when compared to the waist-to-hip ratio (WHR) or even the body mass index (BMI). Overweight and obese individuals are more likely to be insulin resistant and at increased risk of cardiovascular disease. Questions remain as to whether waist circumference or body mass index most effectively identifies insulin-resistant individuals. The purpose of the present research was to analyse and establish a relationship: a) between waist circumference and glycosylated haemoglobin; b) between waist-to-hip ratio and glycosylated haemoglobin; c) between body mass index and glycosylated haemoglobin in a population over 65 years old.

Seventy women (77.53±7.99 years old) and forty four men (75.43±6.64 years old), aged between 65 and 95 years old participated in this study. Biochemical analyses were conducted based on fasting venous blood samples. Anthropometric indices were measured according to standard protocols. The inferential statistical analysis was performed using the bivariate Pearson's correlation.

Regarding the waist circumference only 14.9% of the women and 34,1% of the men studied had a value under 80cm and under 94cm respectively. According to these values, 85.1% of the women and 65.9% of the men were considered has having central obesity. When comparing the relationships between anthropometric indices and glycosylated haemoglobin it is possible to observe that the body mass index did not correlate with glycosylated haemoglobin, not only for the men's group but also for the women's group. The data also show a positive correlation between waist-to-hip ratio and glycosylated haemoglobin and also between waist circumference and glycosylated haemoglobin in the women's group. On the other hand, in the men's group no correlations were found for any of the variables analysed.

In this population the abdominal fatness, evaluated from waist circumference, correlated positively with glycosylated haemoglobin. The body mass index and waist-to-hip ratio did not attained significant correlation with the glucose metabolism variable. When subgroups were analysed, correlations for the waist-to-hip ratio and waist circumference were found in the women's group, but that did not occur for the men's group. Results suggest that central obesity, evaluated from waist circumference, could be a better indicator of the risk of raised glucose levels in over 65 years old population, than the BMI or WHR. The differences observed between women and men could be due to the higher central obesity prevalence observed in the female subjects.

PROOF OF LYMPHATIC VESSELS IN HUMAN VASTUS LATERALIS MUSCLE FROM MALE CYCLISTS

Gehlert, S., Weber, S., Bloch, W., Platen, P.

German Sports University Cologne, Germany

Proof of lymphatic vessels in human vastus lateralis muscle from Male Cyclists

Sebastian Gehlert, Sebastian Weber, Wilhelm Bloch, Petra Platen

Institute of Cardiology and Sports Medicine; German Sport University; Cologne; Germany

Introduction

Lymphatic system has to fulfil important tasks in human organism like Immune cell trafficking and fluid homeostasis. Lymphatic vessels consist of single layered and high permeable, thin endothelial cell walls. In human myocardium, lymphatic vessel density has already immunhistochemical been proved (1). Occurrence and density in human striated skeletal muscle however still has not been estimated. With regard to the mentioned functions of lymphatic vessels, a possible importance in dynamic exercise respectively occurrence in striated skeletal muscle could be assumed. Therefore it was purpose of the study to investigate, the structure and density of lymphatic vessels in human skeletal muscle of endurance athletes.

Methods

6 male amateur cyclists (Age 31 ± 4,55 years) participated in this study. Muscle biopsies were taken from musculus vastus lateralis and bioptic material has been stored in liquid nitrogen. 10µm cross-sectional slices were cut from the bioptate and immunhistochemical staining has been performed using lymphatic endothelial markers "FLT-4" and "LYVE-4" finally developed with the DAB-Method. Several fields were digitally image captured and positive stained structures were counted. Additionally fibre spectrum has been determined using ATPase staining at PH 9.4. Classification of fibre spectrum has been carried out, determining staining intensity for the different fibres.

Results

There were counted in mean 270 ± 168 muscle fibres containing of 39 ± 28 lymphatic structures between these fibres. This means a number of 13.6 ± 4.0 lymphatic vessels per 100 fibres. Participants had 45,03% ± 15,8% Typ I fibres, 40,6% ± 11,2% Type IIa and 14,3% ± 9,0% Type 2x fibres. Lymphatic structures appeared orientated preferentially along interstitial structures and between fibres. The found numbers of positive structures do not correlate with the measured maximum oxygen uptake or the calculated, maximum glycolytic capacity. Correlation between preferential percentage of fibre type I, IIA or IIb could not be found.

Conclusion

Lymphatic vessels can be proofed in a variable density in human skeletal muscle using appropriate antibodies. Occurrence of lymphatic vessels showed no clear preference to an special fibre type. In contrast to the known tasks lymphatic structures have to fulfil, a more precise statement of their function in human skeletal muscle under dynamic strength or endurance exercise and a possible load dependent development, would be desirable.

COMPARISON OF METHODS TO IDENTIFY THE ANAEROBIC THRESHOLD FOR TYPE 2 DIABETICS AND NON-DIABETIC SUBJECTS

Simões, H.G., Moreira, S.R., Hyane, W.C., Do Valle, G., Sotero, R.C., Lima, R.M., Cunha, R.R., Oliveira, R.J., Puga, G.M., Moffatt, R.J., Campbell, C.S.

Catholic University of Brasilia - Brasília DF Brazil and Florida State University - Talahassee FL US, Brazil

Methods to identify the anaerobic threshold (AT) on 10 type 2 diabetics (54.5 +9.5 yr; 30.1 +5.0 kg/m2) and 10 younger non-diabetic subjects (36.6 +12.8 yr; 23.9 +5.0 kg/m2) were compared during incremental test (IT) on cycle-ergometer. The over-proportional increase on the VE/VO2 and the blood lactate ([lac]) responses identified the workload (Watts-W) corresponding to ventilatory (VT) and lactate threshold (LT) respectively. The lower blood glucose ([gluc]) identified the individual glucose threshold (IGT). The VE/W and [lac]/W responses were modeled through a second grade polynomial function (PF) to identify exercise intensities above which an over-proportional increase in VE and [lac] did occur and were named VTVE/W and LT[lac]/W. Additionally, the acid-base balance as related to AT was analyzed. The LT (85.0 +32.1), VT (88.0 +31.7), IGT (86.0 +33.8), LTLac/W (82.0 +20.9) and VTVE/W (90.2 +22.2) identified on diabetics differed from the LT (139.0 +39.0), VT (133.0 +42.7), IGT (140.8 +36.4), LTLac/W (122.7 +44.3) and VTVE/W (133.0 +39.1) identified for non-diabetics ($p<0.001$). However, ANOVA evidenced no differences between methods to identify the AT within groups. After reaching the AT intensity during incremental test a blood pH was significantly decreased. We concluded that the [gluc] responses as well as the modeling of the VE/W and [lac]/W ratio through PF successfully identified the AT for type-2 diabetics and non-diabetics. Also, the studied protocols identified exercise intensities above which the acid-base balance is disrupted and the blood glucose may be increased.

VO2 KINETICS AND BRONCHIAL HYPER-RESPONSIVENESS IN PROFESSIONAL CYCLISTS

Medelli, J., Marefati, H., Campion, F., Lounana, J.

CHU Amiens, France, France

Introduction

The relation between oxygen consumption (VO2) and work rate (W) is classically considered to be linear (Astrand). Recently, the comparison of the VO2 measured during an incremental test with the extrapolated values from the VO2/W relation below the lactate threshold, can show an excessive VO2 in healthy subjects (Zoladz) or a reduced VO2 in professional cyclists (Lucia). A high prevalence (50%) of bronchial hyper-responsiveness has been observed in professional cyclists (Medelli). Clinical investigation, lung function testing at rest or during exercise and pharmaceutical tests are not always discriminatory enough for a diagnosis. Could the analysis of VO2 kinetics below and above VT provide additional information?

Method

37 professional cyclists (27±4.1 years, 179.7±6.8 cm, 71.2±6.8 kg, VO2max: 67.55±5.9 mL.kg-1.min-1, Wmax: 415±35Watts) were separated in two groups characterized by positive (BHR+, N=18) or negative (BHR-, N=19) bronchial hyper-responsiveness according to the following parameters: clinical investigation, lung function testing at rest and after exercise, and methacholine challenge. Subjects performed an incremental test (50W/3min) until exhaustion on a bike ergometer (Lode Excalibur). Physiological parameters were measured continuously (Jaeger Oxycon V) and recorded every 30s until test termination. The values of the last minute of each completed step were averaged and used for regression analysis below and above the ventilatory threshold with calculation of slopes and intercepts.

Results

Except age (29.2±3.4 vs. 25.3±3.9 for BHR- and BHR+; $P<0.05$), there was no significant difference between groups regarding anthropometrics, physiological and lung function testing data. However, during the incremental test the VO2 relation of the BHR+ group exhibited a breakpoint with a steeper VO2 /W slope above compared to below VT (0.497±0.031 vs. 0.561±0.051 respectively, $P<0.0001$) while

the VO2/W relation was linear in the BHR- group. The VO2/W slope above VT was significantly higher in BHR+ compared to BHR- (P<0.05). These results were unchanged when taking into account age effect.

Discussion

In this group of professional cyclists, lung function testing cannot always differentiate between subjects according to their BHR status. However, it appears that the VO2 kinetics during an incremental exercise test can be a discriminatory parameter contributing to the diagnosis of BHR. A possible factor for the excessive VO2 observed at workloads above VT in BHR+ may be the increased solicitation of respiratory muscles to compensate airways obstruction.

SIMULATIONS OF INDIVIDUAL SQUAT JUMPS ON COMPLIANT SURFACES

Tilp, M.

Karl-Franzens-University Graz, Austria

Jumps in sports are all executed on more or less compliant surfaces with different material behaviour. Sport surfaces behave elastic like a trampoline or may be quite rigid like asphalt. In the last decades a lot of outdoor sports on sand like beach volleyball or beach soccer became popular disciplines. In beach volleyball the jumping height is one of the performance determining factors and several, mostly empiric, works (Giatsis et al., 2004; Vetter/Nicol, 2004) have dealt with the different jumping or landing movements on sand compared to rigid surfaces. To get more knowledge about the influence of the surface on the jumping behaviour we simulated individual jumping movements on different compliant surfaces.

The employed 2D-model is described in detail by Sust (1997) and uses the individual properties of the muscle, nervous and anatomical system of an athlete to simulate squat jumps. With the help of the model and some movement measurements it is possible to determine the properties of an athlete and to simulate individual jumps under different movement conditions (Tilp et al., 2004). An augmented version of the model provides the option to simulate different surface properties to research the consequences on kinematic and kinetic quantities of the jumping movement like e.g. developed force, velocity, power or jumping height.

A compliant surface changes the working conditions for the muscle during the jumping movement compared to rigid surfaces. Therefore, the force development changes and jumping performance (maximal height) may decline (Giatsis et al., 2005). Simulations showed that there is another interesting effect. Due to the nonlinear relationship between the muscle properties and the jumping height, it is possible that athlete "A" jumps lower than athlete "B" on a rigid surface but higher from a surface with a specific compliance. Such findings may be explained by the adaptation of the muscle-nervous system to specific movement conditions (e.g. specific surfaces) and should be veryfied empirically.

A possible future application of such simulations could be the individual preparation of an athlete to a specific competition surface when the surface properties are known.

EVALUATION OF SPRINTING PERFORMANCE THROUGH CHARACTERISTICS OF VERTICAL JUMPING

Gouvali, M., Kourias, T., Zapartidis, I., Boudolos, K.

University of Athens, Greece

INTRODUCTION

The strength qualities of sprinters are frequently evaluated through jumping tests. Although various tests have been proposed in the literature, their validity in evaluating critical aspects of sprinting performance is not yet established due to the samples used or to the selected parameters. Therefore, the purpose of the study is to examine the relationship between sprinting performance and qualities measured by countermovement jumping (CMJ) or hopping in place.

METHOD: Sample consisted of 8 male sprinters (75.8±8.1kg, 179.4±8.7cm, 21.6±1.8yrs, 100m record: 10.85±0.3s). Two maximum 50m running efforts were performed from a block start and the best was selected for analysis. Times were recorded at 8, 10, 40 and 50m with 4 pairs of photocells (Brower Timing System) in order to compute velocity (V). Mean step frequency for 10 and 50m was calculated by data obtained with a VC (50Hz) and step length was computed as the quotient of the whole distance to the total number of steps. Subjects also executed 3 CMJ and 2 trials of hopping in place for 10s on a force plate (Kistler, Type 9861A). The vertical height of the CMJ was calculated by flight time, while for hopping trials, the frequency was calculated. Statistical analysis included Pearson correlations (p<0.05), as well as regression analysis.

RESULTS: Velocity between 40 and 50m was 9.89±0.42m∙s-1, while the velocity between 8 and 10m was 76.0±6.3% of the maximum. CMJ height was statistically correlated with velocity at 10 and 50m, as well as mean step length at 10m. Hopping frequency and height was correlated with velocity at 50m and mean step length at 10 and 50 m. CMJ height alone, was a good predictor of velocity at

10m (R2=0.734, p<0.05). Velocity at 50m could better be predicted by a combination of CMJ height and hopping frequency (R2=0.552, p<0.05).

DISCUSSION – CONCLUSION: Sprinting requires strength qualities to accelerate and elastic qualities to sustain maximum velocity. Thus, CMJ height, as a measure of explosive strength, proved to be a good indicator of the velocity at the initial acceleration phase (Bret et al., 2002), however, hopping frequency, as a measure of elasticity, is also necessary in predicting the ability to sustain maximum velocity (Berthoin, et al. 2001; Chelly & Denis, 2001). Consequently, sprinting performance is a result of different qualities, such as strength and elasticity, which should be evaluated through different jumping tests, specific for each one.

FASCICLE BEHAVIOR OF THE SYNERGISTIC MUSCLE GROUP, MEDIAL GASTROCNEMIUS AND SOLEUS, DURING DIFFERENT INTENSITY DROP JUMPS

Sousa, F., Ichikawa, M., Vilas-Boas, J.P., Komi, P.V.

Neuromuscular Research Center, University of Jyväskylä, Finland; Faculty of Sports, University of Porto, Portugal, Portugal

The present study was designed to examine the fascicle behavior of the synergistic muscles, medial gastrocnemius (MG) and soleus (SOL), simultaneously during different intensity drop jumps (DJ). Eight subjects performed unilateral leg drop jumps on a sledge apparatus with maximal effort from four individually predetermined dropping heights: 50, 75, 100, and 120% of the optimal dropping height (DJ1, DJ2, DJ3 and DJ4, respectively). During the exercises, the reaction forces (Fz; parallel to the movement plane of the sledge seat), sledge displacement and velocity were measured simultaneously with the electromyographic (EMG) activity, and fascicle lengths (using ultrasonography) for the MG and SOL muscles. The results showed that muscle tendon unit (MTU) and tendinous tissues of both muscles were stretched prior to shortening during the contact phases. However, the fascicles behaved differently between the two muscles. The SOL fascicles were stretched prior to shortening during the ground contact, following MTU and TT behavior. With increasing dropping intensities, the lengthening amplitudes of the SOL fascicles decreased together with higher EMG activation. However, the MG fascicles behaved differently from its synergistic SOL muscle during DJs. During the lower drop height conditions (DJ1 and DJ2) they primarily shortened during the braking phase. Thereafter in the DJ3 and DJ4 conditions, the MG fascicles did not shorten during the braking phase although the EMG activity was still increasing during the preactivation and braking phases. Instead, they behaved isometrically or lengthened in this particular phase. These results suggest that the MG and SOL fascicles can behave differently during DJ, as well as that there may be a specific length change patterns of the MG and SOL fascicles with increasing prestretch intensity. Results provide evidence that the fascicle behavior is task dependent.

ANAEROBIC POWER PRODUCTION CHARACTERISTICS DURING BICYCLE EXERCISE AND MUSCLE SIZE IN THROWER, SPRINTER, MIDDLE AND LONG DISTANCE RUNNERS

Tanaka, S., Aoyama, T., Tsunoda, N.

Kokushikan University, Japan

Anaerobic power production capacity is important factor in any athletic activities. Its power output capacity affected by athletic training mode was reported previously. The purpose of this study was to observe the anaerobic power production capacity on bicycle exercise and effects of muscle size in track and field athletes.

The subjects were thirty-two collegiate athletes. These subjects were classified by athletic event (9 throwers; TG, 13 sprinters; SG, 10 middle and long distance runners; MLG). The maximal anaerobic power (MAP) was obtained by bicycle ergometer (Power max VⅡ, Combi co. Japan). Subjects were performed ten seconds with the maximal efforts intermitted of three steps work load, and requested to have warm-up and two minutes rest. Relative maximal anaerobic power to body weight (MAP/BW) and to fat free mass (MAP/FFM) were calculated in all the subjects. And also, the relative load and pedalling rate of 2nd and 3rd sets to 1st set were calculated in all the subjects. Muscle thickness of anterior, lateral and posterior of the right thigh were measured by the B-mode ultrasonic method. The index of muscle volume (MVI) for quadriceps was calculated by the muscle thickness and thigh length from trochanter to tibia in the right thigh.

MAP in TG (1150.3 ± 166.1 w) was significantly higher than that of SG (930.5 ± 181.9 w) and MLG (742.3 ± 133.5 w). Relative powers of MAP/BW and MAP/FFM in SG were highest value in all the groups. The highest power was obtained the load of the 2nd set. Significant difference was observed among the groups in work loads of MAP (TG: 9.0 ± 1.6 kp, SG: 7.3 ± 1.2 kp, MLG: 6.2 ± 1.7 kp). However, no significant differences among the three groups were observed in pedalling rate of MAP (TG: 132.2 ± 18.5 rpm, SG: 130.4 ± 19.7 rpm, MLG: 127.5 ± 20.7 rpm). On the other hand, relative load and pedalling of 2nd and 3rd set to 1st set were not observed significant difference. Muscle thicknesses of anterior and posterior in TG were significantly higher than that of MLG. And also, MVI of TG was showed higher value than that of SG and MLG. Significant correlation coefficients were observed between muscle thicknesses of anterior and posterior in all the subjects. And also, the MVI was closely related to the MAP in all the subjects.

In this study, anaerobic power production capacity of TG was higher than SG and MLG. Significant difference was obtained among the three groups in work load of MAP. Moreover, significant difference of muscle thickness was obtained by the groups. From these results, it was cleared that anaerobic power production capacity on bicycle exercise was differed by the athletic event. As the factor, load and muscle size may affect to the anaerobic power production capacity in track and field athletes.

TIME COURSE OF MECHANICAL AND NEURAL CANGES OF THE TRICEPS SURAE MUSCLE GROUP DURING 1 HOUR SSC SIMULATION

Avela, J., Peltonen, J., Kanervo, M., Komi, P.V.

University of Jyväskylä, Finland

It has been shown in several studies that the sensitivity of the short latency reflex component decreases immediately after SSC type of muscle fatigue (e.g. Nicol et al. 1996). In general, the responsible mechanisms have been divided into three different categories, including 1) supraspinal fatigue, 2) disfacilitation of the alpha motoneuron pool, as a result of reduced Ia afferent activity and 3) peripheral inhibition

through stimulation of the small muscle afferents group III and IV (Gandevia 1992). Our recent experiments, which were done with a passive muscle, could also suggest that the changes in the tendomuscular compliance induced by the continuous stretching of the muscle could contribute to this reduction in the reflex sensitivity (Avela et al. 2004). Therefore, the purpose of the present experiment was to examine the time course of the mechanical and neural changes during SSC fatigue condition where the supraspinal activity was minimized. Fatigue of the plantar flexor muscles was induced in a special ankle ergometer, where the initial ankle position was 90 degrees and the knee ankle was fixed to 140 degrees. Mechanical stimuli was set as a 10 degree ankle joint dorsiflexion with an average velocity of 3.5 rads-1 and a frequency of 1.5 Hz. Electrical stimulation (frequency of 30 Hz, duration of 0.2 ms and intensity of 10 % of MVC) was maintained during each mechanical perturbation with a pre-stimulation of 100 ms. The whole fatigue stimulation occupied one hour. The fatigue model induced only a slight reduction in the force production capability (MVC) of the muscle (6.1 ±16.5%, n.s). However, there was a clear decreasing trend for the peak-to-peak amplitude of the stretch reflex and for the H/M –ratio towards the end of the fatigue stimulation. For the stretch reflex this decrease was statistically significant 60 minutes after the exercise (-41.4 ±43.5%, $p<0.05$) and for the H/M –ratio from 45 minutes after the exercise (-25.0 ±24.3%, $p<0.01$). Interestingly, the time course for the reduction in the passive stiffness and fascicle length was parallel with the changes in the reflex sensitivity. Therefore, these preliminary results suggest that during the fatigue task the increased compliance of the muscle-tendon unit results in a reduced mechanical response of the muscle spindle and/or induces a slack in the intrafusal fibres of the spindle, leading to reduced reflex sensitivity in both cases.

CHANGES IN MOVEMENT COORDINATION OF THE THROWING ARM THROUGHOUT A SIMULATION OF A TEAM HANDBALL GAME

Zapartidis, I., Gouvali, M., Bayios, I., Boudolos, K.

University of Athens, Greece

Introduction

The proximal-to-distal segmental sequence pattern is identified in overarm throwing skills of team handball (Joris et al 1985). This movement coordination pattern is probably modified under the influence of the load deriving from the game circumstances. The purpose of the study was to examine if the movement pattern of the throwing arm is indeed modified throughout a simulation of a team handball game.

Methods

The sample consisted of 6 female team handball players (age: 20.6±1.8yrs, height: 1.67±0.7m, mass: 63.84±4.2kg). After a typical warm up, they performed 3 throws on the spot from a 7m distance against a target of 1m2 (initial measure-IM). Afterwards, they followed a 60min simulation circuit (2 halves  30min) where they reproduced the most common handball activities. Every 10min, 3 throws were performed and the second was selected for analysis. Ball velocity and linear velocity of the shoulder (SH), elbow (EL), and wrist (WR) were calculated by 3-D kinematic analysis conducted with 2 HSVC (Redlake, 125Hz) and a motion analysis system (Peak Motus), while accuracy was measured as the deviation from the centre of the target from videotape data. The maximum linear velocities (Vmax) and their timing (t_Vmax) were identified. Anova with repeated measures ($p<.05$) was conducted in order to estimate the effect of time on Vmax and t_Vmax of the joints and the ball and on ball accuracy.

Results

Ball velocity was low at the IM, improved during the first half and it was stabilized during the second half. Accuracy was high at the IM, while, during the game simulation, it was the highest after the 2nd 10min period of each half. The main effect of time on Vmax of the joints and the ball and on the respective t_Vmax was not significant. However, the temporal sequencing of Vmax of the joints was fluctuated. Defining as zero the time of ball release, t_Vmax of SH occurred slightly before t_Vmax of the EL (by 13ms) at the IM. After the 1st and 2nd 10min period, t_Vmax of the SH occurs much earlier than that of EL (32ms and 40ms respectively). After the 3rd 10min period, t_Vmax of the SH and EL gradually approach (3rd period: 20ms, 4th period: 8ms, 5th period: 13ms). During the last 10min period, t_Vmax of the EL precedes (by 8ms) t_Vmax of the SH (75ms). The t_Vmax of the WR remains stable (39ms – 37ms) throughout the game.

Discussion/Conclusion

The results reveal that, under the load of the game, there is an obvious modification in movement coordination. Forestier & Nougier (1998) have reported that the fatigue induced by isometric contractions led to a new inter-segmental organization in order to prolong performance. Consequently, the observed reconstruction of the movement pattern, under loaded conditions, offers a potentially less dangerous upper extremity pattern.

FLAT AND TOPSPIN SERVES IN TENNIS: NEUROMUSCULAR PARTICIPATION IN A TOP PLAYER

Coutinho, C., Correia, P., Veloso, A.

Technical University of Lisbon, Portugal

The purpose of this study is to verify the key factors of the neuromuscular coordination in the tennis serve, and the differences between the Flat and the Topspin serves in the Upper Limb muscles of the racquet arm, performed by a quality tennis player (Davis Cup National Team). The developed methodology in this study can be used in others similar studies of the throwing movements. The following muscles where EMG analysed: Anterior Deltoid (AD), Pectoralis Major (PM), Posterior Deltoid (PD), Latissimus Dorsi (LD), Vastus Medialis and Vastus Lateralis of the Triceps Brachii (VM and VL respectively), Biceps Brachii (BB) and Brachioradialis (BR). The athlete executed ten flat and ten topspin serves. 3D cinematic data was collected. All the data was introduced in SPSS 11.5 program for statistical analysis.

There is a relationship between proximal antagonists and distal agonists in order to maximize the velocity flow over the segments chain of the dominant arm. AD and PM are the first active muscles in the main phase and are the main responsibles for the horizontal adduction of the arm. LD is fundamental in the serve action, with a short activation before hitting the ball. This muscle joins two different functions, antagonist of the horizontal adduction and agonist of the internal rotation of the arm. Comparing the flat and the topspin serves:

AD and PM have higher intensities (iEMG) in the flat serve; VM and VL activate earlier and have a longer activation period in the topspin serve. The sweetspot velocity in the instant of ball contact is higher in the Z and Y axis in the topspin serve and in the X axis in the flat serve.

EFFECTS OF THROW-IN MOVEMENT OF PARTIAL JOINT ON THROWING PERFORMANCE IN SOCCER PLAYERS

Yumigeta, R., Teshima, T., Kumagawa, D., Tanaka, S., Tsunoda, N.

Kokushikan University, Japan

Throw-in is an action, most frequently occurred in soccer game. It was reported that the sequence of segment rotations from the trunk to the forearm during throw-in movement in a few researchers. However, the relation between throw-in movement velocities on partial joint and throwing performance are not yet clear. Therefore, the purpose of this study was to clarify the effects of throw-in movement of partial joint on throwing performance in soccer players.

The subjects were ten male varsity soccer players (SP) and 10 physical education students as a control group (CON). Their mean (SD) values of age, height, weight were 21.4(1.6) yrs, 177.3(6.9) cm, 73.0(5.9) kg in SP, and 21.6(2.0) yrs, 175.4(6.6) cm, 70.5(7.8) kg in CON, respectively. These subjects performed using a parallel throw-in in which was placed both feet side by side. The maximal ball velocity in the distance of 5m was measured by a Radar Gun (Mizuno, Japan). Maximal throw-in movement velocities on partial joint for whole body, trunk and shoulder were obtained a custom-made movement velocity measurement system connected to the Speed Meter (VINE, Japan). The throw-in on the sitting position was performed from a custom-made chair, the subjects were tied up with a strap in order to avoid the participation of lower limbs during the trunk throw-in. And same as lower limbs and trunk were tied up in shoulder throw-in.

Maximal ball velocity was significantly higher in SP than that of CON ($p<0.01$). Significantly higher value of shoulder throw-in movement velocity was obtained in SP. In addition, significantly correlation coefficients were observed between trunk throw-in movement velocity and maximal ball velocity in SP ($r=0.674$, $p<0.05$). On the other hand, no significant correlation coefficients were observed between trunk throw-in movement velocity and maximal ball velocity in CON. Shoulder throw-in movement velocity was not significantly related to the maximal ball velocity in both groups.

From these results, it was considered that trunk movement is important factor for throwing performance in soccer players. Although, from the results for the relationships between movement velocities and ball velocity, throwing performance may influence to the lower limbs movement in untrained subjects.

DIFFERENCES IN GROUND REACTION FORCE ACCORDING TO STRIKING PATTERN

Young-Sook, L., Kyung-Ok, Y., So-Yeon, J., Ji-Hee, S.

Ewha Womans University, Korea, South

Purpose

The purpose of this study was to evaluate the effects of foot striking patterns on ground reaction force during jogging.

Methods

The original test group consisted of over 50 students, however, since only three subjects were able to sustain over 100 minutes of exercise, analysis was done on only those three subjects. Within this group, one subject (A) was a fore-foot striker(normal body weight), and. Subject (B) was a mid-foot striker(overweight). Subject (C) was a heel striker(normal body weight). The Kistler Force Platform was used to measure ground reaction force variables at ten minute intervals for the duration of the test. These variables included three dimensional force variables such as impact and active force. Statistical analysis was performed via the SAS program, utilizing ANOVA. Follow-up analysis was performed via the Duncan method.

Results

1. There is no statistical difference for either lateral and medial impact force and active force between all groups.

2. There is a statistical difference in anterior/posterior ground reaction force for all groups, especially for braking active impulse and breaking time as well as propulsive active impulse and propulsive time.

a. Forefoot strikers have lower breaking active impulse and breaking time, but have larger propulsive active impulse and larger propulsive time.

b. Midfoot strikers exhibited characteristics opposite of forefoot strikers. Midfoot strikers had high braking active impulses and times, while propulsive active impulse and time were both lower.

3. There is a statistical difference in vertical ground reaction force for all groups, Midfoot strikers had low impact force variables (passive impulse, passive loading rate, passive decay rate) for vertical ground reaction forces.

Conclusion

Foot striking patterns had statistically significant effects on vertical, anterior/posterior ground reaction force. Midfoot strikers exhibited low values for vertical impact force variables. Forefoot and heel-strikers showed alternatively high levels of vertical impact force and active force variables. Therefore, midfoot strikers may be best adapted to minimize the negative consequences of impact while jogging.

MODELING OF THE SWIMMERS JOINT MOMENT DURING THE IMPULSE OF GRAB START

Houel, N., Rey, J.L., Boissière, E., Lecat, S., Taiar, R., Quièvre, J., Hellard, P.

Fédération Française de Natation, France

INTRODUCTION: Analysis of the temporal distribution of the races shows that the start phase accounts for 15 % of total time for 50 m freestyle events (Arellano et al., 1994). Regardless of underwater factors, the start phase depends primarily on the quality of the swim-

mer's impulse on the starting platform (Vilas-Boas et al., 2003). A model based on inverse dynamic was developed in order to predict impulse's parameters during grab starts. The study presented here aimed i) to evaluate the precision of this model by comparing predicted speed and power values with experimental data collected in situ, ii) to predict the mean angles for each articulation at the instant of the swimmer's joint moments are maximal during the impulse phase.

METHOD

Eight national swimmers performed a grab start. For each start, the ground reaction force was recorded using a force platform. This one is fixed near the pool in respect of simulating start actually met in international race. The sampling frequency was 1000 Hz. Speed of the swimmer's centre of mass was obtained by integration of its acceleration. In parallel, a high speed camera (125 frames.s-1) was used to record the profile movements which were then analysed in order to determine the angle between the subjects' segments (right side) and the horizontal axis. The sum of segment energies was obtained using the anthropometric tables and equations of sum of segment energies as defined in Winter (1990). For each start, the kinematics and dynamics of the platform signal were synchronised (0.008 s accuracy). Based on swimmer's kinematics and morphological properties, the model permits to determine joint moment, joint power and velocity of take-off of the centre of mass.

RESULTS AND DISCUSSION

The model presented in this study was able to predict parameters, observable by kinematic and dynamic data, with the following mean dispersions: of 0.4 m.s-1 for speed with the force platform, 1 % for swimmer's internal joint power with the time derivative of the sum of segment energies (Winter, 1990). During the impulse phase, the mean angles at the instant of the swimmer's joint moments are maximal are: 77.4° for the ankle, 92.2° for the knee, 57.1° for the hip. The mean maximal joint's moment are: 447.5 N.m for the ankle, 275.2 N.m for the knee, 295 N.m for the hip. The main interest of this model lies in the possibility of analysing and better understanding the joint's moment of each articulation and the segmental coordination of each swimmer performing a grab start.

+University Institute of Sport Science, Rome, Italy

The purpose of the present study was to clarify the velocity changes during the take-off phase and analyze the efficient take-off technique of the ski jumpers participating to the Olympic HS-106 m hill competition. Take-off phase was recorded for the 3-dimensional motion analysis with two fixed high-speed (200 Hz) video cameras synchronized by recording the RF -audio sync pulse in the audio line of the tape. It is well known that the inrun speed reflects the aerodynamic quality of the jumpers' inrun position before the take-off and it is the most important parameter affecting the jumping distance in ski jumping. Therefore this "officially measured" inrun speed of the jumpers (average speed from 8-meter distance during the latter part of the inrun curve) was compared with the different velocities of the jump-ers' segment model used in this study (de Leva 1996, adjusted from Zatsiorsky & Seluyanov). The official speed was examined for the first round (n=50, 88.12 +- 0.42 ms-1) and final round (n=30, 88.73 +- 0.36 ms-1) separately and it correlated significantly with the length of the jump for both rounds (r=0.628, p<0.001 and r=0.418, p=0.021, respec-tively). The comparison between the longest jumps (n=10) and the shortest jumps (n=10) demonstrated well that the best jumpers had significantly higher inrun speed in both rounds (p<0.001 and p<0.01, respectively). The preliminary results of the digitized data (10 best jumpers, 2nd round) during the take-off phase showed that, the CM velocity pa-rameters at the end of the takeoff phase provided no significant (p< .05) correlation to the jumping performance. However, the angular data showed that the high acceleration velocity of the knee during the take-off phase and small torso to X-axis angle at the instant of toe-off are correlated (r=0.561 and r=0.583, p<.05, respectively) to the result of the jump. This way the best jumpers are probably able to maintain the resultant velocity after the take-off and early flight phase.

BIOLOGICAL GROWTH AND DEVELOPMENT FOR SKATING PERFORMANCE, THIGH MUSCLE STRUCTURE AND FUNCTION IN MALE AND FEMALE JAPANESE SPEED SKATERS

Kumagawa, D., Tsunoda, N.

Kokushikan University, Japan

The purpose of this study was to clarify the effects of biological growth and development on skating performance, muscle structural and functional characteristics in male and female Japanese speed skaters. One hundred thirty-three males and 96 female speed skaters aged from 10 to 22 years were served as subjects. All subjects had belonged to speed skating clubs, which were deemed to be representative of the skating clubs in Japan. Therefore, they exercised regularly in technical drills relating speed skating throughout the year. They were classified 11 groups in males (from 130cm to 180cm) and 7 groups in female (from 130cm to 165cm) according to body height every 5cm. Muscle thicknesses of the thigh anterior (MT) as muscle structural parameter were measured by B-mode ultrasonic method. The maximal anaerobic power production capacity (MAP) as muscle functional characteristics was obtained by using a bicycle ergometer. The mean 500m skating velocity as a skating performance (SV) was used to the individual best records recently produced. MT, MAP and SV corresponding to body height were plotted on a logarithmic graph to obtain the allometric equation y=bxa, where "a" is a growth index and "b" is a constant.

Significant correlation coefficients were observed between MT, MAP and SV in all the subjects in both male and female. The relationships between MT, MAP, SV and body height observed broken lines, which had three phases with two critical points in both male and female, respectively. The growth indexes "a" between the first and second critical points in all the above relations were observed large value than that of other phases. Ranges of body height between the first and second critical point in MT were from 152.2cm to 168.1cm in male, and from 142.8cm to 154.4cm in female. It range of MAP were from 139.8 to 166.8cm in male, and from 138.8cm to 157.8cm in female. However, it range of SV were from 147.4 to 167.8cm in male, and from 143.2cm to 153.2cm in female. In addition to these results, the index "a" between first and second critical points on MT, MAP and SV were showed higher values in female than that of males ones.

These results suggest that biological growth and development of skating performance, muscle size and functional characteristics might not correspond mutually in the initial stage of growth process in male and female speed skaters. Moreover, the comparisons between male and female skaters indicate that skating performance of female are more superior growth than that of males ones in pubescence period.

MUSCLE FORCE GENERATION CAPACITY ON ISOMETRIC AND ISOKINETIC DURING TRUNK ROTATION MOVEMENT

Takahashi, Y., Tanaka, S., Kumagawa, D., Tsunoda, N.

Kokushikan University, Japan

Trunk movements are important factor in many athletic activities. Therefore, the purpose of this study was to examine for the force generation capacities to trunk rotation movement at different rotated positions on isometric and isokinetic actions.

The subjects were 13 right-handed healthy males (age: 22.5±0.7 yrs, height: 174.0±1.4 cm, body weight: 69.9±3.6 kg, fat free mass: 55.7±1.8 kg). Muscle force generation capacities during trunk rotation movement were measured by isokinetic dynamometer (Biodex system 3, torso rotation test) on sitting. All the subjects performed trunk rotation movement for right and left directions with maximal effort. The position in turn to front of trunk was defined 0degree, and right hand sides in left rotation were defined plus degrees, on the other sides were minus degrees. In contrast, right rotation was minus degrees in right hand side, and plus degrees in left hand side. Measured rotate ranges were -50 to 50 degrees consist of each 10degree in both rotations. Passive torque during trunk rotation movement was measured of each rotated positions except for 0degree. Maximum voluntary isometric peak torque values (ISM) were measured on pre-sets each rotated positions. ISM-ratios were calculated from both side rotated ISM. Maximum voluntary isokinetic peak torque values (ISK) test were performed with angular velocities of 30, 60, 120, 180 and 240 deg/sec.

Passive torque was less than 8% to ISM. Passive torque in left rotation was higher than that of right rotation in all positions. ISM was increased from –50 to 50 degrees in both rotations. ISM-ratio of left rotation was significantly higher than right rotation in –50, -40 and –30 degrees (-50 and –40 degrees: $p<0.01$, -30degree: $p<0.05$). However, significant differences were not observed from other rotated positions in left and light rotation. On the other hand, ISK decreased from 30 to 240 deg/sec. PT of ISK in 30 and 60 deg/sec observed significantly higher than that of right rotations ($p<0.05$). Positions on the PT appeared phase changed from 30 to 240 deg/sec. Although positions on the PT appeared phase were no significant difference between left and right rotations.

From these results, it was clarify that isometric and isokinetic muscle force generation capacities during trunk rotation movement may difference on left and right rotation movements in male subjects.

THE WINDMILL PITCH OF BALL VELOCITY AND ACCURACY IN JAPANESE FEMALE SOFTBALL PLAYERS

Kitagawa, Y., Kumagawa, D., Tanaka, S., Tsunoda, N.

Kokushikan University, Japan

Windmill pitching performance in the softball game such as ball velocity and accuracy was important factor. Therefore the purpose of this study was to clarify the pitching performance for ball velocity accuracy of target throwing in Japanese female softball players. The subjects were twenty female varsity softball players who were 8 pitchers and 12 fielders. All subjects exercised regularly in technical drills relating softball throughout of the year. These subjects classified according to softball position by two groups of pitcher and fielder.

The maximal ball velocity (MBV) was measured in the distances of 13.11m using a Radar Gun (Mizuno, Japan) for all the subjects. Each subject was requested to have fully warm-up routine before the measurement. Then they performed to 10 fastballs pitch with maximal effort. Accuracy in ball control to the target throwing in all the subjects was evaluated by a number of target hit. The ball velocity of target hit (TBV), the ratio of target hit with 20 pitches (RT) and the ratio of TBV per MBV (RTV) were also calculated as an index of pitching performance in both pitcher and fielder. The coefficient of variation (CV) in MBV, TBV, RTV and RT were also calculated.

No significant difference was observed between MBV and TBV in both pitcher and fielder. MBV, TBV and were significantly higher in pitcher (MBV: 22.7±1.5 m/s, TBV: 23.0±1.6 m/s, RT: 50.0±12.0%) than that of fielder (MBV: 18.6±2.0 m/s, TBV: 18.8±2.0 m/s, RT: 30.0±14.1 %) ($p<0.05$). CV of MBV, TBV and RTV were showed almost same value in both pitcher (MBV: 2.1%, TBV: 2.1%, RTV: 1.9%) and fielder (MBV: 2.6%, TBV: 2.6%, RTV: 3.6%) respectively. On the other hand, CV in RT was obtained higher value in pitcher (24.5%) than that of fielder (47.1%). Significant correlation coefficient was observed between MBV and TBV in both pitcher and fielder ($r=0.979$, $p<0.001$). And also significant correlation coefficient was observed between TBV and RT in all the subjects ($r=0.520$, $p<0.05$).

In this study, it was considered that pitching performance with windmill pitch was not influence on the target in female softball players. The pitcher showed higher pitching performance for pitched ball velocity and accuracy on target throwing.

RLATIONSHIP BETWEEN ATHLETIC PERFPRMANCE AND MUSCLE FUNCTIOIN IN JAPANESE FEMALE THROWERS

Aoyama, S., Aoyama, T., Tsunoda, N.

Kokushikan university , Japan

Recently, there has been a remarkable improving on the throwing performances in Japanese female throwers. Therefore, the purpose of this study was to clarify the relationship between muscle function of lower limb and throwing performance in Japanese female throwers.

The subjects were thirteen female Japanese throwers aged from 18 to 23 years. The peak torque of maximal isokinetic knee extension (PTe) and flexion (PTf) muscular force during concentric action was measured at velocities of 60,120 and 270 deg/sec using by isokinetic dynamometer (Biodex system Ⅲ). Maximal anaerobic power (MAP) was measured by cycle ergometer (Power max V2). Subjects were performed ten seconds with the maximal efforts intermitted three steps of work load, with warm-up and two minutes rest. The Athletic Achievement ratio (AAR) was used by record of each throwing event, so that AAR was calculated by personal best record / Japanese national record ×100 in all the subjects.

The subjects of MAP (891±147.7) were showed near by Japanese male elite athletes. The peak torque has reduced due to increase angler velocities. PTe was closely related to the AAR in both left (60deg/sec: r = 0.774, 120deg/sec: r = 0.744, 270deg/sec: r = 0.732) and right legs (60deg/sec: r = 0.678, 120deg/sec: r = 0.771, 270deg/sec: r = 0.701). There are significant correlation coefficients observed between PTf and AAR in both left (60deg/sec: r = 0.656, 120deg/sec: r = 0.744, 270deg/sec: r = 0.732) and right legs (60deg/sec: r = 0.734, 120deg/sec: r = 0.722, 270deg/sec: r = 0.676). And also, significant correlation coefficient was obtained between MAP and AAR (r=0.812 p<0.001).

In this study, muscle function of lower limb was closely related to the AAR. In addition, it is useful index that evaluation of throwing performance level with female throwers. From these result, it was suggested that increasing muscle function of lower limb may be improvement factors for athletic performance in female throwers. Furthermore, it was considered that increase muscle function of lower limb in training can be expectation of better throwing performance.

EFFECT OF A NEW DEVELOPED PEDAL-CRANK TRAINING SYSTEM ON MECHANICAL EFFICIENCY IN CYCLING

Böhm, H., Siebert, S., Senner, V.

Technical University Munich, Germany, Germany

To improve the transfer of human power into cycling performance, technical solutions such as oval chain rings or pedal-crank systems with varying lengths has been developed to maximize mechanical efficiency (ME), defined as the ratio between total force applied to the crank and the propulsive tangential force (Davis 1981). Because the effect of these systems is small (Zamparo 2002), the present mechanism with fixed crank length and circular chain rings are commonly used in cycling competition. However, these classic systems give the athlete itself the possibility to optimize its mechanical efficiency by changing to a better orientation of the force on the pedal. The task of the athlete is hereby to increase the propulsive force, which is tangential to the crank rotation. The aim of this study is to investigate whether training with the new developed "SmartCranks" (SmartCranks GmbH, Switzerland) training system improves the ME of the athlete during cycling. SmartCranks are bicycle cranks that are completely independent from each other using a free-running bearing.

A group of 20 male healthy, non-professional road cyclists volunteered to participate in this study. The subjects performed a 5-week training program on a cycling ergometer with 10 subjects training with the SmartCranks, the other with a conventional crank system. Before and after the training period, the subjects perform an incremental test to exhaustion, starting at 100W, with 30W increments every 3min at a constant pedalling rate of 90rpm. During the whole test, pedal forces were measured with the PowerTec system (o-tec GmbH, Germany). Lactate was determined to calculate the individual anaerobic threshold of the athlete.

Tangential and radial forces were assigned to 360 degrees and averaged over about 200 cycles of each incremental step. ME was calculated and summed up over a cycle of 360 deg (Davis 1981). Additionally the mechanical efficiency was separately summed up over four sections ranging from 315-45, 45-135,135-225, 225-315°, with 360° defined at the pedal top most position.

Training with smart cranks results in a significantly better ME at 280W as well as on the individual maximal power level. The lower power levels did not show any significant differences between the smart crank training and the control group. Training with smart cranks does not significantly increase the maximum power or the power at the individual aerobic threshold of the athletes. The potential for increase of ME is mainly in the topmost section ranging from 315-45°. This section shows the greatest significant increase in ME during the whole training. The results suggest that training with smart cranks can improve mechanical efficiency when high workloads are required.

BIOMECHANICAL ANALYSIS OF THE JAVELIN THROWING AT 11TH IAAF WORLD CHAMPIONSHIPS IN ATHLETICS IN HELSINKI

Murakami, M., Tanabe, S., Ishikawa, M., Isolehto, J., Komi, P.V., Ito, A.

Graduate school, Japan

INTRODUCTION

The purpose of the present study was to clarify the kinematic characteristics of the javelin throw movements of finalists at the 11th IAAF World Championships in Athletics held in Helsinki Finland. The javelin throwers analyzed in this study were fifty-seven males including eight finalists at the 11th IAAF World Championships in Athletics held in Helsinki Finland (World Championships). The best performance of each throwers ranged from 87.17m (the gold medallist of World Championships) to 45.25m was analyzed.

RESULTS

Although a significant positive correlation was observed between the initial velocity of the javelin and the official record ($r = 0.889$, $p < 0.001$), non significant correlations were obtained between the official record and the release angle, attitude angle, attack angle and release height of javelin. A significant positive correlation was observed between the official record and the calculated theoretical distance ($r = 0.909$, $p < 0.001$).

The pull distance was correlated positively and significantly with the official record ($r = 0.426$, $p < 0.01$), but the pull time was negatively correlated ($r = -0.418$, $p < 0.01$). The significant positive correlation between the official record and the approach run velocity was obtained ($r = 0.742$, $p < 0.001$).

Although the significant negative correlations were observed between the official record and the elbow joint angle ($r = -0.484$, $p < 0.001$) and adduction-abduction angle of the shoulder joint ($r = -0.474$, $p < 0.001$), the horizontal adduction-abduction angle of the shoulder joint showed a non significant correlation with the official record.

Although a significant positive correlation was observed between the official record and the forward trunk rotation angle ($r = 0.463$, $p < 0.001$), a non significant correlation was observed between the official record and the lateral rotation angle of the trunk. The official record and the fore leg knee joint angle showed the significant positive correlation ($r = 0.310$, $p < 0.05$).

CONCLUSION

The direct factor for achieving a high performance was the initial velocity of javelin. And the characteristics of throwing movement of finalists of World Championships to obtain faster initial velocity of javelin were as follows.

They approach with faster velocity and keep the fore knee angle in the extended position during the final phase of throw to change the approach velocity into the forward rotation of trunk. During the forward rotation of trunk, they keep their elbow joint angle small and adduction-abduction angle of the shoulder also small to be able to transfer the internal rotation velocity of shoulder joint to the grip velocity effectively. And they performed large movements in a short time.

INFLUENCE OF CONTRACTION INTENSITY AND JOINT ANGLE ON MEDIAN FREQUENCY OF KNEE AGONIST MUSCLES IN PREPUBERTAL BOYS AND ADULT MEN

Tsatalas, T., Hadjixenofontos, M., Katsanis, G., Giannakos, A., Michailidis, C., Lazaridis, S., Kotzamanidis, C.

Aristotle University of Thessaloniki, Greece

Introduction: Based on evidence, it is suggested that the median frequency (MF) of the EMG power density spectrum can be used as a motor unit recruitment tracking parameter in human voluntary muscular contractions (Solomonow et al 1990). The purpose of this study was to examine the influence of contraction intensity, joint angle and age on the MF of knee agonist muscles during step-wise increasing isometric knee extensions. Methods: 10 healthy adult male volunteers and 10 prepubertal boys 9-10 years old took part in the study. The subjects performed 2 maximal voluntary isometric extension contractions (MVC) on an isokinetic dynamometer at 2 knee angles (30° and 90° knee flexion,0°=full extension) for 5s. The subjects were then asked to perform one voluntary isometric extension contraction at the following intensities:20, 40, 60, and 80% of their best MVC. The MF was assessed through surface EMG for the vastus medialis muscle. A power spectral analysis was performed on a 3s window and MF was estimated based on the study of Pincivero et al (2001). A three factor repeated-measures ANOVA was performed on the MF. The level of statistical difference was set at $P<0.05$. Results: The results demonstrated that the MF was significantly higher for the 30° knee angle (short muscle length) in both age groups. MF values in boys were significantly lower than in men in both joint angles and in every contraction intensity. The effect of contraction intensity on MF was significant only for the 30° knee angle in both age groups. Specifically, a small increase of the MF values between intensities 20 and 80% of MVC was observed. Discussion/Conclusion: The higher MF values for the 30° knee angle can be attributed to the increase in action potential conduction velocity that results when a muscle becomes shorter and its diameter increases. (Trontelj 1993). The higher MF values in men compared with boys could in part be explained by a greater percentage of Type II fibers (Lexell et al 1992) and a greater motor unit recruitment of Type II motor units for men (Halin et al 2003). Finally, the fact that the effect of contraction intensity on MF was significant only for the 30° knee angle suggests that joint angle should be taken into consideration when median frequency is used to examine motor unit control strategies of agonist and antagonist muscles during step-wise increasing isometric knee actions.

THE EFFECT OF LOAD ON ARM MUSCLE ACTIVITIES DURING MOVEMENTS IN THE DIRECTION AND AGAINST THE DIRECTION OF GRAVITY

Laczko, J., Keresztenyi, Z.

Semmelwesi University, Faculty of PE and Sport Sciences, Hungary

Introduction: The electrical activities of skeletal muscles are increasing if a movement is executed under the effect of external loads. We studied arm movements and the effect of load if the movements were executed in the direction of the gravitational acceleration or in the opposite direction. This kind of studies are more frequent for lower extremities Here we studied arm movements and investigated the role of the agonist and antagonist elbow muscles.

Methods Subjects lay on a plate of weight bench and they hold a bar in their hands above their chest (in the starting position the upper arms were placed horizontally along the trunk and elbows were fully flexed, thus the hands with the bar in it were positioned above the shoulder of the subject. Starting from this position they lifted the bar by fully extending their arms and then they reposed the bar removing it to the original position. They performed this movement 10 times consecutively without load and 10 times with a load of 100N. Nine healthy subjects participated in the experiment. The movements were recorded with a Zebris Movement Analysing System. The coordinates of six anatomical points were recorded: one in the shoulder, two in the elbow, and two in the wrist and one on the back of the hand. From these coordinates we approximated the coordinates of the rotational centers of the three main joint of the arm: shoulder, elbow and wrist joints and the angular changes in the elbow joint. Simultaneously, we measured EMG signals from two muscles of one arm: m. biceps brachii and m. triceps brachii – short head. We computed the averaged amplitude of the EMG of the biceps in the lifting phase for the case with load and without load and we computed the ratio of the values obtained from these two conditions. We computed this ratio for the reposing phase as well. We made the same computation for the triceps

Results: The angular position profile in the elbow was not symmetrical, the absolute angular velocity was higher in the lifting phase. In the case of the biceps, the computed ratio of the EMG values was larger for the lifting phase and in the case of the triceps the ratio was much larger for the reposing phase. Thus the load has a bigger effect on biceps activity in the lifting phase and a significantly bigger effect on the triceps activity on the reposing phase.

Conclusion: This quantitatively supports that if the movement is executed with load, the triceps must exert significantly higher force in the reposing phase. Thus it slows down the reposing process to prevent a sudden fall of the bar and the triceps activity insures the smooth reposing. In the pushing phase the biceps activities while working against gravity may regulate the smooth lifting with load and without load as well.

ELECTROMYOGRAPHIC DESCRIPTION OF LIGHT VS. HEAVY RESISTANCE EXERCISE PROTOCOL

Holm, L., Aagaard, P., Kjær, M.

Bispebjerg Hospital, Denmark

Introduction. Recently, we developed an exercise protocol aiming to investigate the acute response and long-term adaptation of muscle and tendon to a light resistance (LR) or heavy resistance (HR) exercise protocol. Based on a 1 repetition maximum (RM) strength measurement the light and heavy loads approximately corresponded to 15.5% and 70% relative load, respectively. The aim of the present study was to provide an electrophysiological description of the two contraction-intensities from surface electromyography (EMG) recordings. Secondly, to compare the relative neural firing to the relative 1RM strength-based intensity determination. Methods. Sedentary males without any known neural disorders had their 1RM determined. On a separate occasion EMG signals were collected during the 1st, 5th and 10th (final) set of the LR as well as the HR exercise protocols. Adjacent electrodes were placed at muscles vastus medialis (VM), lateralis (VL), and rectus femoris (RF) muscles as the main prime-movers of the knee-extension exercise and at the biceps femoris (BF) as a measure of the antagonist activity. Signals were sampled at 1000 Hz, led through an AD-converter and amplified before stored in a computer. Raw data files were analysed in custom-made software (Biomax, v. 2.5), rectified and smoothed out by a root mean square (RMS) filter. The relative firing was calculated by dividing the current obtained from the LR and HR exercises wit the recordings from a maximal voluntary contraction (MVC) test conducted prior to the exercise trial. Data are mean ± SD. Results. The mean relative EMG was 14.0 ± 6.8% during the LR protocol and 51.2 ± 14.3% during the HR protocol. No difference was apparent from the 1st to the 10th set for the

mean relative EMG, neither for the LR nor the HR exercise protocol. Median power frequency tended to diverge slightly for VM in the LR exercise protocol whereas during the HR protocol median power frequency increased significantly for VM and VL and tended to increase for RF throughout the 10-set protocol. Discussion/Conclusion. The relative neural firing for the light resistance intensity corresponded to the 1RM strength-based intensity, whereas for the heavy resistance exercise intensity the relative neural firing was less than the 1RM strength-based intensity. No signs of neural exhaustion appeared during any of the intensity protocols.

DESIGN AND CONSTRUCTION OF AN AMBULATORY ANKLE ERGOMETER DEVICE

Gueib, J., Grosset, J.F., Lambertz, D., Vanhoutte, C., Pérot, C.

Université de Technologie de Compiègne, France

In our laboratory neuromechanical properties are routinely investigated (Lambertz et al., 2003; Grosset et al., 2005). These tests are made by using heavy and huge ergometer devices with a torque motor and thus difficult to be placed in other locations. However, most of the neuromechanical properties did not need the use of a torque motor. The aim of the present study was the design and construction of an ambulatory ankle ergometer device allowing for investigating neuromechanical properties in passive and active conditions of the ankle plantar flexor muscles.

The ergometer device is conceived to be easily carried and therefore built of different parts (around 10 kg each) easy to join and take apart. The ergometer structure is composed of a rigid frame and a mobile footplate to which different transducers are connected. Force measurements in active and passive conditions are carried out by using two exchangeable force transducers (see below) connected at the end of the footplate. A 13-bit absolute optical encoder is fixed within the rotation axis of the footplate providing the measurement of angular position and its derivatives. A 12-bit acquisition board is used for data sampling.

The main tests are:

- the quantification of the force from isometric contractions, used to characterize the contractile properties of the muscles and to quantify the variation of maximal voluntary contraction of the triceps surae as a function of ankle position.

- quick release tests, carried out by a fast and sudden release of the footplate. The release is obtained by switching off a holding magnet, connected between the force transducer and the footplate. Measurements included the isometric force just before the release and angular displacement, from which angular acceleration is calculated.

For these two tests, a 750 N load cell with a sensibility of 2,5 mV / V / F.S. is used.

- Range of motion and passive tension measurements obtained from pseudo isokinetic movements operated manually. In this test, a 125 N load cell with a sensibility of 2mV / V / F.S. is attached on the lower side of the footplate.

In order to provide repeatability and comparability between the measurements, the position of the subject has to be standardized. Consequently, the ergometer structure must be compliant to the subject's morphology and thus adjustable in many ways. Furthermore, quick-release and isometric contraction tests are done with the subject seating while the passive force measurements are made with the subject lying. This leads us to build a chair with a modular architecture.

After validation experiment, the ergometer device will be transported in places as rehabilitation centers or sport halls, in order to test different population in their usual environment.

EFFECT OF STRETCHING VELOCITY ON ACTIVE AND PASSIVE FORCE ENHANCEMENT

Rácz, L., Váczi, M., Costa, A., Sáfár, S., Tihanyi, J.

Semmelweis University, Faculty of physical Education and Sport Science, Budapest, Hungary

Introduction. It is well known that the eccentric force increases in a function of stretching velocity. Also it is demonstrated on muscle fibres, animal and human muscle in vivo that after stretch the muscle force remained elevated for some seconds called passive force enhancement (PFE). In the previous studies relatively low stretching velocities was used (Lee and Herzog 2002). The aim of this study was to investigate the effect of low and high stretching velocity on both active (AFE) and passive force enhancement.

Material and methods. Six physically active male subjects were recruited in the study. The subjects were seated in a dynamometer (Multi-Cont II) and the shank above ankle was attached the lever arm of the servo motor. Isometric knee extension was performed by the subjects at a joint angle of 30, 40, 50 degrees, respectively. Muscle stretch was carried by applying 30/s, 60/s, 120/s and 300/s constant angular velocity flexing the knee between 30 and 50, 40 and 50, respectively. Also, eccentric contractions were carried out between 30 and 40 followed by a second stretch between 40 and 50 with 200 ms delay. EMG activity of vastus lateralis and biceps femoris was also measured.

Results. The peak eccentric torques enhanced gradually in a function of the increasing velocities during the first stretch and AFE was significantly greater at 300/s than at 30/s. Having finished the first stretch the torque dropped to the respective isometric torque level when 30/s, 60/s and 120/s velocity was applied. When 300/s was applied the torque after 200 ms was lower with 12.9 % compared with the respected isometric torque. The decrease in torque during 200 ms interval was not gradual. We experienced oscillating decrease and increase during this period. The amplitude of the oscillation increased in a function of the increasing velocity. The peak torques at second stretch increased in a function of the increasing stretching velocity, however, the trend of the enhancement was lower comparing with those of the first stretch. The iEMG activity of vastus lateralis and biceps femoris did not show significant differences comparing the first and second stretch and 200 ms interval between the two stretches.

Conclusion. The results of the present study confirm that the active force enhancement is depending on the stretching velocity. The applied stretch did not elicit passive force enhancement when relatively low stretching velocities are applied at the ascending limb of the torque-angle curve in agreement with the previous findings. It seems that high stretching velocity decreases the passive force after the stretch which decreases the peak torque in turn during the subsequent second stretch. Because the iEMG activity did not change, neural inhibition can be excluded. It seems that the oscillation manner of the torque decrease can be attributed to the visco-elastic properties of the muscles.

DIFFERENCES IN KINEMATICS, KINETICS AND ELECTROMYOGRAPHIC ACTIVATION PATTERNS BETWEEN PREPUBESCENT BOYS AND ADULT MEN DURING DROP JUMPS

Lazaridis, S., Hadjixenofontos, M., Giannakos, A., Charitonidis, C., Tsatalas, T., Gollhofer, A., Kotzamanidis, C.

Laboratory of Coaching , Greece

Relevant studies in the past examined the neuromuscular strategy of lower limb during a stretch shortening cycle performance (Arampatzis et al 2001). However, this performance has not widely studied in prepubertal population. For this reason the purpose of this study was to identify the neuromuscular differences in a stretch shortening cycle task between adults and prepubescent. Ten prepubertal boys (8-10 years of age) and 10 untrained male adults (23-28years of age) were asked to perform five drop jumps from 0.2m (DJ20) and 0.4m (DJ40). The instrumentation included six M3 cameras with Vicon 612 motion analysis system for the 3-D kinematics of the lower limbs, a Bertec 4060 force plate for the ground reaction forces (GRF) and a BTS Τelemg EMG system for the measurement of the electrical activity of m.gastrocnemius, soleus, tibialis anterior and peroneus longus. The instruction given to the subjects was to perform the highest possible jump. A two factor ANOVA with repeated-measures was used for statistical analysis($p<0.05$). Adults jumped higher in both heights,had shorter braking, propulsion and total contact time periods.Adults presented higher average and peak vertical ground reaction forces, but smaller values when these were normalized to body weight in braking phase, and it took longer time for them to reach peak vertical GRFs compared to prepubescent. The amplitudes of the pre-activation EMG levels of all muscles were greater in the prepuberts. In addition, prepubescents activated earlier their calf muscles before landing compared to adults. Adults displayed higher EMG activity of the agonist calf muscles at both phases of ground contact (braking/propulsion), but the co-activation of tibialis anterior was greater in prepubescents. Prepubescents compared to adults, exhibited reduced knee and ankle flexion at initial foot contact, more flexed angles at these joints at the knee deepest position and as a result greater range of motion over these two joints, mainly in DJ40 condition. Finally in both heights, prepubescents presented higher knee and ankle angular velocities than adults did in the braking phase, but smaller angular velocities in the same joints in the propulsion phase. The obtained results indicate that prepubescent followed different strategy during a stretch shortening cycle task compared with adults. It seems that preactivate earlier their muscles prior to contact. The fact that children landed with smaller joint angles during initial contact and succeeded higher normalized impact forces and preactivation EMG levels, could be attributed to learning factors. The higher joint angular velocities and the deepest joint flexion observed in children during braking phase could be caused by the higher elasticity of their muscle –tendon unit (Kubo et al 2001).On the contrary, the lower achieved height, agonist activity and higher antagonist activity observed in children during and after propulsive phase could be attributed mainly to the children's immature neuromuscular system (Quatman et al 2006).

BREASTSTROKE LEG MOVEMENT PATTERNS IN DIFFERENT TECHNICAL EXERCISES

Alves, F., Louro, H., Cardoso, L., Veloso, A.

Faculty of Human Kinetics, Portugal

Technical exercises using only the legs cycle are very often used in swimming training sessions. The aim of this study was to compare the kinematical characteristics of the breaststroke kick in partial technical drills to free swimming and its influence in body position in age group swimmers. Fifteen swimmers (age: 12.07 ± 1.84 years; height: 155 ± 0.12 cm; weight: 46,71 ± 12.70 kg) performed 3 x 25m at maximal velocity with full recovery, the first in breaststroke (BC), the second using a kick drill with the arms and hands in a glide position (SP), and the third using a kick drill with the hands supported on a kick board (CP). Each swimmer was filmed underwater by two synchronized fixed cameras for digitising and 3D kinematical analysis (APAS). A 30 points control volume (4.42m:1.41m:2.00) defined a global reference system. Ten body landmarks were manually digitised, corresponding to a 7-segment model of the human body, head and arms excluded. Swimming velocity (SV), distance per stroke (Ds) and stroke rate (Sr), were calculated from the intracycle kinematics of the body center of gravity (CG). Maximal trunk inclination decreased significantly from BC to SP and CP swims. Hip maximal vertical position increased from BC to CP. When comparing the two stroke drills we found that stroke frequency were higher for CP (0.88 ± 0.09 vs. 0.78 ± 0.12), keepeing SP a very close frequency to BC. The occurrence of maximal trunk inclination in reference to total leg cycle duration also varied: 57.8%, 50.4% and 30.4% of total duration in, respectively, BC, SP and CP. Average foot resultant velocity during the insweep was lower in CP, probably linked to the higher stroke frequency observed in this condition. The main conclusion of this study is that breaststroke kick drills with the board seem to change in a rather important degree the kinematics of the leg cycle, especially body undulation. This effect is much weaker in the kick drill without arms in gliding position. Swimming with the kick board constrains the body to assume a much flatter position in the water, increasing maximal hip flexion, which is an undesirable movement characteristic since it increases frontal drag. Moreover, the anticipation of the moment when maximal trunk inclination occurs may have negative influence on the synchronization of breathing with the leg cycle, with possible interference with free swimming in young swimmers who have not yet attained a high level of movement stability. Nevertheless, CP can be useful in stimulating higher stroke rates and in inducing specific leg power development.

A 30-MINUTES TRAINING IS SUFFICIENT TO LEARN THE BASIS OF MARTIAL ARTS FALL TECHNIQUES TO REDUCE FALL SEVERITY IN SIDEWAYS FALLS

Weerdesteyn, V., Groen, B.E., Duysens, J.

Sint Maartenskliniek, Netherlands

Falls are a major source of health problems in the elderly, including 90% of hip fractures. Although, fall prevention programs can reduce fall incidence successfully, falls still occur. Hip fracture risk is dependent on both bone strength and mechanics of the fall (1). Therefore, fracture prevention interventions should involve maintenance of bone strength, reduction of falls and fall techniques to fall safely. It has been shown that martial arts techniques significantly reduce hip impact forces in experienced fallers (2). Furthermore, practice of these techniques was feasible in elderly (3). However, it is not known yet whether extensive training is required to benefit from these techniques. The purpose of this study was to determine whether MA techniques can reduce hip impact forces in naive subject after a brief training. Ten young adults without prior experience in MA participated in a 30-minutes training in sideways MA fall techniques. Following this training, MA techniques with and without use of the arm to break the fall (MA-a and MA-na, respectively) were compared with the common way of sideways falling, in which the outstretched arm is used to block the fall (Control). Hip impact force and hip impact velocity were obtained for each fall. Compared to the Control condition, hip impact force was reduced in the MA-a and MA-na falls by 16.7% ($p=.001$) and 15.5% ($p=.006$), respectively. Impact velocity was 6.7% lower than in the Control condition ($p=.003$ and $p=.38$ for the MA-a

and MA-na falls, respectively). There were no significant differences between MA-a and MA-na falls. The present results mirror those previously obtained in experienced fallers, except that the reduction in forces and velocities was nearly twice as large in the experienced fallers (2). The finding that people can learn these techniques during a brief training, is very promising for the use of these techniques in fracture prevention interventions. Further studies are needed to investigate the trainability and effects of these techniques in elderly.

SHOE ORTHOTICS AND GROUND REACTION FORCES DURING SOCCER SPECIFIC 'OFF THE BALL' ACTIVITIES

Scurr, J., Cogger, L.

University of Portsmouth, United Kingdom

Soccer is a dynamic activity with relatively high injury incidences (17-24 injuries per 1000 hrs1). Lower extremity injuries account for over 75% of soccer injuries and approximately one third of these are overuse injuries.2 Overuse injuries are often the result of exposure to high loads, caused by incorrect biomechanical alignment and inappropriate footwear or terrain3. Hawkins et al.4 reported that running, turning, jumping, landing and other non-contact actions accounted for 42% of all injuries sustained by professional soccer players. During sporting activities, the ability of shoe orthotics to cushion high-frequency impact forces is beneficial to the athlete for reducing activity-related injuries. The purpose of this investigation was to assess the effect on GRFs of commercially available foot orthotics designed for use by soccer players, during various soccer specific, 'off the ball' activities. Eight male soccer players completed 6 trials over a force platform, during five activities; walking (1.5 m.s-1), jogging (3 m.s-1), sprinting (maximal), turning (180°) and jumping (maximal), with and without a Superfeet Blue Trim-to-Fit orthotic. Subjects wore new astro turf trainers and the force platform was covered by an astro turf runway (Evergreens, UK; 4.37% absorption property). Results showed that the orthotic significantly reduced impact peak force by 11% of body weight (BW) during walking (p=0.03). In all activities peak medial force was reduced by 1% BW with the orthotic, but this was non-significant. Vertical loading rate, time to impact peak, first active vertical and propulsive peak, peak anterior and posterior force, peak lateral force and stance time all demonstrated no significant differences during any activity with the orthotic. The effectiveness of the orthotic was subject specific, with some subjects demonstrating no effect and others a significant positive effect across a number of force variables and activities. The activity that demonstrated the greatest positive effect with the orthotic intervention was walking. Subject specificity may be due to anatomical, biomechanical and technical differences between individuals. Future research should combine kinetic and kinematic techniques to monitor rearfoot movement with orthotic intervention, within subjects, during soccer specific activities.

THE INFLUENCE OF SNOWBOARD MATERIALS AND DIFFERENT STANCE ANGLES ON THE MUSCLE ACTIVITY DURING BASIC TURNS

Zinzen, E., Hagman, F., Van Gheluwe, B., Dauwe, W., Bossu, J., Op de Beeck, P., Clarys, P.

Vrije Universiteit Brussel, Belgium

Introduction.

The development of snowboarding in the sixties – it was called snurfing at that time – was not an immediate success due to the reluctance of the ski areas in admitting snowboarders on the slopes. It is only from the nineties that snowboarding is considered as a full skiing equivalent with even some predicting that snowboard will be more popular than skiing by 2012 (Coeckelberghs and Urkens, 2000). Quite some studies evaluate the injury risk of snowboarding (Bladin et al., 2004; Made and Elmqvist, 2004, …) but no international publications towards muscle activity were found.

Purpose.

The purpose of this study was to investigate the activity of different leg muscles when using different snowboard material (bindings, boards) and in different stance angles on the board during basic turns. This information may be used to give advice to beginners during several teaching processes.

Methodology.

The investigations took place on a covered slope (18%) in Peer – Belgium (Snowvalley), on a standardized track consisting out of a slalom with 3 backside and 3 frontside turns.

6 test conditions were measured in a randomized order: freestyle board compared with a freeride board; classic strap bindings compared to cap strap bindings, forward stance compared to duck stance. Each condition was performed 3 times (9 back- and 9 frontside turns) by 12 experienced snowboarders.

Muscle intensity was measured by means of portable EMG equipment (Becker-Meditec) with 8 channels. Investigated muscles were the m. rectus femoris, the m. biceps femoris and the m. gastrocnemius lateralis on both legs. The residual channels were used for a goniometer on the knee of the front leg and for a manual synchronization button.

Integrated EMG (IEMG) was calcultated for each experimental condition and for every turn (back- and frontside). Normalisation in time and amplitude (highest peak) were performed. For the quantitative analysis the IEMG variables were checked for normality and comparisons between test situations were done with paired t-tests. A qualitative analysis was performed with the IDANCO technique as described by Clarys et al. (1988) also.

Results.

Quantitative analysis: no significant (all p>0,05) differences were found between the different test conditions for both back- and frontside turns.

Qualitative analysis: In general low muscle intensities of the measured muscles were noted for both turns normalised to the highest peak. The EMG curves during the movement were each time considered as identical according to the IDANCO system.

Discussion and conclusion.

The investigated snowboard situations did not provide different muscle activities. Therefore the material choice for beginners seems to be less important in view of muscular activity. These results however were obtained with experienced snowboarders. It is possible that real beginners have different muscle tones and patterns. Therefore further research with beginners is planned in the near future.

VELOCITY PROFILES AND STRIDE PATTERN IN PREPARATION FOR HOP-TAKE-OFF IN ELITE TRIPLE JUMPERS

Niessen, M., Jürgens, A., Hartmann, U.

Technical University Munich - Faculty of Sport Science, Germany

In contrast to well known statements regarding dependency of achieved triple jump (TJ) distances upon available horizontal velocity in run-up in general (e.g. Hay 1992) and each of the take-offs in particular (e.g. Niessen et al. 2004 & 2005) there is scarcely information about velocity profiles and stride pattern in preparation for hop-take-off in elite TJ.

Multiannual we compiled competition-velocity profiles (CVP) of among several male elite TJ during outdoor-seasons (Niessen et al. 2004). Velocity (v) was registered by a laser distance device (LDM 300C), placed in approach direction and focussed on the lower back of the athlete. Speed curves were edit and filtered by 67pt moving average of distance & speed (Sport 3.9, LavegDrei). Additional 2D-kinematic video-analysis of side movement was performed (Niessen et al. 2003). Descriptive and group-specific parametric statistics were applied.

Elite TJ (n=85: >16 m) achieved, independent to technique alternatives, maximum velocities (vmax) of 10.1±0.1 m/s without a significant coherence to effective distance (Deff: official plus toe-to-board distance) (Niessen et al. 2005). There were several significant linear correlations between vmax and position of vmax (Posmax) (r=0.65, p≤0.001), Posmax and difference of Posmax to take-off position of 2nd last (r=0.95, p≤0.001) resp. last stride (r=0.98, p≤0.001) as well as Posmax versus CVP 1m (r=0.20, p≤0.05) resp. CVP 0m (r=0.28, p≤0.01) to board. The pattern of 2nd and last stride in TJ >16.5 m was "long (2.5 m)-short (2.3 m)". Average difference of toe-to-board was 0.11±0.07 m for mean Deff of 16.91±0.35 m.

An important factor in top-level TJ competition performance is the execution of a fast, accurate and controlled approach run, even when wind conditions are inconsistent. Maximum velocity of >10 m/s needs to be achieved between 6 and 7.5 m during 3rd last stride to adjust stride pattern (set variable 2nd last stride) in order to hit the board accurately and relatively flat at hop-take-off. The faster the athlete (e.g. Speed-Jumper), the broader away Posmax and the more precisely steering on stride pattern "long-short" with less speed drop to hop-take-off due to time pressure. Somewhat slower athletes (e.g. Twin-Arm Jumper) have also to render more accurate pattern of the last two strides to compensate distance pressure due to nearer Posmax.

A TEST OF ELLIOT'S MULTIPLE GOAL MODEL AMONG ATHLETES PARTICIPATING IN THE XVTH MEDITERRANEAN GAMES 2005

Duda, J., Castillo, I., Balaguer, I.

The University of Birmingham, United Kingdom

Elliot and colleagues have argued for the extension of dichotomous achievement goal frameworks (Dweck, 1999; Nicholls, 1989). Specifically, they have proposed a 2 x 2 achievement goal model (Elliot & McGregor, 2001) which assumes that performance (ego) and mastery (task) goals should be bi-furcated into four distinct orientations, namely Mastery Approach (Mapp), Performance Approach (Papp), Mastery Avoidance (Mav), and Performance Avoidance (Pav) goals. The purpose of the present study was to test, among competitive athletes, a model of theoretically hypothesised antecedents and consequences of the four goal orientations. Based on Elliot (1999), perceived competence (PC) was posited to positively predict approach forms of achievement goals and be negatively associated with avoidance goals. Fear of failure (FoF) was postulated to be an antecedent of avoidance achievement goals and also a performance approach goal. With respect to consequences, it was assumed that the four achievement goals would differentially relate to indices of subjective well being. Mapp goals were hypothesised to predict positive indicators of well-being while avoidance goals were expected to correspond to poorer functioning. Participants were 200 athletes (103 males, 93 females; M age = 24.7 years) participating in the XVth Mediterranean Games 2005 in Almeria, Spain. They completed a multi-section questionnaire assessing their achievement goals (Conroy et al., 2003), fear of failure (Conroy et al., 2002), perceived competence (McAuley et al., 1989), self esteem (Rosenberg, 1965), satisfaction with life (Diener et al., 1985), and degree of emotional/physical exhaustion experienced in their sport (Raedeke & Smith, 2001). The assumed underlying measurement model for each of the scales was tested via confirmatory factor analysis and support was garnered for the factorial validity of the measures. All scales exhibited acceptable reliability except for the Mapp and Mav goal subscales (alpha = .54 and .62, respectively). Results of the SEM analysis revealed the model to provide a acceptable fit to the data (χ2 [18]=2.64, p<.001; RMSEA=0.06; NNFI=0.96; CFI=0.98). However, the predicted paths between PC and the achievement goals were not found to be significant and the Pav goal did not predict any of the well-being outcomes. The model explained 26%, 43%, and 29% of the variance in life satisfaction, self esteem, and emotional/physical exhaustion, respectively. In total, the results provided partial support for Elliot's framework in the competitive sport setting.

SIMPLE AND ELECTIVE REACTION TIME AND INTENSITY OF THE EFFORT IN BASKETBALL

Sillero Quintana, M., Carracedo, G.

Universidad Politécnica de Madrid, Spain

Visual reaction time (RT) is one of the more demanded visual skills in basketball (1). Reacting 0.01 seconds earlier could provide the player with the ball or it could be the time that the defender needs to be aware of a pass, allowing him/her to intercept the ball. Therefore, basketball players need short reaction times in order to improve their proficiency (2) not only in simple actions, in which single decision to be taken, but also in elective actions, which require a cognitive process to take the better decision among several suitable actions.

Most of the studies found in literature relating RT to effort intensity have been carried out by using ergometers (3,4) to cause the subject fatigue just before performing the test. In our study, we tested the visual single and choice reaction time (SRT and CRT) with an application designed in SuperLab 2.0.1 (Cedrus Corporation, San Pedro, CA, USA) under real training conditions in 10 amateur basketball players aged between 21 and 32 years, who had normal vision playing without glasses or with contact lenses.

The target for the SRT test was a 4 centimetres spot, which changed from green to red and for the CRT were three randomized images of the same player dribbling with a ball, right or left, or bouncing forward. In CRT, the subject had to press "z" when the image showed the player turning "left", "-" when he turned "right", or "space bar" when he bounced forward. The test was carried out four times: before warming up, after a 10-minutes warming up, after performing a circuit training at moderate speed and after performing the same circuit at maximal speed. As indicator of the effort intensity, the heart rate (HR) was recorded with a CAT EYE CD-1000 heart rate monitor.

The results showed a direct relationship between HR and both SRT and CRT, and they indicated significant differences for HR, SRT and CRT only when the subject performed the circuit at maximal speed compared with the other three conditions.

Our results point out prolonged SRT and CRT after maximal efforts, which could have influence on the basketball player performance. The differences for the CRT could indicate that the lower performance under high intensity efforts (i.e. at the end of the match) could be due to lowlier decision making processes.

APPLYING THE 'FIVE ASPECTS OF YOUR LIFE' MODEL IN A SPORTING CONTEXT: THE USE OF A COGNITIVE BEHAVIOURAL THERAPY ASSESSMENT TOOL IN ATHELTICS, CLAY TARGET SHOOTING AND KARATE

Cecil, S.

English Institute of Sport, United Kingdom

This study examined the utilisation of the 'five aspects of your life' model (Padesky & Greenberger, 1995) in three case studies with international performers. The model proposed that problems are studied by investigating thoughts, moods, behaviours, biology and environmental factors. Padesky & Mooney (1990) have demonstrated how this model can be utilised in the case conceptualisation phase of cognitive behavioural therapy (CBT). The aim of the model is to make the athlete aware how any of the five aspects can impact on each other: "They all sit inside our environment and interact with it as well. What we feel is closely connected to our thinking, our behaviour, our biology and our environment" (Padesky & Mooney, 1990, pg 13), secondly to make the client understand how changing one of the aspects can impact on the others getting 'better'. When applying the model in sport, socratic questions along with guided discovery are used to uncover 'hot' automatic thoughts followed by formulating the remainder of the five aspects. Alternative thoughts are then identified to illustrate the potential for a different five aspect model. Socratic questioning involves asking questions that the client can answer, which draws the client's attention to relevant info that might not be in the client's focus. (Padesky, 1993a). The results are two models/cycles illustrating how different thoughts trigger different moods, behaviours and biology. The model was utilised with three international performers who participated in athletics, clay target shooting and karate. An illustration from K, an international Karate performer shows how these different cycles manifested themselves. Thoughts about hurting his opponent, led to feeling angry, his technique going out of the window and his body feeling tense. In comparison thinking about being tactical, led to feeling calm and positive, throwing the right moves and stomach turning. The environmental factors for each model were different opponents. All three athletes reported a 'eureka' like feeling when they realised how their thoughts directly impacted on the other aspects of the model/cycle. Some reported increased self awareness and increased perceptions of control and some reported a similar sense of relief that Padesky & Mooney (1990) reported. It is hoped this report may encourage others to utilise and research the efficacy of this CBT technique.

DELIVERING PSYCHOLOGY SERVICES TO ELITE SPORTS IN GERMANY - EFFORTS AND TRENDS

Neumann, G.

German Federal Institute of Sport Science, Germany

For a long time, applied sport psychology was not well established in the field of elite sports in Germany. Many reasons can be named responsible for the lack of systematic use of psychological training: prejudices, missing or false information about psychological training methods and their potential for performance enhancing, structural deficits, missing information about the costs, and problems how to contact an eligible sport psychologist are just some of them. In the last years however, the public opinion of the benefits of sport psychological work for reaching top performances seems to have changed a lot - the status of sport psychological work has risen and more top level coaches and athletes take advantage of sport psychological counceling and promote their effectiveness.

But how and why did this happen? One reason for this positive trend can be seen in the combined effort of three institutions that have started in 2002 to systematically reduce the existing deficits: the German Federal Institute of Sport Science (BISp), the German Sport Federation (DSB) and the German Association of Sport Psychology (asp). Without doubt, BISp has been leading in initiating, organizing, coordinating and funding sport psychological research and counceling of elite sports in Germany. Within the last years, the Federal Institute has been established as the top "go to" address for sport psychologists, federations, coaches and athletes.

Especially the following means have contributed to the upwind of sport psychology in elite sports:

2002>: launch of the website "http://www.bisp-sportpsychologie.de": (a) BISp offers an information portal for the fast and easy access to applied sport psychological issues and topics for elite sports, (b) with the help of a sport psychologist expert pool, experienced and top quality addressees for sport psychological counseling and training are provided, (c) quality ensurement of listed sport psychologists: applying persons must fulfill demanding criteria, (d) quality ensurement of the psychological work in elite sports: for the funding of sport psychological projects, only sport psychologists listed on the BISp-expert pool are accepted, (e) regulation of fees for sport psychological services by using a "sport psychological fee scale" as obligatory for federal funding.

2002-2004: the amount and duration of sport psychological counceling for potential Olympic athletes could be increased enormously by funding more than 30 projects in 23 different Olympic summer sports by BISp and DSB.

2005>: sport federations have started to finance sport psychological work (partly) by themselves by considering these services within their yearly budgets.

For the further acceptance of sport psychological work it will be crucial to secure its quality and ethical standards - in particular, to make clear the quality differences between so-called "mental" or "motivation" coaches as compared to sport psychologists.

EFFECTS OF MENTAL AND PHYSICAL FATIGUE ON A COGNITIVE TASK WITH UNPREDICTABLY CHANGING DEMANDS

Tamm, M., Kreegipuu, K., Jürimäe, T.

University of Tartu, Estonia

In task switching experiments, performance is generally slower after a task switch than after a task repetition. However, mental fatigue tends to slower down speed of processing information and the percent of mistakes increases (Lorist, Klein, Nieuwenhuis, De Jong, Mulder, & Meijman, 2000), whereas physical exertion may actually facilitate switching from one task to another (Pesce, Capranica, Tessitore & Figura, 2003). Thirteen healthy non-smoking college age men participated in the study. The subjects were divided into a sports group (SG) and a control group (CG). In a physical exertion task the subjects exercised 45 minutes on a cycle ergometer at approximately 80 % of individual heart rate threshold. To induce mental fatigue, a 45 minute long number comparison task on a computer was accomplished. A cognitively demanding task with randomly (after 3-6 repetitions) changing test question leading observers to attend either structural or semantic properties of numbers displayed on the screen was conducted before and after the fatigue experiments. The performance difference in time or errors between switch (i.e., new) and nonswitch (i.e., repeated) trials reflects additional cognitive load and is analyzed in switch costs (SC). The temporal SC was bigger in mental (787.9 ms) than in physical (517.7 ms, p=.012) task. Interaction between group, test and testing time occurred as the only condition where the SC did reduce, was the physical test for the SG (p=.014). In analyzing the accuracy of the task, the results showed that although responses to the second similar question tended to be more correct than responses to the new question, the difference was bigger in post-test situation. Also, a significant rise in the percentage of correct answers was observed after the physical fatigue experiment (p<.05), whereas after the mental fatigue experiment an opposite effect was present. SG remained relatively more stable throughout the test whereas the CG got relatively heavily disturbed in responding to a new question in the mental fatigue procedure [group x test x sequence x time, F(1, 11)=5.55, p=0.038]. Moderate physical exercise seems to facilitate cognitive processes whereas mental fatigue has an opposite effect. Moreover, facilitation of information processing depends on physical fitness of the subjects.

ACUTE MOOD AND ANXIETY EFFECTS OF QIGONG EXERCISE

Johansson, M., Hassmén, P., Jouper, J.

Department of Health Sciences & Department of Psychology, Sweden

Introduction

Qigong is a low intensity activity that uses slow movements, deep breathing and a relaxed focused mind for health-benefits. Regular qigong exercise has positive effects on health and wellbeing. Less studied than chronic effects are acute psychological effects of qigong exercise. We predict, however, that acute effects on mood and anxiety will be more positive after qigong exercise than in a non-physically active control group.

Method

Fifty-nine individuals (51 women & 8 men with a mean age of 51±13 years, having practiced qigong for 5±3 years) participated. Individuals were randomized to either a Qigong or Control group, according to age, exerciser/instructor and sex. The Qigong group performed thirty minutes of qigong exercise whereas the Control group listened to a thirty-minute lecture. Mood and anxiety levels were assessed by completing the six subscales of the Profile of Mood States (POMS), and also the State and Trait Anxiety Inventory (state form) immediately before and after the interventions.

Results

No significant differences were found between the Qigong and Control group at pretest. Separate Time (pre–post) x Group (qigong–control) mixed ANOVA's were performed. All seven analyses revealed similar results with main effects of Time significant, Group effects non-significant, and Time by Group effects significant (all ps <0.05) except on POMS-Confusion. T-tests revealed significant (ps<0.01) reductions from pre- to post-intervention in Tension, Depression, Anger, and Fatigue in the Qigong group, but not in the Control group. Vigor increased significantly in the Qigong group, but was unchanged in the Control group. Confusion was reduced in both the Qigong and Control group. State Anxiety decreased, but only significantly so in the Qigong group.

Discussion

Our hypothesis that reduced anxiety and improvements of mood would result from Qigong exercise, but not in the Control condition (lecture) was supported, except for scores on the Confusion subscale that was also significantly reduced in the Control group. These results show similar acute psychological improvements found in other forms of exercise (jogging, yoga, tai chi, e.g., Szabo, Meskó, Caputo, & Gill, 1998). Although it is known that exercise may alleviate stress and improve psychological health, a large number of individuals are not physically active. One reason for this may be that more intense forms of exercise, such as jogging or aerobics, do not suit everyone. Qigong may offer a low impact alternative to those finding more traditional exercise too strenuous. The result of this study suggests that health professionals can include qigong exercise among activities recommended for psychological benefits.

HOW DO YOUTH FOOTBALL PLAYERS CONSTRUCT THEIR ENVIRONMENT TO ACQUIRE EXCEPTIONAL PERFORMANCE?

Saito, S., Kitamura, K., Nagayama, T.

Tohoku University, Japan

It is popularly believed that talent are inborn and inherent, and that those players with inborn talent acquire exceptional performance easily．But talent are build through daily cultivated discipline in years (Ericsson,1996). In addition, exceptional levels of talent development require certain types of environmental support, special experiences, excellent teaching, and appropriate motivational encouragement (Bloom,1985). Construction of the environment, or environmental self-regulation plays an important role as a contributing factor for talent development and athletes' sport experiences. Environmental self-regulation is the process of active monitoring, adjustment and readjustment to environmental condition. The purpose of this study is to clarify the process of personal active monitoring and adjusting to environment by youth elite athletes in order to acquire exceptional performance.

The participants were 15 youth elite athletes and their parents in Japan. Their average age was 17.2 years old. Each participated in a semi-structured interview lasting approximately 1 hour. The interviews were focused on the players' environment and the process of deliberate practice during the period from the players' early childhood to the high school age .The interview data was transcribed verbatim and analyzed using inductive procedure for analyzing unstructured qualitative data (Côté, salmela, Baria, & Russell, 1993).

As a result, a total number of 78 meaning units were gathered related to the contextual component from total of 137 gathered from 15 youth elite athletes and 8 parents. The inductive analysis process resulted in regrouping these interview transcripts into 3 definition categories: change in sense of purpose, re-setting of the challenge, and acquisition of the support. They made the practice environment based on a clear sense of their goal and purpose at each stage of development. They feel the importance of addressing the problem on their own way in order to improve self performance. And they set the practice environment continually in order to overcome the more difficult challenge. Moreover they constructed of the most suitable environment for themselves by acquisition of the support from the others. The elite athletes monitored and adjusted the practice environment actively for acquiring or improving personal performance. The sense of environment for the athletes depended on the way they perceived, and constructed the environment. Furthermore, the notion of "environment" is as it is perceived rather than as it may exist in objective reality.

THE INFLUENCE OF COACH'S BEHAVIOUR ON THE PERCEPTION OF THE MOTIVATIONAL CLIMATE IN A TEAM SPORT

Viviani, F., Robazza, C., Bui, C., Bortoli, L.

University of Padua and University of Udine, Italy

The interaction between the individual motivational orientation and the motivational climate created by a coach can influence the athlete' intrinsic motivation, emotion, perception of competence, and sport participation. A purpose of the present study was to examine sex and age differences in the motivational orientation of team athletes. A second objective was to verify the influence of the athlete's perception of coach's behaviour on motivational orientation and motivational climate. The Task and Ego Orientation in Sport Questionnaire (TEOSQ; Duda et al., 1995), the Perceived Motivational Climate in Sport Questionnaire-2 (PMCSQ-2; Newton et al., 2000), and the perception of several positive and negative behaviours of the coach during practice and competition were administered to female (32 senior and 29 junior) and male (20 senior and 21 junior) basketball players. MANOVA analysis (followed by univariate ANOVAs) was performed on the TEOSQ and PMCSQ-2 subscale scores, with sex and age (senior and junior) as independent variables. Females were shown to be significantly more Task oriented than males, and to perceive less intra-team member rivalry. In addition, junior players reported higher scores in Task orientation than senior players. MANOVA analysis (followed by univariate ANOVAs) was also conducted on the TEOSQ and PMCSQ-2 subscale scores, with high (positive) and low (negative) evaluation of the coach's behaviour as independent variable (the median-split technique was employed to separate scores into high and low evaluation categories). Results revealed that those athletes who evaluated more positively their coach's behaviour, compared to those who evaluated more negatively their coach, reported higher scores in Task orientation and Important Role, and lower scores in Unequal Recognition. Findings support the contention that the coach's behaviour can influence either positively or negatively the individual motivational orientation and the motivational climate too.

THE EFFECTS OF PERCEIVED AND RECEIVED SUPPORT ON PERFORMANCE

Rees, T., Freeman, P.

University of Exeter, United Kingdom

Although Sarason, Sarason, and Pierce (1990) proposed that social support might affect sports performance, there have been no explicit attempts to test this proposal in relation to objective performance outcome. The purpose of the present study was therefore to examine the main and stress-buffering effects of both perceived and received support upon objective performance outcome in golf. Participants were 126 high-level male British golfers, mean age 25.2 years (SD 5.4), with handicaps ranging from +2 (national/international level) to 4 (strong club player). Recruitment of participants was opportunistic (convenience sample) but spread across various golf courses in England on the practice day preceding major competitions. Participants completed measures of perceived support, stressors, stress, and received support before competitions. Performance outcome was recorded (low scores represent high performance levels). Moderated hierarchical regression analyses revealed a significant main effect for stress upon performance (Rsqu = .10, b = .66, p = .00), with higher levels of stress associated with lower levels of performance. Over and above the variance in performance explained by stress, there were significant main effects for both perceived (Rsqu ch. = .08, b = -.83, p = .00) and received (Rsqu ch. = .07, b = -.75, p = .00) support upon performance, with higher levels of support associated with higher levels of performance. However, when perceived and received support were entered in a model simultaneously, it was primarily perceived support (and not received support) that was associated with higher levels of performance. The stress-buffering effects accounted for 2% of the variance in performance outcome, but were just non-significant (ps = .07). The results demonstrate that although both perceived and received support have a beneficial impact upon objective performance outcome, perceived support may be more important than received support. In the present study, the knowledge that others were available to provide help if needed may therefore have been more important for performance than support actually received. This observation has important applied implications for sport psychologists and coaches, and suggests that a supportive environment may need to be nurtured over time for athletes to perceive they have high levels of available support. To this end, a number of strategies might be implemented to help develop a supportive environment, including educating athletes, their coaches, family, and friends as to the benefits of social support, and encouraging athletes to be proactive in using this resource. To further develop understanding, future research could examine the psychological states that might mediate the social support-performance relationship.

IDENTIFICATION OF ATTENTIONAL FEATURES IN TOP-LEVEL FENCERS

Taddei, F., Di Russo, F., Zoccolotti, P.

University of Motor Sciences (IUSM), Rome, Italy

Introduction

Fencing is commonly regarded as a discipline that engages cognitive processes and in particular attentional effort. In fact in competition, fencers are required to face highly mutable situations which demand responses involving accuracy and fast execution.

The aim of this study is to identify and isolate attentional features in top-level fencers by comparing them to non-athletes and swimmers (a discipline requiring less cognitive effort than fencing).

Methods: The attentional tasks were selected from the Italian version of the TAP battery for attention (Zimmermann & Fimm, 1992). Three attentional tests were used 1) alertness for intensive features, 2) divided-attention and 3) go/no-go for selective features.

Subjects: Three groups of subjects were studied. Thirty top-level fencers (15 females; mean age 22.5; SD=6.25), 18 top-level swimmers (8 females; mean age 20.6; SD=2.19) and 22 non-athletes (15 females; mean age 23.9; SD=3.67).

Procedure: Participants were requested to press a button as rapidly as possible using their dominant hand and their Reaction Times (RTs) were measured in all three tests. In the alertness test, subjects responded (with or without a warning signal) when a cross appeared at the center of the computer screen. In the divided-attention test, subjects responded to two simultaneous tasks (one visual and one acoustic). In the go/no-go test, subjects responded when two of five equi-probability stimulus configurations appeared on the computer screen and inhibited their response at the appearance of the other three configurations.

Data analysis: ANOVAs, having the Group (fencers, swimmers and non-athletes) as independent factor and the median RTs, the False Responses (FR) and the Omissions (OM) as dependent variables, were performed for each test. Age was considered as a covariate. The Newman-Keuls post-hoc test was used.

Results: In the go/no-go test, the group factor for RTs resulted significant [$F(2,62)=6.16$ $p<.005$; fencers=461 ms, swimmers=509 ms, non-athletes=502 ms]. The post-hoc analysis showed that fencers were significantly faster than the other two groups. The difference between swimmers and non-athletes was non significant.

There were no other statistically significant findings across groups or tests (i.e., alertness and divided-attention).

Discussion: The study showed that the fencers' RTs were faster in the go/no-go task and this may be due to a better administration of the cognitive processes related to the decisional phase and the selection of the appropriate response. The fencers have to respond to a very complex spatio-temporal situation that requires both rapid decision and quick execution. The superiority of the fencer in the go/no-go task could also be related to better inhibition skills, which are a fundamental feature of this discipline.

THE COMPARATIVE RESEARCH OF THE RESULTS OF THE KINETIC SURVEY AMONG CHILDREN BETWEEEN THE AGE OF 5 AND THE AGE OF 6

Katalin, R., Betty, B., Rita, F., Éva, M.

Semmelweis University - Phisical Education and Sport Sciences, Hungary

The focus of interest of many specialists and phsychologists dealing with evolutionism and infant neurology has been the connection between motion and the development of intelligence and it is still today. Between 1999 and 2005 Katalin Lakatos studied the movement and state of mind of nursery school children and she found close connection between the results of the maturity tests before going to school and the kinetic surveys. Furthermore, she showed that intellectually normal children, who had lower cognitive capacity or mental trouble - serious difficulties in reading, writing and calculating - and, who achieved lower results in the test of maturity also accomplished a lower level of the kinetic survey compared to those children, who were higher on the maturity level.

During the kinetic survey, which we started in 2005, we searched the answer for the question whether there is a connection between the maturity before going to school and the complex kinetic survey - referring to the state of the nervous system worked out by the neurologist Éva Marton-Dévényi and her coworkers - or there is not. According to our assumptions the capacity examined on the ground of motion, evolutionary indices, of those children who are not mature enough to go to school lag behind the avarage capacity of the age group. We analysed the motion of 60 nursery school children from Budapest between the age of 5 and the age 6 of. We investigated the infant elemental big movements, the toddler movements, the automated oblique movements, the static- and dinamic equilibrant ability, the growing independence of the lower and upper limbs, the resilience of the children, the auditive- and movement rhytm, fine motor coordination, body schem, the spatial movements and the dominance of the eye, hand and leg. We devided the children into two groups according to the survey made by the generative educators of the nursery school. The first group unites those children, who are mature enough to go to shool, the second unites those who are not. We used groups of movement activities and within these groups we valued each activity on a five-point scale, the points were summed.

We carried out the analyses of the results with the help of the program SPSS. We used T-test for independent samples to show the difference between the capacity of the two groups. As a final result we have found connection between the maturity before going to school and the results of the complex kinetic survey. Moreover we have shown difference between the capacity of the two groups.

TASK AND EGO IN ITALIAN COMPETITIVE OLDER ADULTS: GENDER, AGE AND SPORT DIFFERENCES

Capranica, L., De Pero, R., Amici, S., Benvenuti, C..

IUSM of Rome, Italy

Introduction

The task and ego orientation seems to provide valid predictors of sport achievement and participation (Newton & Duda, 1999), with differences due to gender, age, and type of sport (Duda et al.,1995; White & Zellner, 1996). However, research in older athletes lagged behind that studied on young and elite athletes. Thus, the aim of the present study was to investigate the task and ego orientation for adult participation in sport with reference to gender, age and type of practiced sport.

Methods: To represent the total elite adult track and field (N=306) and swimming (N=125) populations with an error < 4%, 431 individuals (N=82 females and N= 349 males) were randomly pooled. They were divided into three age groups (45-55 yrs; 56-65 yrs; >65). Athletes were administered the Task and Ego Orientation in Sport Questionnaire (TEOSQ) (Duda & Nicholls, 1992), which includes seven items reflecting task-involvement and six items representing ego-involvement. A 2 (gender) x 3 (age group) x 2 (sport practice) MANOVA with two subscales of task and ego orientation as dependent variables was applied to test significant differences ($p<0.05$).

Results: Significant differences for gender (Wilk's Lambda(2.418) = 3.742, $p<0.01$), for sport (Wilk's Lambda(2.418) = 5.164, $p<0.01$) and for the gender x sport interaction (Wilk's Lambda(2.418) = 3.319, $p<0.01$) were found. Gender showed a significant effect for Task ($F(2,174) = 3.208$, $p< 0.01$) with higher values for women (3.93 ± 0.8) than men (3.67 ± 0.8). Sport practice showed a significant effect for Task ($F(2,174) = 3.991$, $p<0.01$) and for Ego ($F(2,174) = 4.729$, $p<0.01$), with swimmers always showing higher orientation (Task: 3.81±0.74; Ego: 2.80±0.85) than track and field athletes (Task: 3.55 ± 0.84; Ego, 2.32 ± 0.80). Ego orientation showed a significant gender x sport interaction ($F(2,174)= 6.410$, $p< 0.01$). Among swimmers, women showed higher values (2.40±0.90) than men (2.35±0.87) while the opposite occurred among track and field athletes, (women: 2.09±0.76; men: 2.35±0.80). No significant difference was found for age and the interaction age x gender x sport.

Discussion/Conclusion: According to the literature for younger athletes (Duda, 1989), gender differences in goal orientation emerged in older age too, with higher task orientation in female than male athletes. On the other hand, older adults did not show the age effect reported for task and ego orientation in young athletes. Furthermore, type of sport practice seems to influence task and ego orientation, with swimmers more task and ego oriented than track and field athletes.

BURNOUT IN ATHLETES: A COMPARISON BETWEEN TEAM AND INDIVIDUAL SPORTS

Gustafsson, H., Hassmén, P., Kenttä, G., Lundqvist, C.

Örebro University, Sweden

Introduction

Athlete burnout is characterized by exhaustion, sports devaluation and lack of sports accomplishment (Raedeke, 1997). It has been suggested that individual athletes are more likely to burnout than team sport athletes (Smith, 1986). Aims of this study were to determine the prevalence of burnout in young competitive athletes, and to test the hypothesis that burnout is more common in individual than team sports.

Methods

Eades Athlete Burnout Inventory (EABI: Eades, 1991) was used to assess burnout; it was distributed to 980 young elite athletes (402 females and 578 males, mean age = 17.5 years, SD = 0.95) representing 29 different sports, 23 individual (n=665) and 6 team sports (n=315). For the purpose of this study, four of the six original subscales in EABI were used: Negative Self-concept of Athletic Ability, Emotional and Physical Exhaustion, Devaluation by Coach and Team-mates, and Psychological Withdrawal and Devaluation of Sport Participation.

Results

Frequency data in relation to low (lower third), average (middle third) and high (upper third) levels of burnout was established (Maslach, Jackson & Leiter, 1996). Between 1 and 4% of the athletes scored in the upper third of the subscales. A higher frequency was found in team sports on all subscales. Especially evident was the difference in Physical and Emotional Exhaustion, with 3.5% in team sports vs. 1.8% in individual sports. A one-way MANOVA with the four EABI subscales as dependent variables and Sport (team vs. individual) as independent variable was significant, ($F(4,975)=9.42$, $p<.001$). Follow up analyses, using Bonferroni adjustments, showed significantly higher values in team sports compared with individual sports for Physical and Emotional Exhaustion ($F(1,978)=6.29$, $p=.012$) and Devaluation by Coach and Team-mates ($F(1,978)=32.69$, $p<.001$).

Discussion/conclusion

In contrast to what earlier has been suggested, our results show that athletes from team sports display higher burnout scores than individual sport athletes. Even if the differences are small, the higher frequency of team sports athletes with high levels of Physical and Emotional exhaustion, which is considered the core dimension of burnout, highlights the need for addressing the issue of burnout also in team sports.

RELATION OF PLATELET MONOAMINE OXIDASE (MAO-B) ACTIVITY TO THE EFFECTS OF MENTAL AND PHYSICAL FATIGUE IN COGNITIVE TASKS

Kreegipuu, K., Tamm, M., Paaver, M., Jürimäe, T., Allik, J., Harro, J.

University of Tartu, Estonia

A possible biological marker of the performance and mental (MF) or physical fatigue (PF) in cognitive tasks, monoamine oxidase isoenzyme B (MAO-B) activity in platelets, was investigated. Platelet MAO activity reflects the capacity of central serotonergic system and has been shown to correlate negatively to sensation seeking, monotony avoidance and impulsiveness. Participants were 13 non-smoking men (mean age 20.6±2.7 years, BMI 22.3±1.7 kg m-2) who were at least moderately fit (VO2 max kg-1 57.1±13.5 ml min-1 kg-1). MF and PF were induced either by 45 minutes of a simple but attentionally demanding number comparison task or cycling on an ergometer (at about 80% of heart rate of an individual anaerobic threshold), respectively. Effects of fatigue were studied in a simple manual reaction time (RT) task in which the onset of motion was detected. In every experimental session, ratings of perceived fatigue (BCR10, Borg, 1998) were asked before and after and ratings of perceived exertion (BRPE, Borg, 1998) after fatigue-inducing tasks. The mean ratings of fatigue on the BCR10 scale showed an increase after both tasks: in the MF condition the ratings rose from 1.6± 0.9 in the pre-task to 3.5±2.1 in the post-task condition (t=-3.81, p<.01) and in the PF from 1.1±0.8 to 3.9±2.2 (t=-4.57, p<.001), respectively. Post-test BCR10 ratings did not differ between the MF and PF condition (t=-0.62, p=.54). Also the BRPE ratings were similar for the MF and PF conditions (13.5±1.5 after the mental task, and 14.3±2.5 after the cycling, t=1.22, p=.25). Post-test ratings correspond approximately to moderate or somewhat strong fatigue (BCR10) or somewhat hard exertion (BRPE). For RT, the interaction between the type of fatigue and the testing time (before or after the strenuous procedure) was statistically significant (F(1, 12981)=11.1, p<.001). There was a considerable rise in the RT after the MF procedure, whereas after the physical experiment an opposite effect was seen which remained statistically insignificant. Subjective ratings of fatigue and performance in the RT task were related to platelet MAO-B activity measured radioenzymatically with beta–phenylethylamine as the substrate. Lower MAO-B activity associated with higher ratings in the BRPE scale in both, the MF and PF task (r=-.69, p=.009 and r=-.63, p=.021, respectively). Perceived fatigue related to MAO-B activity only in the physical post-test (r=-.62, p=.024). Also the simple RT tended to correlate negatively with MAO-B activity, although the relation became statistically significant only in the mental post-test (r=-.77, p=.002). Thus, participants with lower MAO-B activity (and possibly central serotonergic capacity) tended to rate their feeling of fatigue and difficulty of the experimental procedure higher.

PERCEIVED POSITIVE GENERAL AND PERCEIVED INFORMATIONAL TEACHER FEEDBACK IN PHYSICAL EDUCATION: STABILITY EFFECTS AND RELATIONS WITH INTRINSIC MOTIVATION OVER A TWO-YEAR PERIOD

Koka, A., Hein, V., Pihu, M.

University of Tartu, Estonia

Introduction

Research in the field of physical education (PE) have shown that the perceived positive general teacher feedback tends to be a stronger predictor of students' intrinsic motivation than perceived informational feedback (Koka & Hein, 2003, 2005). No study, however, has determined how students' perceptions of feedback might change or exhibit stability over time. The aim of this study was to examine the stability of the perceived positive general feedback and informational feedback, and the influence of these constructs on students' intrinsic motivation in PE over a two-year period. It was expected that perceived positive general feedback would have a stronger effect on students' intrinsic motivation over time than perceived informational feedback.

Methods

In the first part of the study (Time 1) 302 students, aged 11 to 15 years, responded to the items assessing perceived positive general feedback and informational feedback from the PTF questionnaire (Koka & Hein, 2003). Two years later (Time 2), the same students filled out the questionnaire again, along with the measure of intrinsic motivation from the modified version of the SMS (Hein at al. 2004). Data were analyzed using structural equation modeling.

Results

The hypothesized model was specified in which the stability of the perceived positive general feedback and informational feedback over a two-year period were estimated. The model specified a direct effect of the perceived positive general feedback and informational feedback at Time 2 on intrinsic motivation measured concurrently, and a longitudinal direct effect of previous perceived positive general feedback and informational feedback at Time 1 on intrinsic motivation at Time 2. The hypothesized model exhibited adequate fit with the data (CFI=.94; NNFI=.91; RMSEA=.040). Both types of perceived feedback exhibited moderate stability over time. Perceived positive general feedback at Time 2 showed a significant effect on students' intrinsic motivation measured concurrently. Fixing to zero the effect of perceived positive general feedback at Time 2 on intrinsic motivation measured concurrently, an effect of previous perceived positive general feedback (Time 1) on intrinsic motivation over time emerged.

Discussion/Conclusions

Results supported the hypothesis that perceived positive general feedback have a stronger effect on students' intrinsic motivation than perceived informational feedback over time. Nonsignificant effect of the perceived informational feedback on intrinsic motivation may be due to the fact that the enhancing effect of perceived informational feedback on intrinsic motivation may be through the perceived competence that was not measured. PE teachers should bear in mind that previous experience of perceived feedback may have an effect on later intrinsic motivation.

PARENT-INITIATED MOTIVATIONAL CLIMATE QUESTIONNAIRE (PIMCQ) TRANSLATED AND APPLIED TO BRAZILIAN YOUNG ATHLETES

Goulart, C., Valdés, H.

Brasilia University; Brazillian Sport Ministry, Brazil

The purpose of this work is the translated and the validation of PIMCQ (parent-initiated climate questionnaire) adaptation for the Portuguese Language. This questionnaire refers to the motivational climate of young athletes offering an important skill to the sport psychologists that are interest about motivational aspects related to the sports. The PIMCQ instrument was created by White, Duda and Hart (1992) based on classroom activities (AMES & ARCHER, 1988) and on the sporting environment (SEIFRITZ, et al. 1992). The authors have searched about the significant influence that parents and colleagues have in the most motivational climate of the students and athletes, especially the younger than 17, once their parents still have a strong influence. In terms of the development of the initial version of the PIMCQ, 14 items were adapted from three scales of the Learning and Performance-Oriented Physical Education Climate Questionnaire (LAPOPECQ) (i.e., Teacher's Promotion of Learning, Students' Worries about Mistakes, Outcome Orientation without Effort; Papaioannou, 1994) and written with reference to fathers, and the same 14 were written with reference to mothers. One factor (Learning-Oriented Climate) reflected a task-involving situational goal structure, with 5 items and two factors (Worry Conductive Climate and Success without Effort) reflected an ego-involving structure, with 9 items. The translation, application and validation of PIMCQ by White, Duda and Hart (1992) were not found in Brazil. In addition, not any analysis of the validation of this instrument was found, only its means and standard deviations. This research was applied in Rio de Janeiro city and District Federal to 226 athletes who play it at federations and confederations championships of volleyball, handball, basketball, table tennis, soccer, running and swimming. The data's analysis was made using the SPSS 10.0 program for windows. The instrument was analyzed as two questionnaires: one referring to father's motivational climate and another referring to the mother's motivational climate. Exploratory factor analysis showed (principal components followed by orthogonal rotation which method used was varimax) that the matrix predominate the requisites minimum of factorability. The mother's instrument showed: KMO 0,739, consider moderate; Bartlett's test of sphericity 691,353, significance 0,00, qualification significant; This analyses revealed two factors (explaining 31,9% of the variance) that was satisfactory. The father's instrument showed: KMO 0,767, consider moderate; Bartlett's test of sphericity 1007,447, significance 0,00, qualification significant; This analyses revealed two factors (explaining 31,9% of the variance) that was satisfactory. The internal consistency of the scales, using Cronbach's alpha, ranged from .85 (factor 1) to .76 (factor 2).

CONTENT VALIDITY AND INTERNAL CONSISTENCY OF SELF-EFFICACY TOWARDS GENERIC SKILLS TEST FOR PHYSICAL EDUCATION PROGRAMME

Chan, W.K., Hui, S.C., Sum, K.S.

The Chinese University of Hong Kong, Hong Kong

Introduction

This study investigated the content validity and internal consistency, reliability of a questionnaire for secondary school students' self-efficacy towards generic skills regarding their performance in the physical education programme. The Hong Kong Education and Manpower Bureau (HKEMB) has included nine generic skills which should be developed throughout the school curriculum. They are collaboration and communication skills, creativity, critical thinking, information technology skills, numeracy, problem-solving, self-management and study skills.

Research Methods

The research team tried to create as many question items as possible for each generic skills component for junior grade students (Secondary 1-3). A total 80 items for the raw questionnaire were designed. The questionnaire was revised and distributed to 3,205 students in this age range from 28 secondary schools in Hong Kong using statistical random sampling procedures.

Results

1) This research invited five experts, experienced physical education teachers who evaluated 80 designed questions, in order to conduct a content validity analysis. The questions which achieved over 80% agreement by the five experts were adopted. The final version of the questionnaire included a total of 64 questions corresponding to the nine generic skills components.

2) There were 2,840 students who completed the questionnaire. The return rate was 88.6%.

3) The internal consistency for reliability test as revealed from Cronbach's Alpha indicated that the nine generic skill components received fair to good reliability (r=0.55 – 0.80) with the exception of the components related to 'Creativity' (r=0.278). However, the analysis of inter items correlation revealed that there was one item in the component of 'Creativity' and two items of 'Critical thinking' which yielded negative correlations. Hence, when these items were dropped, the reliability of internal consistency for 'Creativity' (r=0.778) and 'Critical thinking' (r=0.656) were improved respectively.

Conclusions

It is concluded that the questionnaire for secondary school students' self-efficacy towards generic skills regarding their performance in the physical education programme demonstrated acceptable consistency validity and reliability resulting in a final version of 61 items.

This study was funded by the Education and Manpower Bureau, Hong Kong SAR.

A FIRST STEP IN EXPLORING REASONS OF DROPOUT FROM MAINSTREAM FITNESS CLUB MEMBERSHIP: ASSESSING NEW CLIENTS' CHARACTERISTICS

Piffaretti, M., Lenzen, B., Kayser, B.

University of Geneva, Switzerland

In view of the epidemics of the sedentary lifestyle and its related burden of chronic disease, factors influencing adherence to an active lifestyle are of great interest. Fitness club membership has become increasingly popular and may help individuals integrating physical activity into their lives. However, attrition rates are high while the factors predicting pursuit or dropout from using fitness clubs have not been much investigated. In the absence of sound data it is difficult to take efficient and scientifically coherent measures to prevent attrition. Ideally, a full investigation of predictors of perseverance and dropout concerning fitness clubs should encompass: a) a description of the characteristics of new fitness club clients at the time of their initial subscription ; b) a descriptive analysis of dropout rates at different times (e.g. 3 and 6 months) after initial subscription; and c) an exploration of potential relations between clients' characteristics and their decision to continue or drop out of the program.

This exploratory study focused on step (a) of this prospective approach. We made an inventory of the psychological, demographical, environmental and physical factors that characterise a group of adults at the moment of entering a program in a fitness-club. Five mainstream clubs belonging to the same fitness-concept located in the two main linguistic regions of Switzerland agreed to participate, allowing us to contact 156 individuals (mean age=36.6 +/- 13.9; 67 male and 89 female), to participate on a voluntary basis and fill in a self-report questionnaire at the moment of their subscription to a fitness program within the club.

Prior to their subscription, 42% of the new clients had already practiced other physical or sport activities for more than 6 months, 23% had practiced irregularly, and 24% had either recently ceased or totally abandoned any form of physical exercise before applying for membership to the fitness club. 48% declared they like physical exercise, whereas the others are either mildly interested (44%) or totally dislike exercising (8%). The most frequently cited fitness goals are improving or maintaining health, improving physical appearance and finding better ways to cope with a stressful life. Attrition rate and factors predicting dropout in this cohort will be assessed in a planned follow-up study.

In conclusion, a large fraction of new clients applying for membership to mainstream fitness-clubs are non- or ex-exercisers who do not particularly like or even dislike physical exercise. Better knowledge of factors that can increase fidelity of members and/or continuation of physical exercise outside membership is necessary in order to increase the chances that these individuals continue exercising, within or without a fitness club.

PERCEPTUAL DIFFERENCES IN TENNIS PLAYERS AND TRIATHLETES: A BATTERY OF TESTS THAT MAKES THE DIFFERENCE

Overney, L.S., Blanke, O., Herzog, M.H.

Brain-Mind Institute EPFL, Switzerland

The link between sport performance and various perceptual and cognitive abilities has been investigated by several authors in different sports such as basketball (Starkes et al., 1994), volleyball (Borgeaud & Abernethy, 1987) or tennis (Goulet et al., 1989). Until now, different types of abilities have been tested in order to identify differences between athletes and non-athletes but only few studies have tried to identify, at a larger scale, the complex network of perceptual and cognitive abilities underlying sport performance, especially in tennis. For instance, rapid target detection, tracking in three-dimensional space and visuo-motor coordination are part of the abilities of a tennis player. Thus, tennis skill requires high-speed visual processing and fine spatio-temporal resolution to reach optimal performance. Whereas many studies have investigated the involvement of higher information processing in sports, much less is known about the basic visual information processes with limited timing.

Here we present a battery of tests that allows to further narrow down which information is used during visual information processing and how this information is extracted. The battery includes low level discrimination tasks in different fields such as motion (coherent motion, speed discrimination), attention (attentional blink, visual detection tasks) or time-related tasks (B-type backward masking, flash-lag), as well as a higher level anticipation task (representational momentum). Tennis players were compared to age-matched triathletes and non-athletes. Triathletes were chosen as a control group because they share the same level of fitness but do not need such fine spatio-temporal resolution as tennis players. Preliminary results show that tennis players seem to perform better on motion- and time-related tasks than triathletes and non-athletes, whereas the other tasks do not seem to significantly discriminate the three groups of subjects. Future steps of this study will investigate how these abilities can be improved.

A GERMAN VALIDATION OF THE ACHIEVEMENT GOAL QUESTIONNAIRE FOR SPORTS (AGQ-S)

Birkner, H.-A.

ASPIRE - Academy for sports excellence, Qatar

Recently the achievement goal orientation concept has been extended by a 2x2 factor structure (Elliot 1999, Elliot & Church, 1997, Elliot & Covington, 2001; Elliot. & McGregor, 1997, Elliot & Trash, 2001). The same workgroup also provided a sport specific questionnaire has been provided by the same work group (Conroy, Elliot & Hofer, 2003) in English, according to the same theoretical structure. To be able to use the AGQ-S in the German setup a German translation has been validated on a sample of 116 adult (M = 30.7 years) participants of introduction courses indoor climbing.

Internal consistencies of the German AGQ-S varied from  = .64 (mastery approach scale), 

= .81 (mastery avoidance scale),  = . 86 (performance avoidance scale) to  = .87 (performance approach scale). By means of confirmatory factor analysis using the unweighted least squares method (ULS) the overall model fit of the data with the theoretical model was found to be very good (GFI = .988, AGFI = .981, NFI = .981, RFI = .971, RMR = .05) thus proving a high construct validity of the German AGQ-S. Criteria validity of the German AGQ-S was proven by significant correlations with external criteria like level of identification with the sports of indoor climbing, level of effort during indoor climbing courses and climbing performance.

A validation of an Arabic version of the AGQ-S is currently under construction and some results of this validation process will be presented as well.

THE IMPORTANCE OF THE MOTIVATIONAL CLIMATE FOR THE PERSEVERANCE IN RECREATIONAL INDOOR CLIMBING

Birkner, H.-A.

ASPIRE - Academy for sports excellence, Qatar

During the last decade there has been a vast amount of research on the importance of a match between the motivational orientation of people and the motivational climate of a sports environment (matching hypothesis) for the development of a perseverance in sports (e. g. Biddle, Wang, Kavussanu & Spray, 2003). Surprisingly research has focused on the school- and elite sports and almost completely neglected out the recreational sports domain (see Ntoumanis & Biddle, 1999). Hence the question arose if the concept of the motivational matching hypothesis could have any predictive value in the area of recreational sports. A five weeks field study (N = 116) in the area of recreational indoor climbing has been carried out. Introductory courses in indoor climbing for adults (M = 30.7 years), differing in achievement motivational course climate (performance vs. mastery climate) were conducted. The course climate was manipulated in a standardized way, referring to basic motivational climate criteria (Nicholls, 1984; Elliot & McGregor, 2001) as well as to Epstein's TARGET concept (Epstein, 1989). The feedback of the instructor, the spectator situation, the competition situation and the image of indoor climbing were manipulated. Achievement orientation was measured with a German translated version of the achievement goals questionnaire for sport (AGQ-S, Conroy, Elliot & Hofer, 2003). Three weeks after the intro course, participants were asked about any further participation in climbing since the course and any identification with climbing. Both participants and the instructors of the intro courses were blind against the purpose of the study. The results with regard to the participation in climbing after the course indicated a matching effect between task orientation and mastery climate (p = .03, h = .64) but not between ego orientation and performance climate (p = .45). With regard to identifying with indoor climbing, a non significant (p = .08), but meaningful (η2 = .052) interaction effect between task orientation and mastery climate was found. The results indicate that further field research on the effect of creating motivational mastery climates in recreational indoor climbing courses are recommended.

COACHES' INTERACTION DURING TIME-OUTS IN NORWEGIAN NATIONAL HANDBALL

Johansen, B.T., Hoigaard, R., Grimestad, B.B., Berglihn, S., Eidem, A., Pedersen, L.K.

Agder University College, Norway

During handball the coach has the disposal of different possibilities to create turnovers, changes tactics, give information, and motivate the athletes. Time-out and the way coaches use this period may be significant for the athletes and the team performance. Based on a sort of best practice approach and in order to gain better understanding in coaching, detailed investigation of what good coaches actually do may be one useful research avenue. The purpose of this study was to make a time-out interaction profile from Norwegian head coaches in handball.

Method Design and participants Four Norwegian female handball matches in World championship (Russia, 2005) and four male handball matches in the European championship (Switzerland, 2006) were video recorded. 23 timeouts (13 female and 10 male) were selected based on the possibility to hear what the coaches said during the time-out. The time-out interaction was analysed by four national top coaches.

Time-out interaction Hasties (1999) instrument for recording coaches' interactions with their players during time-outs were used in order to assess the interactions. The instrument consists of four major categories for the communicative statements. These statements are: technical, those relating to skill performance; tactical, those relating to strategic game matters; psychological, those relating to the emotional/cognitive aspects of play; and other statements, which are those unrelated to the game, or which are not likely to provide any benefit to the players.

Results The results indicated in average 2.4 different interactions content in each time-out. The coach for the female national team use 48% of the available time on tactical statements, 33% on psychological, 8% on technical, and 11% on other statements. For the male national team the distribution was 43% of available time on tactical statements, 21% on psychological, 26% on technical, and 10% on other statements.

Discussion In general the results indicated a focus on the technical or tactical components which may not be surprisingly based on the fact that these factors may directly influence the play. Interesting is also that even on this competitive level and situation psychological statement related to motivation, self confident is highly presented. A closer inspection of the psychological components revealed that the coach for the female team was without critical comments and extremely focused on the supportive. The male coach focused more extensively on correction of errors. Further research should focus how different situational conditions like tight matches, to be ahead or behind in the goal score in general or in the last minute of a competition will influence the interactions during time-outs.

PRESCHOOL PE TEACHING - STUDENTS SELF ANALYSIS - QUALITATIVE APPROACH

Serbetar, I., Sagud, M., Lozancic, A., Evic, K.

Teachers college Petrinja, Croatia

INTRODUCTION

Insight in one owns perception of teaching performance is very important. Qualitative research was performed on the data obtained through videotaping of students teaching and later on notes of participants' recall during the viewing of self performance.

METHODS

Similar to the research of (Palomaki, 2004), 16 kindergarten PE classes were videotaped during one semester practicum - Students Teaching. The data for the study were collected using recall method. Each of 16 subjects' viewed his own teaching performance 1 to 3 days after the performance were done and commented and analyzed his class during watching. All the classes were performed with preschoolers' in age of 4 and 5-yrs and consequently lesson lasted 25 and 30 minutes, respectively. Verbal responses on their own teaching behavior were noted during reflective self-evaluative analysis and then classified.

RESULTS

The main aim's of the study were to gain knowledge of the students reflectional thoughts on his own teaching and to give students the tools for conceptualizing some critical issues in PE teaching. Quality analysis according to Baumgartner and Strong (1998) was done on total of 175 statements and comments. The mass of the data were reconfigured and condensed in 14 new categories based on Pangrazzi (1995) model. Statement's are divided as follows: proper use of equipments and facilities (18), supervision and safety of the children during practice (14), children involvement in class and equipment preparation (9), communication and speaking skills (5), misbehavior and reinforcing the desirable behavior (4), management and discipline (19), instructional process and class management (13), instructional feedback and error correction (10), quality of instructions - establishing the rules - instructional and management errors (12), quality of instructions - meaningful input and check for understanding (9), instructional time - management time, practice time and dead time (11), demonstrating - modeling the task (12), learning through games of pretending and simulation (15). Last 24 comments from original three group's can be summarized in one purely pedagogical category of reflective practitioner (Sagud, 2001).

PONDERAL AND MOTOR DIFFERENCES BETWEEN CHILDREN WHO PRACTICE SOME SPORTIVE DISCIPLINE AND SEDENTARY CHILDREN

Mondoni, M., Casolo, F., Cereda, F., Faina, M., Galvani, C.

Catholic University of Milan, Italy

Sedentariness in infantile age favors the beginning of a pre-disease state on osteo-skeletal apparatus which predisposes to pathologies involving rachis and lower limbs. It has been demonstrated that 1 or 2 physical activity hours at school are not able to sufficiently improve motor abilities and to prevent different pathologies. The aim of our research is to verify if 2 hours of physical education at school are effectively not enough for children wellbeing and accordingly if it is necessary to practice in addition a sportive discipline.

120 boys and girls (10–11y) were divided in two different groups, active and sedentary (ACvsSE). The active children practiced 1 or 2 hours of physical education at school plus 90 minutes training sessions twice or 3 times per week. Sedentary children participated only to physical education lessons. All children were not controlled in their lifestyle. Children underwent 3 times during the year anthropometric evaluation (weight and height), motor field tests for detecting organic-functional qualities (upper and lower limbs' strength, endurance and rapidity) and flexibility tests.

Weight significantly increased during the year for both groups, especially for SE ($p<0,05$). Upper limbs' strength did not change over time, even if AC seem to be stronger than SE ($p<0,05$). Lower limbs' strength significantly improved for both groups, even if AC enhanced more than SE ($p<0,0001$). The Sit&Reach test significantly progressed over time for both groups ($p<0,0001$). Concerning cingulum scapulo-humeral flexibility, AC and SE performances significantly decreased, especially for AC group ($p<0,05$); AC resulted to be less flexible at any time ($p<0,01$). Speed ability is improved for both groups ($p<0,01$), even if it is more developed in AC people at any time ($p<0,001$). Resistance ability significantly increased for both groups, even if the improvement is higher for AC group ($p<0,0001$).

Looking at these preliminary results, it seems that physical education programs in Elementary schools alone are not able to enhance motor abilities. In fact upper and lower limbs' strength, speed and resistance qualities are at any time higher or increase more in AC group than in SE group. For this reason we can think that the SE group improvements are due more to the effect of growth than to the effect of physical activity. The only addition of free-living activities is not sufficient to offer a conditioning of organic-functional qualities. Additional hours of sportive activity are necessary to develop strength, aerobic and anaerobic capacities. It is on the contrary necessary to train flexibility in a specific way if the negative effect of growth must be counterbalanced; the sport specific training programs at this age seem not have this aim.

THE EFFICIENCY OF EDUCATIONAL STANDARDS TESTS IN SPORT RECREATION

Konczos, C., Ihász, F.

University of Western Hungarian Faculty Apáczai Teacher Education , Hungary

More of two-thirds of the Student Council, working in the Hungarian higher education, don't support the obligatory aptitude tests of the students. With the popularization of the physical tests introduced in the USA, they discovered that the number of heart attacks had lowered. (Keresztesi K., Kovács E., Andrásné Teleki J., Gombocz J., Kovács I. 2004). The goal of the examination was to determine the endurance ability with a humane walking test. After the survey the results will be used to make an individual training program for the students. The Rockport Fitness Walking Test was done by female students from the first class. We have monitored the symptoms of the exhaustion, the time results, and the relative maximum pulse. We also estimated the VO2 max from the data. We substituted the results for the valid Rockport Fitness Walking Test table and we found the endurance ability of our students. The students showed a big interest and they undertook the survey with pleasure. They found this test better than the earlier known running survey.

More than half of the student reached "very good" or "excellent" performance, but quarter of them only reached the "acceptable" performance. Each student displayed a positive attitude, accepted the most optimal development possibility, and will take part in the further surveys.

Key-words: educational standards test, sport recreation, endurance ability walking test, female students, efficiency

SOCCER COACH INSTRUCTION IN COMPETITION - BEFORE, DURING AND HALF TIME OF THE GAME

Crispim-Santos, A., Rodrigues, J.

Sport Sciences School of Rio Maior, Portugal

Introduction

We think it is essential that the coaches instruction during a competition reveals a high congruency, because with that he can help the players to achieve a higher performance. Therefore the aim of the present study is based on the comparative analysis of the soccer coach instruction, between different moments in the competition.

Methods

Twelve situations of competition were analyzed. Each competition contained 3 different moments: before game, during game and half time. Six soccer coaches were observed (two sessions each) in male senior teams on 2nd B Portuguese League. We used the System Analysis of the Information in the Competition (SAIC) as an instrument to collect data and evaluate the Instructions. To be able to prove the existing differences between the 3 different moments in the competition, the statistical test of wilcoxon was used, with the error probability (p- value) ≤ 0.05.

Results

Before the game Vs. During the game – regarding the objective of the instruction, we verify significant differences on the prescriptive category, although in both moments this instruction comprehended 80%; concerning the direction of the information, the instruction before the game was mainly focused on the team and during the game focused on the player; regarding the contents of the information, we found significant differences, because before the game, it exist a supremacy of psychological than tactical contents, although in both moments more than 75% of the instruction belonged to this two categories.

Before the game Vs. Half time - regarding the objective, more than 80% of the instruction doesn't reveal any differences, and it's mostly prescriptive; concerning the direction of the instruction, more than 60% of the instruction doesn't reveal any significant difference; regarding the contents of the information, we verified similar results of the last comparison.

During the game Vs. Half time – concerning the objective, in both moments more than 75% of the instruction is prescriptive; regarding the direction of the instruction, clearly exists a significant difference, so during the game the instruction is mainly focused on the player, while at the half time the coach focuses on the whole team or on various groups; concerning the contents of the instruction, the majority of the information doesn't show significant differences.

Conclusion

In all different moments of the competition, the information that is instructed by the coach has a strong remark on prescriptive and descriptive information regarding its objective and the contents are mainly tactical and psychological. Although we found some remarkably specification, such us, a more descriptive information during the half time of the game, a more individual approach during the game and a more psychological contents before the game, when compared with other moments, we can assume that the soccer coaches demonstrate a high congruence profile of instruction in competition.

YOUNG SOCCER COACH INSTRUCTION BEFORE COMPETITION

Crispim-Santos, A., Pereira, D., Gouveia, J., Costa, J.P.

Sport Sciences School of Rio Maior, Portugal

Introduction

Each coach has a specific way to prepare his team, psychologically and tactically for the competition. There are a few studies that characterize the coach's instruction in briefing of game preparation, and only a small amount of them in young teams. We pretend with this study, to analyse a briefing of game preparation (BGP) in a young soccer coaches, and compare graduate and non graduate coaches to verify if it exists differences between them.

Methods

Eighteen situations of BGP were analyzed. Eighteen young soccer coaches (9 graduate and 9 non graduate) were observed in tree young stages (under 19, Under 17 and Under 15 years old), on Portuguese League. The instrument used to collect data was adapted of the System Analysis of the Information in the Competition (SAIC - Pina & Rodrigues, 1993). To be able to prove the existing differences be-

tween graduate and non graduate coaches, the statistical test of Mann-Withney U was used, with the error probability (p- value) ≤ 0.05.

Discussion / Conclusion

In BGP, this young soccer coaches have an instruction with this characteristics:

• Objective of instruction - The information are prescriptive (≥ 80%) and without negative sentences;

• Direction of instruction - Direct to all team although we found some differences between coaches;

• Contents of instruction - Tactical and psychological, with a few technical and physical information and none information about the referees.

We found some important significantly differences between graduate and non graduate coaches. As a result, graduate coaches gave significantly more prescriptive information, and never said any negative sentence. They prefer speak to all team or individual player, however, non graduate coaches prefer speak to groups (defenders - with significantly differences and midfielders).

Concerning the contents of information, graduate coaches gave always more tactical instruction than non graduate. Game methods, missions/functions of players and set pieces (with significantly differences) are the specific tactical instruction of graduate coaches, while non graduate spoke more about game systems. In opposite, the non graduate coaches speak always more psychological information, with special emphasize about self-confidence.

The non graduate coaches have more instruction without contents than graduate coaches, but without significantly differences.

Our results seem that the instruction of graduate coaches is more complexity and specific, because the objective of information is more prescriptive and the contents are more fundamental tactical aspects than non graduate coaches instruction. Based in another studies, this characteristics show a BGP with better quality and pertinence of graduate coaches.

A STADY OF THE CAUSES AND SOLUTIONS OF THE CONFLICTS IN THE INTERACTIONS BETWEEN THE FOOTBALL COACHES OF JUNIOR PLAYERS AND THEIR PARENTS

Németh, Z.

University of Pécs, Hungary

We can encounter with several forms of interpersonal relations around football fields, which potentially include the occurrences of conflict situations. In the course of my career as a coach, I have experienced that my appropriate relationship with the players and their parents has fostered the efficiency of my teams. In this study, I analyze the causes of conflicts between coaches and parents, and make concrete recommendations for their solution.

The aim of the study

I would like to call the experts' attention to the possibilities and significance facilitating the solution of conflict situations. In this way, I would like to emphasize that, beside expertise, pedagogical and psychological knowledge should also be applied. The first step to be taken can be the early recognition and treatment of conflicts.

Questions

Which might be the most frequent causes of evoking conflicts between coaches and parents?

Is it possible to establish a hierarchy of causes evoking conflicts between coaches and parents?

Is it possible to draw any conclusions from the sites of the occurring conflicts?

What opportunities are the parents provided with for expressing their opinions?

Hypothesis

One of the most frequent first causes evoking conflicts between coaches and parents is considered to be when the child is assigned to play as a beginner or as a bench player.

The second cause occurs when the child is assigned to play on an inappropriate post.

Materials and methods of the study

Handing out questionnaires 12-18.05.2005

Sampling

The junior players' (U 13, U 15) parents: n=129 subjects.

The junior players' coaches: n=16 subjects.

Methods

Observation

Questionnaires handed out to parents (anonym, 10 closed and open questions)

Deep interview with coaches

Data processing

By means of mathematical and statistical methods

Results and their analysis

My first hypothesis was justified. 71% of the parents got into conflict because their child was assigned to play as a bench player; and 24% of the parents got into conflict because their child was assigned to play on an inappropriate post.

Considering these facts, it can be concluded that the majority of the parents accept the expertise of the coaches, but they would like their children to spend more time on the field, providing them with more opportunity of development.

This study supported my assumption that the same coaches preferred to assign the goalkeepers on the principle playing for equal time; in case of field players, they forgot about this principle. This was one of the most frequent causes evoking conflicts. The coaches can solve this problem by assigning children for equal time, a practice justified in case of goalkeepers; naturally, within the framework of rules. Otherwise the parents in question will take their children from the club. In several cases, it also turned out that the coaches could not always employ the best methods for solving the conflicts.

THE DIFFERENCE OF PSYCHOPHYSIOLOGICAL AND VEGETATIVE FUNCTIONS OF SPORTSMEN DEPENDING ON THE DOMINANCE OF BRAIN HEMISPHERES

Praulite, G., Spunde, A.

Riga Teacher Training and Educational Management Academy, Latvia

Wide observation about functional asymmetry of brain hemispheres in mental processes, emotional perception as well as information processing of tactical, spatial and time analysis neural mechanisms is found in works of various authors (Zigmond et al, 1999). The extent of functional asymmetry of brain hemispheres may be different for different people. Most of all the specialisation of brain hemispheres are characteristic for people with right hand dominance. In general more typical for left handers is dominance of right hemisphere. Statistic data show that in various branches of sports (for example box, tennis, fencing) left handers have some advantages in comparison with people with right hand dominance (right handers). Investigations carried out with sportsmen, showed that in definite branches of sports, for example box or wrestling, in some elements better are right handers but in some elements left handers. During motor and postural skill acquisitions (long term judo training) lateral preference are modified probably due to neuroplasticity (Mikheev et al, 2002).

The analysis of psychophysiological and vegetative functions of sportsmen was carried out. The estimation of sportsmen physical condition level was made. Accomplished work, capacity, maximal oxygen uptake as well as will properties, typical reactions in conflict situations, distribution of attention, precision of work and the speed of information processing was carried out.

Estimation of functional asymmetry of brain hemispheres was carried out using Coren test. All tested sportsmen were divided into three groups: people with exact left hemisphere dominance, people with exact right hemisphere dominance and people without exact asymmetry of brain hemispheres. All tested sportsmen were with excellent physical condition level. Determination of physical condition level was made by Harward steptest index (HSTI). The results of investigation showed that relative maximal oxygen uptake was statistically significant higher for person with right hemisphere dominance (left handers) than for person with left hemisphere dominance. The analysis of typical reactions of sportsmen in conflict situations by Tomass test showed that competition reaction is more expressed for person with left brain hemisphere dominance.

SURVEYING SCHOOL-CHAMPION PLAN FROM THE PERSPECTIVE OF EXPERTS, SCHOOLS MANAGERS, AND PHYSICAL EDUCATORS OF IRAN

Khajavi, D., Kashef, M.

Iranian Association of Physical Education & Sport Sciences, Iran

Before the development and performance of School-Champion Plan, school competitions of Iran were held electively. In these champions, selected student-athletes were qualified from districts, zones, states, and finally country respectively. On the basis of School-Champion Plan, qualified schools (not selscted ones) should participate in higher levels of school champion competitions.

The objective of this research was surveying and analyzing the way in which School–Champion Plan competitions were held from the perspective of experts, schools managers, and physical educators of both successful and unsuccessful provinces. This research is a descriptive one and was field–based. The required data were collected by a questionnaire, validated by 4 physical education experts. Its reliability was calculated (0.9). The statistical population included all school managers, physical education and sport science teachers and experts of physical education at Education Organizations. Cluster sampling was performed randomly. On the basis of Morgan Table, the number of statistical sample of male and female teachers of physical education, of both successful and unsuccessful provinces, was 381; the number of statistical sample of male and female school managers of these provinces was 381; the number of statistical sample of male and female teachers of physical education of unsuccessful provinces, was 375; and the number of statistical sample of male and female school managers of these provinces was 375. in order to analyze the data the researcher has used descriptive and inferential statistics(Kruskal Wallis Test, Mann-Withney-U Test, X2).

The results of the research showed that from successful and unsuccessful statistical population's perspective, School-Champion Plan had a significant effects in the following areas of development: 1) developing schools sports and increasing the number of engaged students (α = 0/000). 2) providing the grounds for development and progress of student's sports abilities (α = 0/000). 3) Using empty capacities of schools facilities for physical education and sports (α = 0/000). 4) creating more appropriate background for the development of physical education and sports at schools (α = 0/000). 5) Moreover, the results exhibited that, according to statistical populations of successful and unsuccessful provinces, School-Champion Plan is significantly superior than traditional method of holding schools matches (α = 0/000).

ETNOPEDAGOGICHESKIYE CONDITIONS OF USING OF GAMES AND CONTESTS OF THE TRADITIONAL PHYSICAL TRAINING OF THE RADICALSMALL PEOPLES OF THE NORTH

Krasilnikov, V.

Russian state is professional -pedagogiceskogi1 university, Yekaterinburg , Russia

Russian state is professional –pedagogical university, Yekaterinburg

Article is prepared on the basis of the materials, obtained as a result of expeditions (conducted from 1990 through 1993 j.) in the places of dense population center of one of the ancient peoples of Siberia - Hunts. As a result of field etnopedagogicheski studies we have revealed more than hundred people games, which we classified.

Our classification consists of four blocks: the 1st block - the game of children from 1,5 to 6 years, 2-1 - from 6 to 10, the 3rd - from 10 to 14; the 4th - game, contest, the original physical exercises of young people and adult.

The results of theoretical analysis and field etnopedagogicheski studies made it possible to isolate and to base the totality of the etnopedagogicheski conditions.

The first condition for the effective use of people games - this is realization in the pedagogical process of the intellectual potential of the carriers of traditional knowledge about the content, the rules of the games, transferred from one generation to another.

Second condition - system scope by the people games of the diverse spheres of the vital activity of hunts (trades, school, housework, way of life, holidays, etc.).

Third condition - use of traditional technology of organization of play activity (organization and management of game by elders, the gradual complication of rules, content of games and an increase in the load on the organism of children and adolescents; conducting games under the conditions, approximating nature and trade activity).

Fourth condition - application of an adequate traditional symbolism, attributs (toys, inventory for the games and the contests, the sport equipment), of the accompanying conducting games and observing the traditional rituals.

People pedagogy of Hunts manufactured means and in parallel with this it formed the system of the etnopedagogicheski conditions for the effective use of people games for purposes of training the growing up generation. That presented makes it possible to consider that the use of people games, contests with the specially created etnopedagogicheski conditions will make it possible to considerably enrich the spiritual life not only of Hunts, but also other peoples of the north, also, as a whole of Russia.

HOW BOYS AND GIRLS PERCEIVE GENDER RELATIONS IN PE CLASSES

Silva, P., Botelho-Gomes, P., Graça, A., Queirós, P.

University of Porto, Portugal

Introduction: PE programs at Portuguese schools are developed in the mixed gender classes, in which boys and girls experienced a variety of physical activities and sports.

However, the fact that PE classes take place on a mixed regimen that does not mean that relationships, whether positive or negative, were evaluated in the same way by boys and girls (Bain, 1985; Scraton, 1995; Bonal, 1997). So, how do boys and girls relate to one another within the context of PE classes? How do boys and girls perceive those relations?

Method: This study aims at examining students' perceptions about the gender relations in physical education.

We have applied structured interviews to 60 Portuguese secondary school students from both sexes (30 boys and 30 girls). In order to inspect the material we have applied content analysis technique.

Results: It is interesting to verify that a large majority of boys (72%) consider that relations between sexes are good, while 57.1% of girls report the existence of problems in the relationship between boys and girls during PE activities (only 28% of boys think the same).

Results convey that the opinion about the relationship between boys and girls is highly dependent of the sex (X2=4.567; p=0,031).

The thoughts and feelings underlying this evidence are patent in the following quotes of girls' voices:

"I think that they [boys] should not be sexist, they should give us more opportunities. But no chance, it's always the same thing." [Girl, Af1FN: 6, 64-76].

"... for instance if we [girls] lost the ball, if we do anything wrong they jump on us arguing the team is weaker because of the girls, and they see us as weaker and not so competent as them. That's what I think." [Girl, Lç2FN: 6, 63-69].

"I think that over and over again we are criticized for not doing things correctly or they see themselves as superior, and this also interfere. It's not motivating for us. Sometimes the way they talk to us «oh! You don't know how to do this, you don't know to do that» or «you have no aptitude for this. Sometimes we are demoralized by that»" [Girl, RTIS1FS: 6, 83-85].

"... I think sometimes, you know, boys are more, yeah; they can be more offensive than girls. Girls sometimes even dare to call «hey moron» but only as a joke. Now, boys are different, sometimes they bad-mouth us «you girls, you are good-for-nothing»." [Girl, RTIS4FN: 6, 64-74].

Conclusion

The context of PE lessons seem to reproduce and reinforce androcentric beliefs and ideologies of sport; some female students complain about their colleagues' behaviours and attitudes which bother them, offend them and lead them to a disinvestment in the activities.

A STUDY OF THE POSSIBILITIES OF INTEGRATED PHYSICAL EDUCATION AT SCHOOLS IN HUNGARY

Prisztóka, G., Vass, M., Tóvári, F., Papp, G.

University of Pécs, Hungary

Keywords: integrated physical education at schools, "adapting school", coeducation

Integrated education more and more frequently becomes the topic of discussion and debate in Hungary being a member country of the European Union.

Does integrated education have a reality and possibility in the Hungarian public education?

No doubt, a serious change in stance is needed among teachers of physical education: the curricula-minded and achievement-minded stance should be transformed into a child-minded strategy. Physical education at schools is an area where the integration of children with different abilities and particular educational background can be established by providing them with common experience and by the utilization of the positive impact of sport activities on their health and mental development.

The aim of study

In our opinion, the first steps in bringing about changes in the teachers' stance in practice should be taken in the education and training of the would-be experts. In the first part of our study (2004), we assessed the knowledge levels of notions and information of the regular and correspondent students participating in the teacher training programs of physical education (n=157). Then we gathered information (2005) about the issue in question from the active PE teachers (n=80), parents (n=100) and students (n=100). These data were compared in order to be capable of deciding how far the current teaching practice, the PE teachers' and parents' stance should be considered.

The main results

• The participants in the investigation have a low level of knowledge of notions:The notion of segregation is not known by 72% of the university students, by 44% of the teachers of physical education, by 71 % of parents and 81% of schoolchildren. The situation is even worse in case of inclusion.

• 60% of the teachers of physical education cannot accept endeavors of integrating children of special education, whereas 76% of the parents and 64% of schoolchildren regard endeavors of integration as achievable in physical education.

• 56% of the university students would undertake common education with children of special education after sufficient preparation, whereas only 32% of the teachers of physical education would do so.

• According to teachers, parents would regard a situation as disadvantageous for their children if children of special education could participate in common lessons of physical education. Contradictory results were obtained from the investigation.

• Schoolchildren regard common education with children of special education as correct. In their opinion, in this way, they would be able to come to know the problems of children of special education better, and their acceptance could become more natural.

ERASMUS MUNDUS MASTER IN ADAPTED PHYSICAL ACTIVITY: AN IDEAL STRUCTURE FOR INTERCONTINENTAL COOPERATION IN TEACHING AND RESEARCH

Van Coppenolle, H., Dobreva, I., Djobova, S., Van lent, M.

Katholieke Universiteit Leuven, Belgium

In January 2005, a proposal for a joint Master in Adapted Physical Activity (APA) was selected for a period of 5 years, under the call of Erasmus Mundus Master Programmes. With these Erasmus Mundus Programmes, the European Commission aims to enhance the quality of higher education in Europe by improving the collaboration between European Universities and providing a joint diploma for non-EU students.

The Erasmus Mundus Master in Adapted Physical Activity (EMMAPA) originated from the European Master Degree in Adapted Physical Activity which has existed for over 14 years. The Erasmus Mundus framework allows us to extend this programme beyond the borders of Europe by providing substantial scholarships for both students and scholars from outside Europe to either attend or teach the course.

The master course has a duration of 1 year, consists of 60 ECTS and involves a study period in at least 2 of the 4 consortium universities: K.U.Leuven (Belgium), Norwegian School of Sport Sciences (Norway), University of Limerick (Ireland), Palacky University of Olomouc (Czech Republic). For the first academic year of the Erasmus Mundus Master in Adapted Physical Activity, 39 students from 25 different countries (10 European and 15 non-European), were selected. All the students studied the first semester in the K.U.Leuven and are currently completing the master course in a second consortium university. Upon completion of the course, the students should have sufficient knowledge on the nature of indications and limitations of physical activities for persons with disabilities, the current initiatives in APA and the state of the art in research in APA.

The unique aspect of this Master course is the intercontinental character. Under action 3 of the Erasmus Mundus framework, this international aspect was even extended by establishing partnerships with 3 non-EU universities: Queensland University (Australia), the University of Stellenbosch (South Africa) and the University of Virginia (USA). EU-students have the opportunity to apply for a 3 month scholarship to study in one of these partner-universities. Scholars from the consortium can also teach and work in these universities. This dynamic exchange of knowledge, experience and ideas of the EMMAPA course will make a substantial contribution to the establishment of an intercontinental cooperation in teaching and research in APA.

THE EFFECTIVENESS OF SECONDARY SCHOOL PHYSICAL EDUCATION IN DEVELOPING GENERIC SKILLS OF JUNIOR STUDENT

Chan, W.K., Hui, S.C., Sum, K.S.

The Chinese University of Hong Kong, Hong Kong

The Hong Kong Curriculum Development Committee (HKCDC) believes that generic skills are a part of students' basic ability and must be learned. These should be developed through learning and teaching in the context of different school subjects. They classify the generic skills as including collaboration and communication skills, creativity, critical thinking, information technology skills, numeracy, problem solving, self-management and study skills. This study attempted to evaluate the effectiveness of the secondary school Physical Education (PE) curriculum in developing junior students' generic skills. The samples included 2,840 junior (Secondary 1-3) grade students from 28 secondary schools in Hong Kong using statistical random sampling procedures. The questionnaire for secondary school students' self-efficacy towards generic skills test for physical education programme was adopted. The content validity (over 80% agreement by five experts) and the reliability (Internal Consistency (r) range from 0.55 to 0.80) of the questionnaire have been evaluated.

There were 61 items in the questionnaire which was designed for students' perception of performance corresponding to the nine generic skills components in the physical education programme. Five-point Likert scale was adopted, where 5 was 'strongly agree'. The results indicated that there was a positive trend in students' perception of their performance of the nine generic skills (Mean = 3.34) in the PE programme. The top three generic skills for junior secondary students were the skills of collaboration (Mean = 3.65), self-management (Mean = 3.48), and problem solving (Mean = 3.45). The findings suggested that the Hong Kong PE curriculum has adopted a traditional teaching approach in which the traditional team games are the core teaching contents and the skill-oriented teaching approach is adopted. This approach contributes towards students' development in certain generic skills, as proposed by the HKCDC. However, the findings showed that this traditional teaching approach may contribute comparatively less development on the generic skills of numeracy (Mean = 3.08), information technology skills (Mean = 3.19) and creativity (Mean = 3.22) in the junior secondary school PE programme. These findings may be useful references for educators in the design and evaluation process for the physical education programme during the educational reform.

This study was funded by the Education and Manpower Bureau, Hong Kong SAR.

PEDAGOGICAL QUALITY EVALUATION OF THE FITNESS TEACHERS

Rodrigues, J., Franco, S., Lougo, H.

Escola Superior de Desporto de Rio Maior, Portugal

This study it is fit in the evaluation of the health and fitness council program "Mais Desporto Mais Saúde" (MDMS), appointed in the area of Evaluation of the Pedagogical Quality. For such, it was proceeded an evaluation in the beginning and another one in the end of the time, with the objective to verify if the teachers and clients had modified its opinions and behaviours. The sample of this study was constituted by 6 groups of Fitness for adults and 2 groups of Sport Education of the related council program, in Rio Maior, Portugal. For each group two sessions of data collection had been carried through (filming video), one in the beginning (December 2004) and another one in the end (June 2005). In this way, we got 17 interviews and 18 videotapes of lessons. The interviews had been codified in units of information, through the use of the analysis of the content of the answers. The sessions had been analyzed through the SOTA (System of Observation for Coaches and Athletes) or of the SOCIF (System of Observation the Behaviour of Fitness Instructors), in accordance with the type of lesson. The pupils opinions had be treated from the results evidenced in the questionnaires that reflected an appreciation in ratting scale (5 levels). A descriptive analysis of the results was carried through. We conclude the following: a) related to the daily pre-interaction decisions, the teachers have expectations simultaneously to the session and to fit within the MDMS program and in accordance with the plan; this plan duly does not seem to be elaborated, having some errors when they tell us about the general objectives and the exercises; b) related to the pedagogical behaviour, this is fit in the desired profile of the efficient teacher, existing however, some difficulties in the groups of sport education that evidence a lower preparation of the involved teachers; c) in the supervision of the experienced teachers these difficulties and some fragility in the explanation of the exercises and the correction of the pupils execution had been proven; d) related to the preferences of the pupils, the positive interventions of support and encourage are valued, as well as the had explanation of the exercises and tasks; e) in the comparison between 1st and 2nd session we did not get great differences, however, the data that we obtain to get do not allow to trace conclusions on this objective. The recommendations can easily be taken care of will have an effective supervision of the lessons, with the formation of the teachers through the self-analysis and mentorship. We still recommend, that this study it is talked back with regularity in order to exert the determinative function of evaluation of program MDMS and simultaneously to supply information concerning the income of this program.

PHYSICAL EDUCATION SCHOOL BOOKS: HOW GENDER IS REPRESENTED IN 7TH, 8TH AND 9TH GRADE

Botelho-Gomes, P., Caetano, S.

University of Porto, Faculty of Sport, Portugal

Physical Education School Books: how gender is represented in 7th, 8th and 9th grade

Botelho-Gomes, P.; Caetano, S.

University of Porto, Faculty of Sport, Portugal

Introduction

School books are pedagogical instruments of unquestionable importance within the learning process. They also can carry gender stereotypes and transmit social representations of men and women in sport.

The purpose of our study was to find out which were the representations of gender, portrayed by Physical Education (PE) school books.

Methods: 4.252 images from seven PE school books were analyzed by content analysis technique. We have defined 4 categories a priori: male image, female image; image representing both genders, and undefined image, when was not clear which gender was represented.

In each book we also have inspected images and illustrations in: book cover, front page, index, thanks, and introduction.

Results: The results reveal that male images were the predominant (55.3%). Girls were represented in 25.7% of the images, and images with both genders counted only 12.0% of the total images. These results were unexpected in a coeducational school.

The association between gender and content showed that girls were more represented than boys only in gymnastics (48%), golf (58%), swimming (46%), and rhytmics (43%).

Conclusions: This kind of results reveals that PE school books portray mainly the masculine model. Because feminine representations are more associated with some contents and masculine representations are associated to others, we believe that there is a strong tendency to represent girls and boys in sports that are "appropriated" to them. According to this, PE school books reveal inequalities, asymmetries of gender and reinforce stereotypes, conveyed by the majority of the social patterns.

PROBLEMATIC OF EXCUSING FROM PE LESSONS IN SLOVENIA

Jurak, G., Kova, M., Strel, J., Starc, G.

University of Ljubljana, Faculty of Sport, Slovenia, Slovenia

The increased level of body fat as a consequence of modern everyday life is one of the main health risk factors in children and youth (Strel et al., 2004a). It is accompanied by a growing number of youth with excess weight (Strauss & Pollack, 2001; Wedderkopp et al., 2004; Currie et al., 2004; Strel et al., 2004) and consequential diminishing of their motor potential, especially their endurance and strength (Beunen et al., 1992; Strel et al., 2004).

These trends triggered many declarations in which the experts recommend at least one hour of sport per day. Slovenian school enables children 3 school hours of physical education (PE) per week (135 minutes) and a vast palette of extracurricular sport activities (Kovač, 2001). The question of efficient realisation of PE lessons still remains problematic, especially because of the absence of pupils and their excusing from active participation.

The analysis of pupils' excusing from PE was carried out with a questionnaire on the sample of 1333 secondary and high school students. The characteristics of differences were analysed by t-test and variance analysis while the characteristics of correlations were analysed by correlation coefficients.

The results reveal a poorly developed system of excusing from PE. Its deficiencies are especially obvious in high school adolescent girls who are far too inactive in the times when they would need the most physical impulses.

Our estimation is that 8,8% of high school girls is inactive more than one fifth of the lessons. Other groups (secondary school pupils and high school boys) show far lower frequency of excusing than high school girls. Excusing from PE lessons is negatively correlated with general success in school. The most common used excuses to avoid physical activity are health related while material or hygiene reasons are not very common.

Many times pupils tell the teacher the real reason of their inactivity which shows that, in addition to many inexcusable reasons, teachers to easily excuse pupils from physical activity and thus enable abuse of excuses. These abuses are visible from a large share of false parents' excuses and improperly issued medical excuses.

In the time they are excused pupils remain inactive or do what they want. It is concerning that during this time they are more often learning other school subjects than theoretical subjects of PE that are parts of new PE curriculum in Slovenia.

The problematic of excusing in PE classes demands specific solutions. In order to decrease excusing we should combine two mechanisms: 1) we need to limit the reasons for excusing by pointing out the characteristics of pupils who are often excusing, 2) schools need to implement a system of excusing from PE lessons by obeying school legislation and at the same time plan the activities of the excused pupils that are in accordance with the curriculum. The teachers should remain professionally autonomous in planning and implementation and should thus take responsibility for the decrease of excusing from PE lessons.

FACTORS AFFECTING THE PROFESSIONAL LIVES OF PE TEACHERS IN HONG KONG

Sum, K.W., Ha, S.A., Chan, W.K., Johns, P.D.

The Chinese University of Hong Kong, Hong Kong

This study endeavours to understand the impact of the pressures on teachers and to determine the factors that affect the professional lives of PE teachers in Hong Kong.

Methods

The data for this research were gathered through an in-depth interview with a group of PE teachers during a teacher development program. Twelve teachers participated in the interview. Open-ended questions were asked with the following core themes: (1) the influence of work on the personal lives of the PE teachers, (2) their participation in ongoing professional development opportunities, and (3) their perception on satisfaction with their career. The data collected were examined using qualitative analysis techniques. Applying the principles of grounded theory (Strauss & Corbin, 1998), theoretical constructs that focused on factors affecting the professional lives of PE teachers were developed. Qualitative data generated from the interviews were analysed, coded and utilized to classify the constructs. These constructs were then adopted and formed the framework upon which a description and explanation of the factors that influences teachers' professional lives could be presented.

Results: This study found that there were 10 factors which affect the professional lives of PE teachers. They were (1) family and marital status, (2) gender, (3) years of service, (4) education/curriculum reforms, (5) school culture/leadership, (6) distinct nature of the profession, (7) preference of professional development, (8) identity and status, (9) sense of achievement, and (10) nature of the dynamic subject. Most of the factors underlying these core themes were interlinked

Conclusions and Discussions

This research suggests that education/curriculum reforms have a significant impact on the daily lives of PE teachers and are often perceived as a source of stress. In contrast, PE teachers perceived student achievement and satisfaction with their roles as coaches to compensate for the stresses encountered in their school life.

From the data collected in this study, it appears that PE teachers may experience a degree of ambivalence over the importance of PE. Many teachers are required to teach up to three other subjects besides PE and ranked them as more important especially when required to identify subjects for professional development. While PE has few opportunities for such in-services development there is substantially more opportunity to enjoy professional development in other subjects.

A third area of significance in the lives of teachers concerns the years of services and the experience that long service provides in elevating the status and identity of PE as a school subject. It appears that with age comes maturity, respect and even admiration for the role that PE plays in schools. It would seem that reputations are earned with regards to the impact that PE has on school life. With a sustained effort and consistency, experienced teachers and their subject enjoy a higher status.

ATHLETES RETENTION OF COACH'S INSTRUCTION IN JUDO PRE-COMPETITIVE INSTRUCTIONS

Rosado, A., Breia, E., Mesquita, I.

Faculty of Human Movement, Portugal

The aim of the present study was to describe coaches' instructional profile in pre-competitive meetings preceding the judo competitions and the athletes' level of retention of coaches' instructions. We observed 11 coaches and 58 athletes. The independent variables were gender and competitive level. The dependant variables were the quantity of information on coach instructions, the nature of the information and the information's reproduction by the athletes, both in a quantitative and qualitative (coherency) approach. The coaches pre-competitive instructions were audio and video recorded and immediately afterwards athletes were asked (by interview) to reproduce the coach's information. The information given by the coach and the athlete's answers were analyzed through quantitative and qualitative (content analysis) procedures, being the data described and compared.

Coach instructional profile showed a focus on technical and tactical aspects, in information's about the adversaries and about psychological aspects. Globally, athletes reproduced and perceived coaches instructions but there are always an important lost of information (31,3%). Male athletes presented a significant better retention level. The retention of the information was, globally, inversely related with the number of transmitted ideas and its extension. The results suggest that the retention of the information depends, generally, on its nature and structure but some personal characteristics, however, were, also, associated with retention (gender and practice level).

Poster presentation (PP)

PP2-08 Nutrition 1/1 - "Exhibition Hall"

DIETARY BEHAVIOUR AMONG COMPETITORS OF THE HUNGARIAN NATIONAL TEAM OF RHYTHMIC GYMNASTICS

Fogarasi, G., Nikl, A., Katics, L.

University of Pécs, Hungary

In case of competitors in the National Team of rhythmic gymnastics by apparatus, thin physique and low-built body mass are basic requirements. It can cause problems if the competitors are able to achieve slimness only with great difficulties.

The investigation was performed in the National Team of rhythmic gymnastics (six persons, mean age: 18.2 ± 3.2 ys). Female university students, not pursuing any sports, of Pécs University, (14 persons, mean age: 18.8 ± 0.2 ys) were studied as a control group. Despite the low number of subjects, we did not intend to involve any more competitors of rhythmic gymnastics not belonging to the National Team.

Body height, body weight and percentage of body fat were measured; Body Mass Index was calculated. In addition, an anonym questionnaire including questions about the date, frequency and length of their periods, contraceptive pills, fluctuation in body temperature, bone fracture and about their satisfaction with their bodyweight. The competitors were supposed to complete two standard validated questionnaires, the Hungarian versions of Eat-26 and the Eating Disorder Inventory including 64 items. The results obtained in this way were analyzed by the means of the SPSS-13 statistical software.

Significant differences were found in the following variables: Body Mass Index, body fat percentage, body fat kilogram, the date of first period. Two of the 6-member National Team have regular periods at present; three have periods irregularly, 3-4 times a year; one member has no period at all; whereas 14 members of the control group have their periods regularly, 28.4 ± 1.3 days as an average. All the members of the team would like to lose weight; whereas six subjects with higher body weight of the control group would like to lose weight. One competitor and one control subject had fluctuation in body temperature. In case of Eat-26, two of the team members and one of the control group produced pathological symptoms. One of the competitors and two of the control group inclined to get into the subscale of EDI. No one of either groups got into the Bulimia subgroup, whereas one of the team and two of the control group got above the pathological symptom level of the Body Dissatisfaction subgroup of EDI.

To summarize it should be noted that, though all the team members, despite their low body weight, would like to lose weight and most of them have disturbances in their periods, it can be supposed to be a transitory state, and these complications will cease when they stop pursuing this sport. To obtain realistic data about their real state of health, whether these complications are transitory or not, the same investigations should be performed again following their sport career.

A STUDY OF DIETARY BEHAVIOUR IN SECONDARY SCHOOL FEMALE STUDENTS MAJORING IN BALLET

Fogarasi, G., Ockenfusz, E.

University of Pécs, Hungary

Slim, ethereal physique in female ballet students is a basic requirement. Certain components of physique are genetically determined, e.g. body height, thickness of bones. However, fat content, the proportion of lean body mass and fat body mass can be affected by diet, physical activity, and mode of life.

We carried out a study among female ballet students of Pécs Arts School (n=22, mean age: 17.2±1.2 ys). As a control group, the dancers of a hip-hop sport club participated in the study, who regularly dance but their physique is not a determining factor (n=30, mean age: 17.7 ys). Body height, body mass, body fat were measured, and the BMI was calculated. Their dietary behaviour was studied by the means of EAT-26 and Eating Disorder Inventory, and a questionnaire with items concerning their periods, changes in body temperature, bone fractures, contraceptive pills. The groups were compared by the SPSS-13 software. In the two groups, significant differences were found in the following parameters: body weight, body mass index, body fat percentage. Seven ballet dancers (32%) have rare periods, 3-5 times a year, while in the control group seven subjects (10%). 64% of the ballet dancers, despite their low body weight, would like to lose weight; 43% in the control group. In case of the EAT-26 questionnaire, seven ballet dancers (30%) and three control subjects (10%) scored above the risk level. Four ballet dancers and no control subjects scored above the cut-off-score in the subscale Drive for slimness. No subjects scored above the cut-off-score in the Bulimia subscale. Four ballet dancers and one control person scored above the risk level in the Body Dissatisfaction subscale.

To summarize, it was found that the ballet dancers were taller and slimmer than the control dancers; their body fat content was lower; third of them had disturbances in their periods; despite, most of them would like to lose weight in order to meet the requirements concerning the physique.

ENERGY AND MACRONUTRIENT INTAKE IN FEMALE WINTER UNIVERSIADE ATHLETES

Lee, A.S., Meyer, N.L., Krulatz, A., Burtscher, M.

University of Innsbruck, Austria

INTRODUCTION: Adequate energy and macronutrient intake are essential in maintaining performance and health in female athletes. Several studies show that female athletes are not meeting their energy and carbohydrate needs (Burke, 2001). Nutrition research on female Winter Universiade athletes is lacking. The Winter Universiade is an international sporting festival open to all student athletes and is highly competitive. Success requires academic and athletic excellence, and adequate nutrition plays a key role. PURPOSE: To describe the energy and macronutrient intake and supplement use in female Winter Universiade athletes in comparison with non-athletes and current sport nutrition recommendations. METHODS: Participants were female Winter Universiade athletes (n = 21) (cross-country ski [n = 14], alpine ski [n = 4], and snowboard halfpipe [n = 3]), and non-athlete controls (n = 20), aged 19-27 y. Energy and macronutrient intake and supplement use were assessed using a standardized Food Frequency Questionnaire (Block et al., 1989) and a self-developed questionnaire on dietary history, addressing the athletes' intense autumn training period prior to the 2005 Winter Universiade. RESULTS: Independent t-tests revealed no significant differences between athletes and controls for average daily energy (34.8 + 13.2 vs. 35.6 + 22.8 kcal/kg/d), carbohydrate (4.2 + 1.7 vs. 5.1 + 4.2 g/kg/d), protein (1.5 + 0.6 vs. 1.1 + 0.6 g/kg/d), and fat (1.2 + 0.5 vs. 1.1 + 0.6 g/kg/d) intake. Athletes had significantly lower intakes for energy (comparison value: 45 kcal/kg, [Economos et al., 1993]; $p<0.01$) and carbohydrate (comparison value: 7 g/kg/d; [Burke et al., 2004]; $p<0.0001$), using one-sample t-tests. Expressed in frequencies, 11 % of the athletes

met these guidelines for energy and carbohydrate. Only the athletes reported supplement use, specifically sport drinks (57%), sport bars (48%), and protein powder (24%), and the use of multi-vitamin and vitamin C supplements was higher in athletes than controls (47.6 vs. 15.0%; 57.1 vs. 20.0%; p<0.05, Chi-square test). CONCLUSION: The findings show that female Winter Universiade athletes and non-athlete controls have similar energy and macronutrient intake. Although underreporting should be considered, it appears that female winter sport athletes do not meet current sport nutrition recommendations, and thus, may not adequately prepare for and recover from intense training. Further research in this population should investigate athletes' knowledge of nutrition, where they obtain such information, and the availability of sport nutrition services at training facilities. PHYSICAL ACTIVITIES AND NUTRIENTS INTAKE OF ELDERLY HEALTHY PEOPLE

Assanelli, D. 1, Bandera, F. 1, Tolomio, S. 1, Scudellari, A. 1, Corsetti, G. 2, Bernardi, M. 1, Perdetti, E. 1, Pasini, E. 3, Salvetti, M. 1, Bianchi, R. 2

1 Chair of Sport Medicine, 2 Division of Human Anatomy, University of Brescia,
3 S. Maugeri Foundation IRCCS, Gussago, Brescia - Italy, Italy

Many studies investigated the nutritional habits of elderly people but no study has already analysed both the nutritional habits and the physical activities of old people. We investigated the dietary habits and the physical activities in a group of selected old healthy people. The study was conducted in 70 (13 men, 57 women) selected health subjects aged from 66 to 86 years resident in the town of Brescia (Lombardy, Italy). People were visited by a multispecialist team to exclude chronic and/or acute diseases. ECG, blood pressure, body mass index, tricipital skinfold thickness and arm muscle diameter were evaluated. Total and HDL/LDL cholesterol, triglicerides, glycemia, C-reactive protein and fibrinogen were measured. The EPIC questionnaire was used in order to evaluate nutritional habits and the Laval questionnaire quantified the kilocalories spent in leisure-time physical activities. Cognitive deficit, medical history, demographic and socio-economic variables and lifestyle informations (ie: tobacco smoking or alcohol drinking) were collected.

Subjects had a daily intake of total protein, total fat, disposable carbohydrates of 70.8±3 g, 66,4±2 g, 216±9 g respectively. We found a high intake of saturated fats in 25% of the subjects. In the majority of the elderly we noted a reduced intake of calcium, potassium and vitamin D. Elderly men had also low intake of vitamin E and niacin. The mean daily energy intake was 1791±74 kcal. All subjects had a constant daily physical activities, both in week-days and in Sundays. The SCORE resulted 3 in men, 2 in women. Conclusion: healthy elderly people had a constant daily physical activities and adequate macronutrients intake. However, in the 25% of the subjects we found increased saturated fat intakes. In spite of that habits, all patients were healthy. Probably genetic features and constant adequate physical activities are important to have a healthy senescence more than fat intake.

ORAL AMINOACIDS SUPPLEMENTATION INCREASES MITOCHONDRIA AND SARCOMERE VOLUME IN MYOCARDIUM OF OLD MOUSE

Assanelli, D. 1, Corsetti, G. 2, Pasini, E. 3, Bianchi, R. 2

1 Chair of Sport Medicine, University of Brescia, 2 Division of Human Anatomy, University of Brescia; 3 S. Maugeri Foundation IRCCS Medical Center, Gussago, Italy

Senescence is characterised by reduced proteins synthesis and decreased mitochondrial number which can cause muscular wasting and metabolic alterations. Loss of muscular proteins and mitochondria is not only peculiar of skeletal muscle but it is present in the cardiomyocites as well. Indeed, old heart has specific alteration of systolic and diastolic performances due to structural and energetic disarrangements. Alternated cardiac mechanical activities cause impaired physical activities of the elderly. Recently, it was demonstrated that chronic oral administration of a specific mixture of aminoacids (AAs) stimulate protein synthesis and improve oxidative muscle metabolism. However, data on the effects of specific nutrients such as AAs on morphometry of cardiac cells are not available, yet. Thus, to evaluate the morphometric effects of oral AAs supplementation on mitochondria (Mi) and sarcomere (Sr) of old male mouse (14 months) we performed an experiment using two groups of five animals each. The standard dry food was added with water (controls) or aqueous solution of AAs mixture (1,5g/kg/day) for 90 days. The amount of fluid intake was measured daily. At the end of the treatment animals were killed, the heart was removed, fixed in glutaraldehide and processed for electron microscopy (EM) technique. For each group, data were collected from about 90 EM photographs (x5,900) , randomly taken at different levels of muscle. The morphometric measures were taken twice by three persons using 5mm-gauge stereological grid. We calculated: the total volume of fibres (TotV), the volume of sarcoplasm (SpV), Sr (SrV), Mi (MiV). From these data we calculated the ratio SrV/TotV and MiV/SpV. After 90 days there was no difference in fluid intake and body weight : respectively 6.4+/-1.5ml and 28+/-2g in controls; 5.1+/-1ml and 29+/-1g in AAs treated. In each group, the total area examined was about 7000.003. All parameters changes statistically in AAs treated animals. The MiV/SpV increases about 28% (0.35+/-0.08 vs 0.45+/-0.11), whereas the SrV/TotV, increases about 15% (0.34+/-0.1 vs 0.39+/-0.06). Conclusion: chronic AAs supplementation improved Mi and muscular functionality in old rats. So, we can postulate that nutritional supplementation can : a) prevent sarcopenia and b) increase muscle strength and cardiac performance probably able of improving the quality of live of old subjects.

THE CHANGES IN BRAIN AND MUSCLE METABOLISM BY THE COMBINATION OF CAFFEINE SUPPLEMENTATION AND LOW VOLUME EXERCISE TRAINING

Esaki, K., Yashiro, K., Sako, T., Yoshitake, Y., Ohkubo, M., Kuwamori, M., Yamaguchi, K., Kinugasa, T., Takemasa, T., Hamaoka, T.

University of Tsukuba, Nippon Sport Science University, Japan Women's University, National Institute of Fitness and Sports, Tokyo Therapeutic Institute, Meiji University, Yamanashi Gakuin Junior Coll., Japan

The purpose of this study was 1) to determine whether the changes in energy metabolism and circulation of the brain and muscle by the supplementation of caffeine (CAFÉ) were associated with the increase in resting metabolism and 2) to determine the effects of CAFÉ intake and 1-month, low-intensity exercise training.

Six obese subjects (32-55 yr., BMI 26.2) were recruited for the experiment in a double-blind, cross-over design.

In Exp.1, subjects were given CAFÉ (5mg/kg) or placebo with 200kcal meal and kept rested for 60 min., then performed a 60 min. exercise testing at 40% maximal systemic oxygen consumption (VO2max). Blood samples were collected at rest, 60 min. post intake, and 60 min. post exercise for analyzing blood CAFÉ, glucose, triglyceride (TG), and free fatty acid (FFA).

In Exp.2, the same protocol was used as the Exp.1 pre and post exercise training. The subjects performed 60 min. exercise training at 40%VO2max, 3 times a week 1 hour after the intake of the supplement (CAFÉ or placebo).

We measured body weight, body fat, visceral fat, blood CAFÉ, glucose, TG, FFA, daily food intake, physical activity, total resting metabolic, fat oxidation rates, muscle oxygen consumption, blood flow, brain oxygenation, heart rate, blood pressure, and sympathetic nerve activity (SNA).

CAFÉ intake significantly increased blood CAFÉ, total resting metabolic rate, and blood pressure and decreased brain blood volume and oxygenation. There were no changes in heart rate, glucose, TG, FFA, daily food intake, physical activity. CAFÉ intake also blunted meal-induced decrease in fat oxidation (p=0.065).

There were no changes in body weight, body fat, and visceral fat after exercise training. During exercise after CAFÉ intake, there was an increase in SNA and a blunt response of the decrease both in total metabolic rate and in fat oxidation after training.

It is suggested that CAFÉ increased resting metabolic rate. The physiologic effects of resting CAFÉ intake were the increase in blood pressure, decrease in blood flow in the brain and the elevation of fat oxidation. After the low intensity exercise training, CAFÉ-induced response of fat oxidation would be enhanced both at rest and during low intensity exercise.

This study was supported by part of a grant from the Nestlé Japan science promotion committee.

CREATINE FOOD SUPPLEMENTS IN THE NUTRITION OF ENDURANCE-TRAINING SPORTSMEN

Milasius, K., Dadeliene, R., Tubelis, L.

Vilnius Pedagogical University, Lithuania

Food supplement, creatine, have found a wide application in enhancing the physical performance and functional capacity among sportsmen. However, comprehensive studies on the effect of creatine complexes with other food supplements are lacking.

The aim - to elucidate the effect of creatine mono-hydrate and the vitamin MULTI VITA+ complex on the sportsman's organism.

We examined 20 sportsmen aged 20-24 years. After the first examination when the physical development performance capacity, blood morphological and biochemical indices had been determined, all the subjects were divided into two groups 10 subjects in each. The food ration of first (E1) group was supplemented for five days with creatine monohydrate at a dose 0.3 g/kg body mass. The second (E2) group was supplemented for five days with creatine monohydrate at a dose 0.3 g/kg body mass and one capsule of vitamin daily.

We determined their physical development, single muscular contraction power (SMCP), anaerobic alactic muscular power (AAMP). The mixed anaerobic alactic - anaerobic glycolytic power was evaluated according to a 30-second maximum strain work on an ergometer (Wingate test). Anaerobic glycolytic capacity (AGC) was evaluated according to a 60-second work on a veloergometer.

We studied the peripheral blood picture, determined the erithrocyte and leucocyte counts, hemoglobin concentration, hematocrite percentage. To assess creatine metabolism in the body, we determined the creatinekinase concentration and creatinine content in blood urine with the aid of a REFLOTRON biochemical analyzer.

The sportsmen's food supplementation with creatine and a combination of creatine with the MULTI VITA+ vitamin was beneficial for their physical development. Supplementation of creatine and its complex with vitamin increased sportsmen power in various energy production zones, however, this increase was not statistically significant in either of the groups. The indices of SMCP, AAMP- AGC were higher in the E1 group administered creatine alone.

Changes in the indices of blood morphological composition in the both groups were insignificant. However, leucocyte count was found higher in the group of sportsmen administered creatine with vitamins.

Rather great differences were noted in the changes of creatinekinase concentration. In the group E1 members, blood creatinekinase activity increased on average from 254.6 to 337.9 u/l whereas in group E2 members this index decreased on average from 210.3 to 177.5 u/l. The decreased blood creatinekinase level in E2 group members shows that performing a load of the same intensity takes less reserves of creatine. This implies that the subjects administered creatine in combination with vitamines undergo a less katabolism under physical loads than do the subjects administered creatine alone.

REDOX REGULATION OF VITAMIN C METABOLISM IN C2C12 SKELETAL MYOTUBES

Savini, I., Rossi, A., Duranti, G., Arnone, R., Bartoloni, L., Avigliano, L.

University of Rome , Italy

Reactive oxygen species are naturally produced during physical exercise inducing muscle damage, in this context, small antioxidant species such as vitamin C and alpha-lipoic acid (LA) are essential to protect cells from oxidative damage. LA is a cofactor for several important enzymes related to energy metabolism as well as a modulator of cellular redox balance (1). When large amounts of free LA are available (e.g., with supplementation), LA is reported to function as an antioxidant (2). Vitamin C is involved in a number of biochemical pathways needed for metabolism and health of exercising individuals, including synthesis and activation of neuropeptides, collagen and carnitine, and protection against exercise-triggered ROS generation. The skeletal muscle cells content of vitamin C depends both by the efficiency of transport systems and by the ability to maintain the vitamin in its active reduced form. Mouse C2C12 skeletal muscle cells possess efficient mechanisms to accumulate vitamin C i.e. SVCT2 transporter for ascorbic acid (AA) uptake, GLUT transporters for dehydroascorbic acid (DHA) uptake and enzymatic activities for vitamin C regeneration (3). Several data suggest that the requirement of exogenous vitamin C is closely related to intracellular redox state. The purpose of this study was to investigate, in C2C12 myotubes, the relationship between LA and vitamin C metabolism (i.e transport and recycling activities) and how the modulation of intracellular redox state influences these pathways. Two well-defined transcription factors, nuclear factor NF-kB and activator protein AP-1 are regulated by oxidants, antioxidants, and other factors that influence intracellular redox status. Thus, we evaluated the effect of LA or AP-1 and NF-kB inhibitors on vitamin C metabolism.

C2C12 myotubes, treated with LA (1 mM) for 24h, increased DHA uptake 2.6 fold over control. This increase was associated with increased DHA reductase activity (1.3 fold over control). On the contrary, myotubes showed decreased AA transport (0.6 fold over control), but unchanged ascorbyl free radical reductase activity. In agreement with transport functional data, LA-supplemented cells showed decreased SVCT2 protein amount. Also AP-1 and NF-kB inhibitors treatment lead to a similar result: 0.4 and 0.2 fold over control respec-

tively. On the contrary, oxidative stress induced by H2O2 (300 microM) caused a 2 fold enhancement of SVCT-2 amount. These results suggest that intracellular redox state modulates SVCT2 expression via AP-1 and NF.kB.

In conclusion, in skeletal muscle cells there is a strict relationship between vitamin C and LA. This compound by ameliorating the ability of myotubes to regenerate vitamin C from DHA. lowers the AA requirements, and therefore SVCT2 expression.

THE EFFECTS OF JAPANESE DIET ON BODY FAT, METABOLISM, INSULIN RESISTANCE, AND AUTONOMIC NERVOUS SYSTEM ACTIVITY IN YOUNG LEAN WOMEN WITH EXCESSIVE BODY FAT

Nagai, N., Sakene, N., Nishida, M., Moritani, T.

Okayama Prefectural University, Japan

The dramatic increase in thinness or the decline in BMI values has been observed in young Japanese women (Takimoto et al. 2004), however, prevalence of latent obesity (normal weight with excessive body fat) have also increased and reached around 40% (Takahashi et al. 2002) of twenties who have altered their food intake from a low-fat, balanced Japanese diet to a high-fat, Westernized diet for several decades (Yoshiike et al. 1996). This study, therefore, investigated the effect of a low-fat, Japanese food-based diet on body fat, metabolism, insulin resistance, and autonomic nervous system (ANS) activity, while controlling for physical activity in free-living young women.

Eleven young lean women with excessive fat (21.7±0.8 yrs; BMI, 21.0±0.5 kg/m2; body fat, 29.8±0.7 % [mean±SEM]) received a low-fat, Japanese food-based diet (20% fat, 60% carbohydrate, and 20% protein, 5000 kJ/day) for 2 weeks at laboratory. Body fat, waist circumference, resting metabolic rate, insulin resistance, and the ANS activity were measured at baseline and 2 weeks. Insulin resistance was calculated using a HOMA-R (homeostasis model assessment for insulin resistance). The ANS activities were assessed by means of power spectral analysis of heart rate variability, and we evaluated a low frequency component (LF power, 0.03-0.15 Hz) as an indicator of the sympathetic nervous system activity (Akselrod et al. 1981, Moritani et al, 1993, Nagai et al. 2003).

Results demonstrated that significantly improvements ($p < 0.001$) were observed for body fat (-1.7 ± 0.2 kg fat mass), waist circumference (from 72.2±1.1 to 68.5±1.0 cm), fasting glucose (from 90.4±2.7 to 83.7±1.8 mg/dL), fasting insulin (from 5.9±0.5 to 3.3±0.4 μg/mL), HOMA-R (from 1.3±0.1 to 0.7±0.1), and glycoalbumin (from 14.4±0.2 to 13.9±0.2 mg/dL). Fat oxidation (from 45.6±5.4 to 65.3±5.5 mg/min) as well as LF power (from 5.7±0.2 to 6.1±0.2 ln ms2) significantly increased ($p < 0.05$), and serum triglyceride (from 68.4±5.9 to 47.8±3.2) significantly decreased ($p < 0.01$), suggesting increased overall lipid metabolism in the body.

In conclusion, despite a short-term and modest energy restriction, a low-fat, Japanese diet can contribute to significant decreases in body fat and waist circumference and improve the insulin resistance. In addition, overall lipid metabolism was enhanced. Our results provide evidence that a proper nutritional intervention may be useful in regaining desired body composition among young lean women with excessive fat, thus possibly preventing the future metabolic syndrome.

CALCIUM INTAKE AND BONE HEALTH STATUS AMONG YOUNG FEMALE ATHLETES

Hamzah, S., Mohd Ali, M.

University of Malaya, Malaysia

The effects of physical activity on bone have been extensively reviewed (1). Since physical activity, particularly high impact, is associated with greater bone density (2), one might expect that female athletes need not worry about the possibility of bone loss. However, identification of a syndrome of disordered eating, amenorrhea and reduced bone density (3) overshadows this positive aspect of physical activity and may contribute to a greater consideration for adequate calcium intakes in female athletes. The aim of this study was to determine the associations between calcium intake and bone health status among young female athletes who are either state or national level representatives. A total of 48 female athletes aged between 14 to 19 years old from 9 different types of sports were studied. Parameters measured were weight, height, body fat percentage and body mass index (BMI). Calcium intake was determined through a Food Frequency Questionnaire. Bone health status was assessed using Quantitative Ultrasound Sonometry, which measures Broadband Ultrasound Attenuation (BUA, dB/MHz) at the calcaneus. The mean weight and height of the subjects were 53.15 ± 9.83 kg and 161.21 ± 6.89 cm respectively. The body fat percentage was 17.16 ± 5.08% and BMI was 20.34 ± 3.14 kg/m3. The mean calcium intake was lower than the Recommended Nutrient Intakes for Malaysia (4). The mean BUA of bone health status was 97.38 ± 15.56 dB/MHz and the mean T-score was 0.67 ± 1.25. According to the WHO (5) classification, 87.5% of the subjects have normal bone health status (T-score >-1.0) and 12.5% were classified as osteopenic (-2.5≤T-score ≥-1.0). Data from each sport showed a significant relationship between daily calcium intake and BUA among the gymnasts ($r=0.23$, $p<0.05$). This group had the lowest mean calcium intake and BUA. However, there was no significant relationship between calcium intake and BUA in the rest of the sports. In conclusion, low calcium intake was associated with low bone health status especially among the young girls who trained in sports in which low body weight is emphasized for athletic activity or appearance. A proper dietary intake and training practices are needed to prevent low bone mass leading to stress fractures.

Poster presentation (PP)

PP2-09 Motor Learning 1/1 - "Exhibition Hall"

THE EFFECT OF AUGMENTED FEEDBACK ON THE FOOTSTEPS LEARNING

Berchicci, M., Bertollo, M.
Faculty of human movement science, Italy

Among the different variables known to affect learning in physical practice context, augmented feedback following the completion of the response is considered to be one of the most important (Schmidt & Lee, 1999) and a necessary phase that the learner must go through in order to reach the autonomous stage where movement control is more or less automatic (Masters and Maxwell, 2001). These observation are discussed in view of the benefits and pitfalls of augmented feedback in relation to task context and instructional condition (Badets & Blandin, 2004).
101 volunteers, aged from 16 to 31 years (M=23; sd=3,76) were required to perform complex skill by "all music dance". It was originally composed by an electronic game in which the player had to follow the luminous arrows sequence on the screen with the dance mat controller. No participants had prior experience with the performance on the task. The software assigned a score in function of spatial and temporal precision. Scoring could see on video during the practice.
The protocol is composed by three phases:
In the test phase, three different footsteps sequences in order of difficulty were performed by all subject after a baseline test.
During second phase, the participants was divided into two homogeneous groups:
 one group (56 participants) acquired a footsteps movement with normal vision of performance and results in real time (with augmented feedback);
 another group (45 participants) performed the complex skill without augmented feedback.
The latter group performed the task on posters that reproduced the arrows like the original, so participants didn't knew knowledge of performance (KP) and knowledge of results (KR). Both group exercised thrice in each footsteps sequences.
In the last phase all subjects reproduced the footsteps sequences on mat controller.
The test refers to the score obtained from the first experience and the re-test refers to the score obtained from the last phase.
One ways ANOVA 2 groups (with and without augmented feedback) revealed that the augmented feedback encourage skill learning (F=(1,99)116,42; p=.000) (Wallace and Hagler, 1979). In fact learners who practiced with augmented feedback showed a further performance improvement relative to the end of practice, like as report in literature (Wulf, Shea and Park, 2001).

MECHANICAL EFFICIENCY AND MUSCULAR CONTROL VARIATIONS IN CYCLING BY USING DIFFERENT TRAINING INFORMATION PROCDURES

Pozzo, R., Neuman, K., Plaino, L., Schwirtz, A.
University of Medicine Udine, Italy

Introduction. The efficacy of cycling concerns the biomechanical relationship between the cyclist and the bicycle as well as the muscle activity patterns. Tangential crank force can increase (pushing) or decrease (breaking) the propulsion total net torque. Subjects show various capacity of motor and sensory cues to match the biomechanical demands especially in the transition between extension and flexion. The aim of this study was to investigate the effectiveness of different training information procedure to improve the biomechanical efficiency of pedaling.
Methods. Tangential and radial crank forces were recorded at 100 Hz by a special system (Powertec). EMG (Biovision) of principal muscles (RF, VM, BF, TA, GAS, SO) was made according to the SENIAM guidelines. RMS and IEMG values were calculated. 2-D kinematics of the legs were calculated via video analysis (SIMI). Two groups of cyclists participated in the experiment (PC= 6 professional , NC= 6 sport students). Subjects complete pedaling items with 70 b/min cadence, 1 minute duration and under four loading conditions (100, 150, 200, 250 W), 3 minutes rest between loads and no fatigue. Items were carried out in the following sequence: I-1) actual technique, I-2) repeat first item receiving visual information on the shape of the tangential force after each previous load, I-3) pedaling with online visual feedback on the shape of the tangential force for the left and right leg separately, I-4) repeat all the loading steps without information. After two days subjects were required to repeat item I-4. Results. Most of the subjects reveal a breaking action of the legs during the upwards phase crank. This negative effect was more pronounced at 100W load. After I-2 no substantial variations on the tangential force were observed for both groups. Some subjects modified the force profile, but not necessary increasing the efficiency. During online feedback, all subjects were able to modify correctly the force curve and to obtain an increased biomechanical efficiency. During item I-4 the new technique was well reproduced and different kinematics and EMG adaptations between groups, with respect to the I-1 technique, were depicted. NC have greater and PC lower knee extension, while the flexion was the same as in I-1. Ankle extension angle was reduced in PC for all the loads, while in NC it was lower for 100W and greater for 250W loads. Ankle flexion showed similar values with respect to I-1, but was greater in NC (75° vs 65°).Some muscles showed identical variations for both groups, TA increased and VM and SO decreased activity. GM decreased significant only for PC and RF increased for PC and decreased for NC. BF showed no clear tendency. After two days, most of the subjects were able to reproduce the new acquired force patterns. In order to obtain a comprehensive view of this locomotor adaptations, especially for long duration effort, analysis of the metabolic efficiency should complete this approach.

ENHANCED VARIABILITY AND ACCURACY OF TENNIS SERVE

Moreno, F., Menayo, R., Fuentes, J.P.

Universitiy of Extremadura , Spain

Variability is a natural feature of the behavior or organism. Evidences reveal that there are not two movements identical, even trying to repeat exactly the same. The invariance of movement has been interpreted even in contrasting theoretical frameworks, as a reflection of the order of biological motion and the essential window into theoretical approaches to action (Newell and Slifkin, 1998). Actually, some studies suggest that compensatory variability can be observed in performers who are skilful at exploiting the high dimensionality offered by the degree of freedom of the movement system (Davids et al., 2003).

This study analyzes the relationship between variability showed by tennis players executing a service and accuracy obtained from the boll bounce after the service. There is a saying tennis that you are only as good as your serve. The ability to hold serve at higher levels of competition is usually what determines how far a player can progress competitively in the game. As with other strokes, good technical executions of the core elements of the motion are a prerequisite for effective and consistent serving.

Twelve intermediate-level tennis players participated in the experiment. Kinematic variables (position, velocity, acceleration, angles and timing) were measured from the serves performed in different variability task constraints. For variability purpose, perturbations were induced in serve movements as constraints; the players were required to perform serves with different ball weight, racquet weight, velocity requirements and from different positions and orientations near to their preferences. Also the players served as usual.

Kinematic data were collected by a Polhemus Fastrack located on the forehand at 120hz with a accuracy of 0.08 centimetres in position and 0.15 grades in angle.

A video camera was used to record the ball bounce in order to measure de precision of the serve. Ball velocity in the serves were recorded by and Sport Radar SR-3600.

The correlations between kinematic variables, precision and velocity have helped to identify variables which determine the server performance. How perturbations induced in the task modified kinematic patterns are described in this study. Perturbations affect variability but this changes observed in the variables analysed must be interpreted in relation with the spatial and temporal precision. The results suggest alternative theories far from noise un-functional interpretation about variability, and functional role of variability is revised in order to enhance the performance of the serve.

IMPLEMENTING COMPUTER SIMULATION IN GYMNASTICS TRAINING

Heinen, T.

German Sport University Cologne, Germany

Computer simulation can be seen as a safe and effective tool for optimisation and further development of sport specific movements (Glitsch, 2001). Especially models of the whole body seem to be useful to understand existing movements or make prognostic statements about new imaginable movements in sports. There are several interesting attempts to use multibody modelling and simulation in gymnastics (e.g. Arampatzis & Brüggemann, 1998; Yeadon & Mikulcik, 1996). New developments in modern computer technology have oppened possibilities to simulate and animate such model systems almost in real-time and therefore utilize them for the training process. According to the mentioned aspects we constructed an interactive simulation system that can be implemented in the training process in gymnastics. The systems consists of two modules: 1.) a module for movement analysis and 2.) a module for movement simulation on the basis of a particularly developed 16-segment model of the human body. The first module is based on a simple optical method for movement analysis. The second module uses the data from the first module as well as anthropometric measurements of the gymnast as input. After a validation procedure has been performed the system is arranged in such a way that the trainer or the gymnast has the ability to manipulate essential aspects of the movement and study the effects of these manipulations on the movement outcome. The system was used (and validated) so far with rotational movements on the high bar as well as somersault and twisting movements on the floor and trampoline with regard to the optimization and further development of existing gymnastic techniques. For example in rotational movements on the high bar it can be shown under which conditions the free hip circle to handstand can further be developed to difficult flight elements (e.g. free hip circle to tkatchev) and new imaginable dismounts from the high bar and which coordination patterns of joint torques will be necessary to perform these movements. The developed system may also be coupled with special forms of psychological training. The gymnast can understand the movement by exploring for example the same movement under different initial conditions. Early experiences emphasises that gymnasts who regularly use the system are faster in learning new skills. Last but not least it can be stated that new methods to understand the structure of gymnastic skills seem to be an essential resource to optimise gymnastic techniques.

ERRORS IN JUDGING "OFFSIDE" IN FOOTBALL AND THE ROLE OF EXPERTISE

Catteeuw, P., Gilis, B., Helsen, W.

Katholieke Universiteit Leuven, Belgium

According to different studies (1,2), the flash-lag effect (FLE) may account for the errors that ASR make, not only in real life situations, but also in computer animations (3). The FLE is defined as a moving object that is perceived as spatially leading its real position at an instant defined by a time marker (in the particular case of judging offside the moment the ball is passed). The first aim of the present study was to examine the impact of the movement of the second last defender on the FLE. The second aim was to examine if international FIFA ASR can better deal with this perceptual problem than national ASR.

FIFA ASR (n=54), who were all potential candidates for the World Cup 2006, and Belgian ASR (n=34), who were all active in matches of the professional league, had to assess 2 sets of 32 computer-based offside situations. In these animations, the position of the attacker relative to the offside line was experimentally manipulated. For the onside positions, the attacker was either 20 or 10 pixels behind the offside line or on the offside line. For the offside positions, the attacker was 10 pixels ahead of the offside line. Furthermore, the movement of the defender was also manipulated. The second last defender was either standing still at the moment the pass was given, or he was moving in the opposite direction of the attacker (as often is the case in matches).

First, the results clearly showed a better performance (P<.048) for the FIFA ASR (70.6%) compared to the Belgian ASR (64.2%). Second, significantly more errors were made in situations where the attacker was on the offside line than 10 pixels behind the offside line. In situations where the attacker was 10 pixels behind the offside line, significantly more errors were made than 20 pixels behind and 10 pixels ahead of the offside line. These results support previous findings (3) and clearly support the flash-lag hypothesis. Finally, situations with a static defender (74.9%) were assessed more correctly than situations with a dynamic defender (61.4%) (P<.0001). FIFA ASR better assessed situations with a static (75.9%) as well as with a dynamic (65.3%) defender than Belgian ASR (static 65.3%, dynamic 55.2%).

Interestingly, FIFA ASR made fewer errors in onside situations than Belgian ASR, particularly in onside situations with a static defender. In situations with a dynamic defender, the FLE was still clearly present, also in FIFA ASR. In conclusion, when the second last defender and the attacker were moving opposite, the FLE enlarged the difficulty of judging offside. Future research is needed to examine if there are other ways outside the game using video simulations and computer animations to let ASR master the offside situations during a match in a better way.

MUSCULAR STABILITY OF THE GOLF SWING AND THE PROPORTIONAL DURATION MODEL

Fernandes, O., Barreiros, J., Cabri, J., Pezarat-Correia, P., Hoolthuis, A.

Faculty of Human Movement, Technical University of Lisbon, Portugal

Purpose: The main purpose of the present study was to investigate the proportional duration model in the golf swing. In this model the temporal structure of muscle activity remains constant, despite different overall duration of the movement. Temporal structure of swing was assessed by means of peak activity of several shoulder and arm muscles.

Methods: Three low-handicap golfers (handicap lower than five) performed sixteen golf swings with a pitch iron. Trials were ranked according to their duration and two trials with the longest and shortest duration were selected for analysis. A three axis accelerometer (1000 Hz) fixed at the back of the golf club head informed about movement start and ball contact time. One camera (300 Hz) was focused on the ball to detect movement start. Surface EMG was recorded from 12 muscles of the dominant upper limb: p. clavicularis (AD), p. acromialis (MD) and p. scapularis (PD) of the deltoideus, pectoralis major (PM), latissimus dorsi (LD), infraspinatus (IS), vastus lateralis (VL) and long portion (LP) of triceps brachii, biceps brachii (BB), brachioradialis (BR), wrist flexors (WF), and wrist extensors (WE). The EMG signals were sampled at 1000 Hz, full wave rectified, low pass filtered (second order Butterworth filter at 12 Hz) and normalized in amplitude using the EMG of the maximal voluntary contraction as a reference. Peak activity of each muscle was calculated and the correspondent time (ms) was then recalculated as a percentage of the overall swing duration. Six muscles were selected for posterior analysis: BB, IS, LD, WF, VL and PD. Absolute time of peak activity and relative position (percentage of overall swing duration) were calculated.

Results: The six muscles demonstrated peak activities at significantly different absolute timings (Friedman Test, p=0.03 for short swings; p=0.02 for long swings). The same temporal sequence in the EMG peak activities was found, regardless the condition and the subject. When considering the absolute timing of the swing, all muscles observed were active at different times, the slowest swing having later activation. However, when normalizing these activation times to the percentage of the total swing time, these differences disappear. The time normalization did not reduce inter-individual differences. Differences between subjects were markedly noted in IS which demonstrated different strategies of follow-through preparation. On the contrary, LD activation timing was very similar in all subjects, both in the short and long duration swings.

Conclusion. It is hypothesized that some muscles' activities are scaled to a fixed proportion of swing duration. If this is the case, then an EMG approach, when analyzing the temporal aspect of muscle activity, using a proportional duration model must account for muscle specificity in a particular action.

TIMING THE GOLF SWING IN THREE DIFFERENT CONDITIONS

Barreiros, J., Cabri, J., Diniz, A., Bruno, P.M.

Faculty of Human Movement, Technical University of Lisbon, Portugal

Purpose: Timing refers to the coordination of a sequence of actions in the downswing to obtain the greatest possible club head speed. It implies adequate downswing sequence and acceleration, at the right moment, i.e. at ball impact. The purpose of the present study was to verify the temporal stability of different swing phases under varying conditions of speed and amplitude.

Methods: Three low-handicap golfers (handicap lower than five) performed various golf swings with a pitch iron, under three different conditions: (1) full swing, (2) swing at reduced speed (target speed of 90% of the full swing speed), and (3) swing at reduced speed (90% of the full swing speed) but with reduced backswing amplitude. Four trials in each condition were selected for analysis. Swing speed in all conditions was controlled using radar. A three-axis accelerometer (1000 Hz) fixed at the back of the golf club head informed about movement start, end of backswing phase, time of maximum acceleration and ball contact time. Two cameras (300 Hz), one in a sagital plane and one focused on the ball, provided additional information about those moments. Three phases were characterized in terms of absolute duration (ms) and relative duration, as a percentage of overall duration: (1) backswing, (2) forwardswing, (3) acceleration phase. Two aggregated phases were also considered for analysis: (4) duration of downswing (2+3), and (5) overall swing duration (1+2+3). The follow-through phase was not analyzed.

Results: A Friedman Test showed slight higher club head speeds in the full swing condition (p=0.09) and significant longer overall swing duration in the reduced speed condition (p=0.05). No significant differences were observed between trials in the three conditions (p>0.10). Furthermore, an exploratory analysis suggested no statistical differences in absolute duration and relative duration between conditions in the four swing phases. However, when individually analyzed, all subjects demonstrated some differences in absolute duration of specific phases in different conditions. For instance, in one subject a variation of 13% in backswing duration between the full swing and the reduced speed condition was observed. But, in another subject, a variation of 33% in the duration of acceleration phase of downswing was

observed. In general, these variations in some phases are substantially reduced in relative duration analysis. Subjects tend to keep a uniform relative duration of the swing phases between conditions. This trend was observed in all three subjects.

Discussion: Despite their similar experience and handicap, subjects evidenced important differences in their swing temporal structure. The observed variations in phase duration between conditions are strongly reduced in a relative duration analysis. This result offers limited support to a temporal scaling hypothesis in golf swing. Individual differences strongly recommend within subject analysis.

THE EFFECTS OF VARIABILITY OF PRACTICE ON LEARNING A NOVEL MOTOR SKILL

Lyons, M., Al-Nakeeb, Y., Moreton, J., Duncan, M.

Newman College of Higher Education, United Kingdom

Introduction

Research has shown that varied practice scheduling may affect learning and performance of motor skills. However, despite the acknowledged importance of practice no coherent picture has emerged as to what type of practice variability is most effective in learning skills. Magill and Hall (1990) found that blocked practice produced better learning results than random practice. However, Ota (1999) found that variable practice conditions were more effective than constant practice. According to Shea et al. (2000) little research has examined the benefits of spacing practice across days especially with respect to learning motor tasks, hence this warrants further investigation.

Methodology: Thirty College students participated in a novel dart-aiming task. They were randomly assigned to three groups; group one performed four blocks of 30 trials in one session, group two performed 2 blocks of 30 trials on two consecutive days, group three performed one block of 30 trials on four consecutive days. A total of 120 trials were performed by each participant. The target contained four concentric circles, with the centre circle having a diameter of 5cm. Each of the other circles increased by 4cm in radius. Four points were awarded for a hit on the centre circle. The score for each concentric circle radiating out from the centre decreased by 1 point.

Results: A three by four ways repeated measures ANOVA indicated no group by condition interaction. There was however, a significant ($p = 0.027$) within-subject effect over the blocks of trials. The mean values over the 4 blocks of trials were 33.80 ± 1.49, 38.53 ± 1.87, 37.20 ± 1.52 and 38.13 ± 2.05. The post hoc indicated a significant ($p = 0.010$) difference between the first and second block. There were no other differences observed.

Discussion: Initial findings indicated that the variability of practice did not affect learning of this task. This disagrees with memory consolidation theory. There was a significant improvement ($p = 0.010$) between the first two blocks of trials across all three groups. No further improvement was evident in subsequent blocks. While spacing practice over two days is beneficial, there is no evidence that further improvement occurs thereafter. Future investigation should examine contextual interference effects and whether longer inter-session intervals impact on learning.

COORDINATION MEASUREMENT IN PRESCHOOLERS - TRADITIONAL VS DYNAMICAL SYSTEM MODEL

Serbetar, I., Kranjcina, Z., Kurtanjek, M.

Teachers College Petrinja, Croatia

INTRODUCTION: Coordination data were gathered on basis of two different approach. First, children were measured in «traditional» motor tasks where the outcome was measure of time how fast can child accomplish complex motor task while the second task was from dynamical system perspective. The authors were interested if there are any connections between variables from two models.

METHODS: The sample comprised from 23 children in the age of 5-yrs.

«Traditional» coordination motor tasks were taken from the battery MOT 4-6 (Zimmer, Volkamer, 1984). They were: crawling under the bench, running after rolling, crawling with the ball, walking back through hoops and rolling the ball around the hoop. «Dynamic pattern» movement tasks were composed of isolated cyclical flexion-extension movement of the wrist and the ankle on the both sides according to the isodirectional and nonisodirectional mode. During isodirectional coordination, both limb segments were moved in same direction, while during nonisodirectional coordination segments were moved in opposite direction. The movement were paced by metronome on frequency of 1 Hz whereby full movement cycle was completed on every second beat. Movement was controlled visually and correctly performed cycles were counted.

RESULTS: Since analysis of variance didn't revealed any significant differences between boys and girls, further analysis were done with mixed group. Distribution of MOT 4-6 data was normal while in nonisodirectional coordination mode normality curve was significantly flat. Correlations between two test batteries were very low and insignificant. Accordingly, canonical correlational analysis failed to establish association between subsets of data.

T test applied on variables of hand-foot rhythmic coordination showed that significant differences exists between all variables in that subtest ($T = 4.75 - 8.60$, $p < .001$). Children performed poorly in nonisodirectinal mode on both side, which can be explained developmentally although there are also evidence from many studies (Amazeen & Amazeen, 1998; Serbetar & Sertic, 2004.) that in-phase mode is much more stable than the anti-phase mode. Children simply could not maintain or even started the movement, and anti-phase heavily switched into in-phase. Young children have week coordination regime (Fitzpatrick et al. 1996) and lack of connections establishing between the data from two measurement models confirmed again well known fact that the problems of movement coordination are extremely difficult to explain and resolve.

EXAMINATION OF A MODEL OVER SELF-CONTROLLED MOTION-LEARNING

Bund, A., Ferwagner, D.

Technical University of Darmstadt, Germany

Introduction: Self-controlled motion-learning occurs, if the learner has control over at least one component of the learning process (e.g. the use of learning hardware). The few studies on this topic show a consistent pattern. This is what the pattern says: In short-term, especially in the time when things just learned are still only being exercised, there are no significant differences between the self-controlled learning groups and the non-self-controlled learning groups in their performance skills. Nevertheless in longer-term, in a retention test, the self-controlled groups show significant better skills than the externally-controlled groups. Until now there is no conclusive explanation for this phenomena. Bund and Wiemeyer (i.R.) assume in a model, that while learning self-controlled the motivational and cognitive processes have an antagonistic effect: A higher learning motivation is compensated by a higher cognitive demand. Only in the retention test, when there is no more self-controlling necessary, the advantage of this form of exercise shows. The following learning-experiment was used to check this model with empirical means.

The learning experiment: Students of difference faculties (N=48, M=23,67 years) had to learn a baseball specific target-throw with the non-dominant hand. A learning-phase of 100 throws in two days was followed after 4 days by a retention test with 20 throws. Target misses (MRE) and quality of the movement execution as dependent variables were determined.

The model examination took place through constitution of the following groups of learners: 1) self-controlled feedback; 2) externally controlled feedback (parallel group to 1); 3) self-controlled feedback with additional demotivation notice; 4) externally controlled feedback with additional demotivation notice (parallel's group to 3). From the model the hypothesis can be derived, that the groups 3 and 4 show worse exercise achievements than the groups 1 and 2, while in the retention test the self-controlled groups of 1 and 3 come off well better than the external regulation groups 2 and 4. The following reports only the results on the target misses.

Results and discussion: All groups of learners improved their achievement during the exercise course(day: $F(1,44)=9.24$, $p<.01$; Block: $F(9,396)=11.56$, $p<.01$). In the process group specific effects stepped on (day x group: $F(3,44)=4.59$, $p<.05$). The post-hoc analysis gives a reference for smaller target misses of the groups 1 and 2 in relation to the groups 3 and 4 on the second exercise day (group: $F(3,44)=5.22$, $p<.05$). In the retention test group 1 improved their achievements better as the groups 2 and 4 ($F(3,44)=6.14$, $p<.01$).

These findings refer to back the acceptance of the model.

ERRORS IN JUDGING "OFFSIDE" IN FOOTBALL AND HOW TO BETTER DEAL WITH IT

Gilis, B., Helsen, W., Catteeuw, P.

Katholieke Universiteit Leuven, Belgium

Several authors proposed the flash-lag effect to explain the errors made by assistant referees (ASR) both in real life (1,2) as well as in computer animations and video clips (3). The most important aim of this study was to examine if offside decision-making in computer animations can be improved with specific instructions and appropriate feedback.

Belgian elite ASR (N=20), who were all involved in professional football, had to assess computer-based offside situations. In these animations, the position of the attacker relative to the offside line was experimentally manipulated. Specifically, for the onside positions, the attacker was 20 and 10 pixels behind the offside line as well as on the offside line. For the offside positions, the attacker was 10 pixels ahead of the offside line. In a first exposure, the participants had to assess a first set of 32 animations. After a 5-minute break they had to assess a second set of 32 similar animations. Eighteen months later, the same ASR had to assess the same animations of set 1 (control condition). Then instructions were given to explain the impact of the flash-lag effect. The animations were shown again and paused at the moment the ball was played. The ASR were provided with their own responses, so that they could compare their answers with the correct ones. Afterwards, they had to assess the animations of set 2 (experimental condition). Six weeks later, a retention test was done with the animations from the experimental condition.

First, the results showed less errors when the attacker was 10 pixels ahead of the offside line than 10 pixels behind the offside line. An equal number of errors was found when the attacker was 10 pixels ahead of the offside line and 20 pixels behind the offside line. This can be fully explained by the flash-lag effect.

More important was to see whether offside decision-making improved with specific instructions. First, no difference was found between set 1 (63.3%) and set 2 (64.8%) of the first exposure. It can be concluded that there is no difference between these 2 similar sets of animations. Second, an improvement was found for the control condition (71.1%). This can be explained by the repeated exposure to the same situations. Third, the better performance in the experimental condition (78.1%) compared to the repeated exposure in the control condition showed that instructions and feedback lead to better decision-making in computer animations of offside situations. Fourth, no differences were found between the experimental condition and the retention test (79.8%). Future research is needed to investigate the relationship between offside decision-making in computer animations and during actual games.

THE RELIABILITY OF EUROFIT SHUTTLE RUN TEST ON FIVE-YEAR-OLD CHILDREN

Gundersen, K.T., Fiskum, T., Estil, L.

North-Troendelag University College, Norway

The Shuttle run test is a part of the EUROFIT motor fitness test battery, which is recommended for children from the age of six. In Norway the test is also a part of a test battery recommended from the age of four. Even if some reliability studies of the Shuttle run have been made, no reliability studies for specific age groups as young as five years old has been reported. For younger children less or different motivation may influence the test results and reduce reliability. Two studies were carried out in two different kindergarten groups. In the first study (n = 7) the test was carried out in accordance with the standards in the test manual, while the test procedure was changed in the second study (n = 9), in attempt to reduce the influence of motivational variables. The test was scored in accordance with the manual, but in attempt to decrease small sources of error two alternative scoring procedures, involving data reduction, was tried out. The results showed no significant correlations between first and second test in any of the alternatives in study 1 or study 2. It was concluded that for five-year-olds the Shuttle run test is not a reliable measurement when the sample of subjects is small.

Poster presentation (PP)

EFFECTS OF EXERCISE TRAINING ON THE ENDOTHELIUM FUNCTION IN PATIENTS WITH CHRONIC HEART FAILURE

Karatzanos, L., Chatzimichail, E., Karaseridis, A., Anagnostakou, V., Sakellariou, D., Tasoulis, A., Avdikou, M., Pappas, C., Vasiliadis, P., Roussos, C., Nanas, S.

University of Athens, Greece

Exercise training has been an important means of rehabilitation in patients with chronic heart failure (CHF). Furthermore, exercise training has been found to induce favourable effects on endothelium function. This study was designed to investigate the effects of exercise training on endothelial function in CHF patients.

Sixteen stable CHF patients [(Μ±S) 57.2±9.4 years, VO2peak: 15.7±6.4 ml/kg/min] participated in an exercise training program for 12 weeks, 3 times/week. Participants were randomly assigned to either aerobic (AG, n=7) or combined group (CG, n=9), which included aerobic and strength training. Aerobic exercise was performed in interval type on cycle ergometers. Strength training involved exercises for various muscle groups of the legs, the shoulder zone and the arms. Both regimes were of the same duration. The endothelial function was assessed at the beginning and the end of the program with 'flow-mediated dilation' at the right brachial artery (Welsch et al., 2002). The diameter of the artery was evaluated with ultrasound before and after 5-min occlusion. Variable was the difference of the artery diameter in absolute (DDabs) and relative (DDrel) values.

In concern to DDabs, the whole cohort was improved significantly from 4.1±1.7 to 5.7±5.7 mm ($p<0.05$). The CG (from 3.6±1.7 to 6.2±1.6 mm) tended to improve more the AG (from 4.9±1.6 to 5.0±1.2) ($p=0.06$). In relation to DDrel, the whole cohort tended to improve significantly (from 9.1±4.2 to 12.3±3.2 %, $p=0.8$). The CG (from 7.7±3.5 to 13.3±3.8 %) also tended to improve more than the AG (from 11.0±4.5 to 10.9±1,7 %) ($p=0.07$).

Exercise training seems to affect favourably endothelial function in CHF patients. A combined regime of strength and aerobic regime may be more effective than a regime mostly aerobic. These findings need to be further investigated in a larger cohort.

Welsch, M., Allen, J., and Geaghan, J. (2002). Stability and reproducibility of brachial artery flow-mediated dilation. Medicine and Science in Sports and Exercise, 34, 960-965.

AN ADAPTED EXERCISE PROGRAM IMPROVES PERFORMANCE OF ELDERLY PERSONS WITH MENTAL DISABILITIES

Peters, C., Schoenfelder, F., Ohanian, J., Zalfen, B., Wacker, E., Michna, H.

Technical University of Munich, Germany

Introduction

Rehabilitative and preventive effects of adapted physical activity are very important for elderly people to age healthy and to keep independency. Therefore, we developed an exercise program for elderly handicapped persons with mental disabilities. Furthermore, we wanted to ascertain if training may improve physical performance or quality of life.

Methods

In co-operation with the Federal Association of Lebenshilfe in Freising/Germany 7 male and 21 female persons (52 +/- 9,4 years old) with mental disabilities were engaged under the following conditions: minimum age of 40 years, capability to follow simple instructions and non-activity in other sports.

An exercise intervention was implemented over 11 month and split up in 5 emphases: balance and gait, internal and external perception and relaxation, force of the upper and lower extremities, coordination of eye and hand movement and endurance. Participants were divided into 4 groups and instructed once a week during 60 minutes with basic exercises and games. To evaluate training effects before and after the intervention endurance performance (2-minute-walk), keeping balance, traction and pressure-force of the arms, leg-force (3-chair-rise), reaction-time on a visual sign, tapping (number of footsteps during 30 seconds), peak expiratory flow and activities of daily living were examined.

Results

Participants improved significantly in most of the tested parameters: the distance accomplished during the 2-min-walk increased significantly (74,7 +/- 32,8 to 99,3 +/-49,8 m), balance-time enhanced (from 48 +/-22 to 60 +/-23 sec) ($p < 0.05$) and the amount of footsteps during 30 seconds raised (from 58,3 +/-30,2 to 72,1 +/-27,5) ($p < 0.05$). Furthermore, the time needed to rise 3 times from a chair decreased (from 17,0 +/-8,9 to 9,5 +/-6,0) ($p < 0.05$) and reaction-time shortened (from 1,91 +/-1,19 to 1,39+/-0,75 sec) as well as peak expiratory flow augmented from 298 +/-132 to 359 +/- 134 l/min ($p < 0.05$). Only a slight decrease was found in traction-force and pressure-force.

Discussion

Although other studies observed positive effects of controlled exercise with training three times a week for periods of several weeks in similar populations (1, 2), performance of our cohort improved significantly in most tested parameters by training only once a week. Feed back of the participants in regard to lesson contents was also positive. For elderly people with mental disabilities we can conclude from our findings that even with moderate exercise once a week general fitness may be improved.

ASSESSMENT OF STATIC AND DYNAMIC BALANCE OF FEMALE VOLLEYBALL ATHLETES WITH ERROR SCORING SYSTEMS

Enangelodimou, A., Athanasopoulou, E., Tsipropoulou, A., Barzouka, K., Athanasopoulos, S.

National and Kapodistrian University of Athens, Greece

Introduction: Maintaining postural stability is a complex process. The neural system receives afferent information from the visual, vestibular and somatosensory system, integrates them and coordinates the appropriate musculoskeletal responses, so that balance is achieved. The majority of injuries in the lower body of athletes in volleyball are due to loss of balance, during the landing phase. Injuries, incomplete rehabilitation or insufficient training can all have an effect on sports performance causing kinetic dysfunctions.

Purpose: To assess the dynamic balance of female volleyball athletes; to correlate this balance with injuries of the lower body and the playing position; to investigate static balance in single-leg stance on the dominant leg, on the non-dominant and tandem stance and in three different conditions: open eyes, closed eyes, closed eyes with head extension (3*3=9 stance variations); the extent to which static balance is affected by lower body injuries; the relationship between errors in static and dynamic balance tests.

Method: In the study 27 female volleyball athletes participated. Their somatometric characteristics and lower body injuries were recorded. The assessment of dynamic balance was performed through an error-scoring system test with "multiple single-leg jumps". The static balance was assessed using also a balance error scoring system, according to which the number of predefined errors was recorded in the nine stance variations.

Results: The statistical significance of errors between the two injury groups (major injuries N=13 and moderate-minor-none N΄=13) was 0.069 (p=0.05), indicating a trend between injuries and balance errors in the dynamic test. No statistical differences were found when comparing the playing position of the three groups with the total number of errors in the dynamic balance test as well as with the individual landing and balancing errors. Significant differences were found when comparing the errors in the three conditions of afferent information, in both injury groups. The t-test between the two groups, in each of the 9 conditions, showed no significant differences. In contrast, the t-test of the errors in the three stance conditions, regardless of afferent information, showed statistical difference between the tandem stance and the other two conditions (p=0,05).

Conclusion: These results indicate that the balancing mechanisms were not affected by the magnitude of the lower body injuries or that the latter were restored, taking into account that in every stance condition the same balancing strategies were recruited in both injury groups. The proprioceptive deficits were probably insignificant and did not affect the balancing ability. Even if significant deficits existed, these were counterbalanced by increased proprioceptive information from the anatomic structures of adjacent joints of the injured areas or from other mechanisms in the central nervous system.

CHRONIC EFFECTS OF COMBINED EXERCISE TRAINING ON RESTING METABOLIC RATE IN MEN SUFFERING FROM CORONARY ARTERY DISEASE

Bento, T. 1, Santa-Clara, H. 1, Almeida, J. 1, Fernhall, B. 2

1 Faculty of Human Movement, 2 University of Illinois, Portugal

Aging is generally associated with a decline in resting metabolic rate (RMR) partially due to an age-related loss of fat-free mass (FFM). Exercise is believed to have beneficial effects on preservation of FFM and reduction of fat mass (FM). In cardiac rehabilitation these variables are of extreme importance since one of the major goals is to contribute to reduction of risk factors that contribute to progression of coronary artery disease.

The purpose of this study was to determine the effects of 2 years of a combined aerobic- and weight- training (CAWT) exercise program on RMR and body composition of men suffering from coronary artery disease (CAD). Twenty-three (23) patients, enrolled in a cardiac rehabilitation program, aged 40- to 72 years participated in a combined aerobic-and weight- training for 2 years. Subjects performed 30 minutes of aerobic exercise 3 days/week and weight training was performed 2-3 days/week, on non-consecutive days. All variables were evaluated before and after the application of the exercise program. RMR was measured by indirect calorimetry and body composition was determined from dual energy x-ray absorptiometry. There were no significant changes in absolute or relative RMR (pre, 0,13 L.min-1; post, 0,14 L.min-1, p>0,05 and pré, 1,69 mL.kg-1.min-1; pós, 1,85 mL.kg-1.min-1), and CAWT exercise program resulted in a significant decrease of respiratory quotient (pré, 0,86 +/- 0,0 VCO2/VO2; pós, 0,81 +/- 0,05 VCO2/VO2, p<0,05). There were no changes found in FFM values (whole body: pre, 55,8 +/- 4,5 kg; post, 55,2 +/- 5,0 kg; or trunk region pre, 27,2 +/- 2,6 kg; post, 26,6 +/- 2,6 kg) . These results suggest that combined exercise training contributes to maintenance of RMR values, preservation of FFM and FM (whole body and trunk region) and decrease in respiratory quotient revealing a significant increase in fat oxidation. This type of exercise training appears to be effective for reduction of the CAD risk factors associated with increasing FM.

THE EFFECTS OF REHABILITATION PROGRAM ON LUMBAR EXTENSION MUSCLE STRENGTH, BONE MINERAL DENSITY IN OPERATION PATIENTS OF LUMBAR DISK HERNIATION

Gi Duck, P., Sung-Bum, J.

Namseoul Univ. Keimyung University, Korea, South

The purpose of this study is to evaluate the effects of rehabilitation program on lumbar extension muscle strength, bone mineral density in operation patients of lumbar disk herniation.

Subjects was divided in to 4 group(control group, exercise therapy group, exercise therapy group+kinesio taping and aquatic rehabilitation group) from 32 operation patients of lumbar disk herniation.

The patients were treated with exercise therapy, exercise therapy+kinesio taping and aquatic-rehabilitation for 12 weeks and the effects on body composition, lumbar extension muscle strength, bone mineral density have been evaluated.

The body composition, lumbar extension strength, bone mineral density will be organize the statistical treatment. SPSS 12.0 statistical program will be utilize.

The changes of body composition

The body weight, fat mass and %body fat was significantly lower in aquatic rehabilitation group as before and after applying(p<.05). And lean body mass was significantly higher in exercise therapy, exercise therapy+kinesio taping and aquatic rehabilitation group as before and after applying(p<.05).

2. The changes of lumbar extension muscular strength

The lumbar extension muscular strength from 0° lumbar flexion angle was significantly higher in exercise therapy, exercise therapy+kinesio taping and aquatic rehabilitation group than control group(p<.05). And the lumbar extension muscular strength from 12° 24° lumbar flextion angle was significantly higher in therapy+kinesio taping group than control group(p<.05).

The lumbar extension muscular strength from 30°, 48°, 60°, 72° lumbar flexion angle was significantly higher in exercise therapy, exercise therapy+kinesio taping group than control group(p<.05). But the lumbar extension muscular strength from 36°, 48° was significantly higher in therapy+kinesio taping group than aquatic rehabilitation group (p<.05).

3. The changes of bone mineral density

The bone mineral density of pelvis, lumbar, total was significantly lower in aquatic rehabilitation group as before and after applying(p<.05).

To conclude, Applying of exercise therapy, exercise therapy+kinesio taping and aquatic rehabilitation program for operation patients of lumbar disk herniation will be effectively appeared to improvement of lumbar function and decreasing of pain. Especially, exercise therapy+kinesio taping program component program will be applied to improvement of lumbar function and decreasing of pain has effective much bigger. And aquatic rehabilitation program effectively appeared to positive effects blood lipid factor and bone mineral density. For this example of research operation patients of lumbar disk herniation reformed program the severe effect of evidence with the patients diagnosis establishment basis.

In short, in such a case of applying lumbar disk herniation for the operation patient I think this would be more help for the sake of health and rehabilitation for everyone.

PROGRESSIVE EXERCISES IMPROVED MOTOR PERFORMANCE OF THE ARM IN CHRONIC EPICONDYLITIS

Pienimäki, T., Kauranen, K., Tarvainen, T., Siira, P., Vanharanta, H.

Finnish Institute of Occupational Health, Oulu, Finland

Chronic epicondylitis causes a worsened function of the arm noted in clinical, pain, muscle strength and also in motor performance which has been showed. The aim of this study was to investigate the effects of progressive exercises on motor performance of arms in epicondylitis.

Fifty-three patients, 19 males, 34 females, mean age 42 years, with chronic epicondylitis and 53 healthy controls participated the study. After clinical examination, motor performance (MP) of the upper extremities was tested in the patients and controls using the Human Performance Measurement System/Basic Elements of Performance (HPM/BEP)-device (HPM Inc., Arlington). Reaction times (RT), speed of forward (FWD) and lateral (LAT) movement, accuracy (ACC) and coordination (COORD) as a result of speed of movement and accuracy (% of correct hits) were taken for analysis. Because epicondylitis causes bilateral decrease in MP, each patient had a gender and age ( 2 years) matched control from a sample of 200 healthy persons to help evaluation. Maximal isometric grip strength (GS) was tested with a dynamometer (New-Test, Oulu), pain thresholds (PPT) with a dolorimeter (FS-Products, Hyvinkää) on humeral epicondyles and the arcade of Frohse, pain using a questionnaire (PQ) with VAS and pain drawing (PD). The measurements were taken before and after the the 8 weeks´ four-step progressive home exercise program, which was trained and controlled by a physiotherapist.

The rehabilitation resulted in significant improvements (p<0.01) in all PQ scores, PD and manual tests, in 35 % increase of PPTs of epicondyles (p=0.003), 12 % for those of Frohse´s arcade (ns), 20 % in GS (p<0.001). The patients reached 86-97 % in RTs, 56 % in FWD, 67 % in LAT, 109 % in ACC and 99 % in COORD of the values of controls. 37 % of the patients showed decrease in MP, 27 % had a moderate and 36 % a good improvement in MP items. The good result in RTs was associated with negative palpation (p=0.015) and improved GS (p=0.02), in FRW and LAT with improved manual tests (p=0.02), PD (0.013) and sleep disturbance (0.005), ACC with improved manual tests (p=0.007) and COORD with improved GS (p=0.03). Declined MP showed a poor result.

Progressive exercises used in this study resulted in improved MP of the arms. The associations between MP and other measures show that good RTs require painless elbows in palpation, a good LAT or FRW negative manual tests and a good COORD significantly improved GS. It remains unclear which is the optimal rehabilitation to good response in MP levels. Improvement in MP was lesser than in other measures because all patients did not response. According to the results the rehabilitation of epicondylitis must also include coordinative exercises besides the normal stretching strengthening programs and pain relief.

CONVENTIONAL INCREMENTAL EXERCISE TEST PROTOCOL UNDERESTIMATES PEAK OXYGEN UPTAKE DURING STIMULATED CYCLE ERGOMETRY IN PARAPLEGIA

Berry, H., Perret, C., Hunt, K., Grant, S., Saunders, B., Allan, D., Kakebeeke, T.

University of Glasgow, United Kingdom

Introduction

Incremental exercise test (IET) protocols for determination of peak oxygen uptake (VO2peak) during stimulated cycle ergometry in paraplegia have been designed [3] in accordance with those for volitional cycling where VO2 increases approximately linearly with exercise work rate until the highest VO2 is attained [1]. Maximal incremental stimulated-cycling tests, however, terminate when stimulation saturates and power plateaus or even falls. The VO2 value at this point is taken as VO2peak for the test. Subjective observations during stimulated cycle training sessions suggest, however, that higher VO2 values are achieved during training than during an IET. The aim of this study was to compare the VO2 attained during a stimulated cycle training session at maximum possible resistance with the peak value achieved during an IET, to determine if the IET VO2 represents the subject's highest VO2 for this exercise modality.

Methods

3 motor-complete paraplegic subjects (2 male, 1 female, lesion levels T7-T9) were monitored during a stimulated cycle training session (10 min warm-up with minimum resistance, 50 min pedalling against maximum possible resistance to maintain 50 rpm). Cardiopulmonary responses were recorded and compared to those of a corresponding work rate and cadence controlled IET.

Results

Training session VO2peak was 118-127% of that measured during the IET. Average VO2 during the last 15 min of the session was 103-112% of the peak IET value. VO2peak was attained after 40-53 min of exercise during training and after 10-13 min during the IET.

Discussion

The fact that the training sessions elicited both a higher peak and mean VO2 than the IET peak value indicates that the IET value underrepresents peak VO2 for this exercise modality. A possible explanation for these findings may be that the slow aerobic responses of SCI subjects result in an inability to attain a representative maximum in an IET. During stimulation, both anaerobic and aerobic motor units are progressively and synchronously recruited in a non-selective manner [2] to meet the incrementing reference power demand. The recruitment of anaerobic motor units is likely to promote fatigue before the aerobic mechanisms have had time to operate maximally.

Conclusion

The VO2 value at stimulation saturation during an IET does not represent the peak VO2 attainable by an individual during stimulated cycle ergometry. Investigation of IET tests with longer durations at each power level and/or continuation after stimulation saturation may be worthwhile as these amendments may elicit higher VO2 values.

ROLE OF PHYSICAL EXERCISES IN REHABILITATION PROGRAMME OF MULTIPLE SCLEROSIS

Rusu, L., Vasilescu, M., Paun, E., Dragomir, M., Danoiu, M., Ciocanescu, D., Diaconescu, D.

University of Craiova, Romania

Multiple sclerosis(MS) can go to severity stadies if the rehabilitation programme begin to later.Also is important to inlcude in rehabilitation programme physical exercises. The aim of this study is to present the role and efficency of physical exercises in rehabiliattion programme, and also the role of a good assesment during this programme.

Material and method: The study including 20patients with age between 20-55years. They are in different stadies of MS but 17 patients are in first stady. Assesment of subjects including: clinic evaluation(fatigue, muscle force, mobility, coordination, balnces, ROT, optic nevrite), assesment of spasticity using Ashworth sclae(0-5), muscle spasm scale, neuromusucular function including gait and ADL activities. Also we evaluated muscle fatigue using EMG parameters like amplitude and frequency and assesment of effort capacity because we measured VO2max consumption. Rehabilitation goals are: decrease spasticity, increase effort capacity using aerobic exercises, increase muscle force , mobility and flexibility, increase balances. We used RIC method that include 120 exercises and that have 3 principles: intensity, constant and personalised programme. Programme has the next structure: aerobic exercises, manual stretching, passive mobilisation, active movements from all posture, global movements form ADL activities, balances exercises using Bobath posture and Bobath ball, The RIC method has first phase that has analytic exercises, second phase for integration the first motor aquisition and skills, third phase for improvement automatic movement and increase the balance during gait at orthostatic posture. Programme has been applied 5days/week, during 45min, during 3months, after that we made a new evaluation.

Results: After 3month we observd the increase of fatigue resistance and effort capacity that are most important aspects in rehabilitation of MS patients. Also we observed that VO2max increase form 30% to 60%, mobility increase with 10%, spasticty goes from level 3 at level 1, muscle force, balance and stability have a good evolution and muscle fatigue are at minim level. EMG parameters, index of muscle fatigue show us a good evolution.

Conclusions: Apply each day the kinetic rehabilitation programme at MS patients, between 2-4clock p.m., improve the resistance at fatigue, increase effort capacity and help to development the muscle force and mobility. Also complex rehabilitation programme can help patients to functional improvement for development ADL activities and to be independent for long time.

FUNCTIONAL ELECTRICAL STIMULATION FOR CYCLING OF PARAPLEGICS: INDIVIDUAL ADAPTATION OF THE CLINICAL ENVIRONMENT IN HUNGARY

Szecsi, J., Fincziczki, A., Laczko, J., Klauber, A.

Semmelweis University, Faculty of PE and Sports Sciences, Budapest, Hungary, Hungary

Introduction: At the beginning of 2003 the first German feasibility study of Functional Electrical Stimulation (FES) propelled cycling with 7 completely paraplegic patients was started at the Neurological Department of the University of Munich. In spring 2005 the pilot investigations were extended to the Rehabilitation Department of the MAV Hospital in Budapest. To fully benefit from the well known advantages of leg propelled FES-cycling, paraplegic patients need to exercise not only at the hospital or laboratory of Munich, but also in other institutes like the Hungarian rehabilitation centres, and also at home with home-trainers that they either own themselves or their health insurance provides. Thus there is a practical and economical need to fit rapidly a diversity of devices to different patients at different locations.

Goal: The goal of our study is to extend the measurements in Hungary with the realization of their individual features and different devices, by finding a convenient method for fitting of patient characteristics and device parameters in Hungarian clinical environments.

Methods In the experimental part of this work we extended one of the commercially available tricycles by adding a torque-measuring sensor (ATI, USA) and changing the pinion gear and the drive chain, transforming the tricycle to a torque measuring testbed for determination of the individual torque profiles (drive profile) of the six stimulated muscle groups (quadriceps, gluteus, hamstrings) of the patient. Further, mechanical simulations were performed to characterize tricycles and ergometers used in FES-cycling by means of specific load profiles. These profiles are dependent on the rotational speed, and the geometrical-, inertial- and frictional properties of the respective tricycle (ergometer).

Results: By comparing the drive profile of the individual patients and the load profile of the device it was possible to determine whether the patient is capable of FES cycling on a particular device, and if yes, to deduce an optimal stimulation pattern. In subsequent validation test series of the 7 untrained complete paraplegic subjects and the 3 Hungarian subjects on the pool of different tricycles and the er-

gometer we noticed in 2 of the 10 subjects a kilometre plus FES-cycling capability, the 2 spastics of the subjects presented a strong acute spastic reducing capability, and 7 patients showed a fluid cycling gait with covered distance in the range 400-1800 m.

Conclusion: The study formed a practical fitting method of the technical system (load) to patient (drive). It builds on a physiological model, informing the physician or physiotherapist about the actual physical condition of the patient. We tried this method with 3 patients in the MAV hospital. One of them was in especially good condition, 3 years after the accident. Since our method has been introduced in Hungary, this patient used the tricycle in laboratory environment and in open air, in the city traffic.

CONTROL OF CYCLE ERGOMETER TRAINING INTENSITY BY MEANS OF BLOOD LACTATE CONCENTRATION DETERMINATION DURING CARDIAC REHABILITATION

Traninger, H., Harpf, H., Harpf, L., Harb, S., Tscheppe, G., Wonisch, M., Hofmann, P.

Institute of Active Exercise Therapy Eggenberg, Graz, Austria

Introduction: Training intensity must overreach a certain threshold but training effect is higher with increasing intensity. On the other hand, too high effort can be hazardous and must be avoided. Therefore, defining the optimal exercise intensity remains a difficult task. Furthermore, progression of training intensity during a several months lasting training program is necessary to force adaptive processes.

Aim of the study was to proof lactate steady state tests as a method for the validation the training intensity during cycle ergometer training in CHD patients.

Methods: Before starting the training program 105 patients (100 male, 5 female) performed a symptom limited incremental cycle ergometer test to define the individual training intensity. The target intensity for training was set at 75 – 85 % of the heart rate (HR) at the heart rate threshold. To control the chosen intensity a lactate steady state (LSS) test was performed in each patient. Within one 30 minutes endurance exercise training, capillary blood was collected before exercise (La1), in the 5th (La2), 15th (La3), and 25th min (La4) as well as at the end of the test (La5) (BIOSEN C_line sport)

Results: 72 out of 105 patients presented a lactate steady state (Laststst) with a constant La concentration between La3 and La5 (changes in La <0,5 mmol.l1). 21 presented a significant decrease (Ladecr) between La3 and La5 (change > 0,5 mmol.l1 (p=0,001), and 12 patients showed a significant increase (Laincr) between La3 and La5 greater that 0,5 mmol.l1 (p=0,001). The maximal La concentration at the end of exercise (Ladecr: 2,4+1,0; Laststst: 2,5+1,1) was significantly higher in the Laincr patients reaching 5,0+2,0 mmol.l-1. The intensity of training load was not significantly different between groups (Laststst: 59,4+10,8 %Pmax; Laincr: 65,5+8,3 %Pmax; Ladecr: 60,9+ 9,4 %Pmax). Average heart rate during training load was not significantly different between groups (Laststst: 76,2+9,2 %HRmax; Laincr: 79,3+7,9 % HRmax; Ladecr: 77,7+8,0 % HRmax).

Discussion: Physical exercise is one of the most important cornerstones in cardiac rehabilitation. A very important task is to prescribe and to control the intensity of exercise training. Guidelines for exercise training intensity prescription have a wide range which makes it difficult to choose an individual target training intensity. Even with a very sophisticated individual determination of training intensity using the heart rate turn point method giving comparable %Pmax exercise load an overexertion may occur.

Conclusion: The same %Pmax and %HRmax target training load may lead to overload during exercise training in CHD patients. The control of exercise intensity by means of La measures may be recommended on basis of these results.

THERAPEUTIC PHYSICAL TRAINING EFFICIENCY IN AN ORTHOPEDIC SANATORIUM FOR CHILDREN

Kovalenko, T.G., Shklyarenko, A.P.

Volgograd Stat University, Russia

The increase in the number of children and adolescents suffering from scoliotic disease progression (SD) is a serious problem in our society.

This research was carried out from 1992 till 2002 in the local specialized sanatorium for children (Guelendgik town). The approved system of therapeutic physical training helped to increase human organism tolerance towards negative consequences of scoliotic disease progression. According to the anthropometrical research, in the main group positive changes in bearing were combined with body length tachyauxesis by 1,7% in the "sitting position" in comprising with "standing position". In the control group this index is equal to 0,8%. As for the indexes of flexibility and muscle-strengthening endurance, there are no differences between the groups. The examined patients of the main group had positive adaptative changes in cardiovascular, respirator and nervimuscular systems and by the end of the treatment they had a rising lung-capacity, back-strength, muscle-strengthening tolerance back strengthening by 49 sec relative to the physical efficiency (0,4 W/h). In the control group these indexes of course cure rate efficiency were much lower. A decrease in asymmetry level (24%) in the main group was due to rising motion coordination during therapeutic physical training (in gymnasium using orthopedic balloons, in swimming-pools) with the help of special techniques. As for the control group, this index declined by 11% during the therapeutic physical training. Overall effectiveness of bearing correction by the approved physical training techniques in the control group was marked by visual defection adjustment of body constitution. Objectively, it was characterized by reducing of the coefficient average value of body deformation by 2,9 standard units, subjectively, by a positive cosmetic changes in self approval. Shoulder girdle, horizontal scapula evident asymmetries were removed, as well as angles between shoulder girdle and neck, waist triongle and body deviation from the long body axes. Less positive results in bearing correction were due to the torsion decrease in the form of costal humpback. Girls from the control group didn't have positive bearing cosmetic changes during therapeutic physical training.

Cure rate of complex sanatorium therapy was much more efficient when therapeutic exercises were combined with muscle-strengthening exercises using exercise machines and exercises in the water. In the average increased dynamic of back strength after using conventional techniques during therapeutic physical training was 7,2 kg (9%). When patients, besides therapeutic exercises, trained at exercise machines and in the swimming-pools their strength gains were 17,2 kg (29%). Strength index efficiency tripled during the therapeutic physical training. Contractibility and spine stability increased by 12-15%. Long and intensive muscle tension, functional back and stomach muscle capacity grew as well.

AEROBIC FITNESS IN PATIENTS WITH ATRIAL FIBRILLATION BEFORE AND AFTER AV NODE ABLATION SURGERY

Brickley, G., Mullan, P., Beale, L., Dholakia, H., Lloyd, G., Siberbauer, J.

University of Brighton, United Kingdom

Atrial fibrillation (AF) compromises cardiac output and may lead to a reduction in aerobic fitness. Typically patients have breathlessness and palpitations on exertion. Treatment for AF may involve medication and/or surgery. Qualitative research suggests that AV node ablation surgery may improve quality of life. However there is limited information concerning improvements in cardiac function and aerobic fitness following the intervention. The aim of the present study was to determine the changes in cardiac output and aerobic fitness 3 months after AV node ablation surgery in patients with AF.

Methods: Seven patients (5 males 2 females; age: 75± 8.3 y; mass 84.7± 26.5 kg) with existing AF, volunteered to take part in the study. Each subject completed an incremental exercise test on a recumbent exercise bicycle (Tunturi F530, Finland) to exhaustion. Echocardiographic readings were recorded at rest and peak exercise using a commercially available Vingmed system 5 (General Electric, Norway). Three to five consecutive beats of sinus rhythm were measured and the average taken. Images were analysed offline (EchoPAC 6.4.2). Breath by breath expired air was collected via Oxycon Pro (Jaegar, Germany) and analysed using a 5 second rolling average.

Results

Peak cardiac output decreased from (mean± SE) 6.25 ± 0.76 to 5.25± 0.57 L.min-1 post-ablation but this was not statistically significant (t=1.48, p>0.05). There was no significant change in peak oxygen uptake PRE: 1.23± 0.13 to 1.12 ± 0.24 L.min-1 POST and peak Ve 42 ± 5.4 to 41± 4.9 L.min-1.

Discussion

Patients with existing AF have a limited aerobic fitness and cardiac output. AV node ablation surgery does not appear to have altered key markers of cardiac function and aerobic fitness. The small change in cardiac output did not appear to alter peak oxygen uptake. The lack of change may be due to poor existing aerobic conditioning but does not appear to result in further deconditioning. Pacing of the heart was not altered following surgery and more evidence is needed to determine if device therapy may improve cardiac function. Future studies should consider aerobic training conditioning following AV node ablation surgery.

CLINICAL-BIOLOGICAL PARAMETERS IN REUMATHOID ARTHRITIS PATIENTS WITH COMPLEX REHABILITATION PROGRAM

Dragomir, M., Matei, D., Dragomir, M., Traistaru, R.

University of Craiova, University of Medicine, Craiova, Romania

Aim

The objective of this study is to analyse the importance of the correlations between the clinical and biological parameters in the case of rheumatoid arthritis with complex rehabilitation program.

Material and Methods

We observed 54 pacients with rheumatoid arthritis during 2 years, aged between 50 and 69 (an average of 62,55) and the sex proportion F/M=8/1; 8 pacients are entered in the functional class Steinbrocker I, 36 in class II and 10 pacients in class III. The goals of rehabilitation include pain relief, increased range of motion and strength and endurance, prevention/correction of deformities; we used the following methods: education and therapeutic exercise programs, therapeutic modalities, splints and orthotics, assistive device equipment, joint protection and energy conservation techniques and occupational therapy. For each pacient different biological parameters were established: the CRP- reactive C protein, the RF- rheumatoid factor, ESR-erythrocyte sedimentation rate, the titre of the antiCCP- cyclic peptide citrulinated antibodies and of the ANA- antinuclear antibodies. The activity level of the illness was established with : DAS28, the evaluation of the morning stiffness(minutes), of the PAN, SAN-number of painful and swollen joints and of the pain(with VAS 10mm). The results were analised with the medical statistics programme SPSS.

Results

An important correlation was underlined for the functional class towards the anti CCP, RF titre and betwen SAN and the ESR and CRP values. The starting age and the period of the illness proved to be well correlated to the functional class and also the ANA values towards the RF or the oldness of the illness towards the anti CCP and RF. On the contrary, a weak correlation of the morning stiffness towards the ESR and the CRP or towards the RF and anti CCP values was noticed. The activity level of the illness DAS didn't correlate to the SAN, the RF values or the anti CCP.

Conclusion.

The significant correlation between the parameters analised in our study enables the supporting of the necessity for paying a considerable attention to rehabilitative treatment in cases with RA since people who receive this kind of treatment are more likely to be able to be lead an active life and are enabled to participate in work, social and self-care activities. Our results confirm the literature date that exercising for fitness is as important for people with arthritis as for anyone else. If everyone respects the kinetic principles of the rehabilitation program, that are associated with the correct pharmacological treatment, all patients have optima prehension and adequate quality of life.

MEDICAL REHABILITATION PROGRAM FOR PATIENTS WITH CERVICAL MUSCULOSKELETAL SYNDROME

Dragomir, M., Dragomir, M., Traistaru, R., Matei, D.

University of Craiova, University of Medicine, Craiova, Romania

Aim.

Cervical musculoskeletal syndrome (CMS) is one of the pathological conditions what is characterised through stiff neck, headache and chronic neck pain, with or without shoulder-arm pain. These aspects can generate restriction of cervical spine functions and can lead to impairment, disability and handicap. The problems associated with neck pain have medical, social and economic aspects, so benefit from rational management of CMS is expected.

Our study is an attempt to prove the importance of team approach and management / pharmacological, physical and masso-kinetic – in control of CMS.

Material and Methods.

We studied (between October – December 2005) a group of 48 patients (males = 30, females = 18), with mean age of 35,3 years (SD = 13,3), suffering from CMS. The essential means in diagnosis of CMS include elicitation of the history, physical and radiological examinations and laboratory tests. All patients performed the 3 week outpatient rehabilitation program (educational sessions, pharmacotherapy, electrotherapy, physical training), after functional analysis. Each patient was asked to score pain intensity on a 10 point visual analogue scale (VAS) and to fill the adapted Sickness Impact Profile (SIP) at entry into the study (Time 1), after 3 weeks (Time 2) and after 10 weeks (Time 3). Adapted SIP consists of 14 items rated on a three – point 0 – 2, the total score ranges from 0 to 28 (higher scores indicate a greater impact on health changes on daily life).

Results.

The mean scores of VAS and SIP at Time 3 were better (VAS=1,8, SD=0,6; SIP=6,4, SD=1,6) than the mean scores at Time 1 (VAS=4,2, SD=2,4; SIP=18,4, SD=8,2) and at Time 2 (VAS=2,6, SD=1,8; SIP=12,4, SD=6,2). This aspect reflects improvement in pain status and individual's perceptions of physical and psychosocial functioning.

Conclusions.

The successful treatment of CMS including a multidisciplinary approach has a major clinical importance and it's relevance to the overall quality of life. A co-operation between specialists is preferable to one that is merely schematic or limited to one speciality alone. If medical therapy aims at the relief of pain and stiffness in the neck and arms, the cervicothoracic stabilisation requires training and coordination of the muscles in the neck area.

Rehabilitation program is the best method for maintain or perform the unit between all structures of cervical area.

EFFECT OF EXERCISE-INDUCED FATIGUE ON ELDERLY KNEE´S POSITION SENSE

Ribeiro, F., Oliveira, J.

University of Porto, Faculty of Sport, Portugal

Background: Aging is accompanied by marked decline in functional performance. Coordination is one component of functional performance that declines during the aging process, in part due to the deterioration of proprioception. Proprioception could also be impaired by physical and mental fatigue.

One of the methods most commonly used to assess proprioception include the determination of joint position sense (JPS). However, to our knowledge no studies have been conducted so far to assess the effects of local fatigue loads on elderly's proprioception.

Purpose: The purpose of this study was to describe the effect of exercise-induced fatigue on elderly knee's position sense.

Methods: JPS was measured at rest and after local fatigue loading of the knee extensor and flexor muscles. Participants in the study were sixteen volunteers males (mean age±SD: 69,81±3,92yrs).

JPS was evaluated by the technique of open-kinetic chain and active knee positioning. Five trials were recorded with a video camera. At a convenient time later, target and response positions of the knee were determined by computer analysis of videotape images of the joint using the Ariel Performance Analysis System software (Ariel Dynamics, CA:USA).

JPS was reported using three measures: absolute error (AAE – defined as the absolute difference between the target position and the response position), relative error (ARE – defined as the signed arithmetic difference between a test and response position) and variable error (VE – determined as the standard deviation from the mean of the relative errors).

The local load applied to the lower extremity consisted of 30 maximum concentric repetitions of the knee extensors and flexors on the isokinetic dynamometer (Biodex System 2) at an angular velocity of 120.s-1 (2.09rad.s-1).

Results: Peak torque of knee muscles significantly decreased from rest (flexors: 41,21±18,94Nm; extensors: 96,99±30,51Nm) to the fatigue (flexors: 31,80±14,61Nm; extensors: 66,47±18,22Nm).

After local load to the knee significant increase of absolute angular error was detected (2,56°). Exercise-induced fatigue had exacerbated the over-estimation of the test position (3,03°) (directional bias in the extension movement). However, the reliability and accuracy to estimate knee angles as showed by the variable error (standard deviation of relative error) is similar in both moments.

Conclusions: This study had showed that exercise-induced muscle fatigue significantly alters knee JPS in old age adults.

COMPARISON OF THE BLOOD REDOX STATUS BETWEEN LONG-DISTANCE AND SHORT-DISTANCE RUNNERS

Jamurtas, A.Z., Theodorou, A., Stavrakoudi, A., Kostaropoulos, I.A., Nikolaidis, M.G., Ikonomou, G.V., Makrygiannis, V., Papadopoulos, G., Kouretas, D.

University of Thessaly, Greece

Exercise increases the production of reactive oxygen species, which may damage a number of cell constituents. Organisms have developed a sophisticated antioxidant system for protection against reactive oxygen species. Our aim was to compare the adaptive responses of antioxidant mechanisms and the blood redox status of two groups of athletes, long-distance and short-distance runners. Thiobarbituric acid reactive substances, catalase activity and total antioxidant capacity was measured in serum, while reduced and oxidized glutathione as well as their ratio were determined in blood hemolysates. Serum catalase activity ($P < 0.001$), was found three times higher in long-distance compared to short-distance runners (25.4 vs. 8.9 μmol ∙ min-1 ∙ mL-1, respectively), whereas no differences were observed between the two groups in the other markers. Catalase activity was also correlated significantly with maximal oxygen consumption in long-distance runners. In conclusion, we report here that long-distance and short-distance runners exhibit similar blood redox status judged by several oxidative stress indices, except for the much higher activity of catalase in long-distance runners. This different effect of the two training modules on catalase activity of long-distance runners might be partly due to the high oxygen load imposed during their repeated prolonged exercise bouts.

INCREASED OXIDATIVE STRESS INDICES IN THE BLOOD OF CHILDREN SWIMMERS

Kouretas, D., Gougoura, S., Nikolaidis, M.G., Kostaropoulos, I.A., Koukoulis, G., Jamurtas, A.Z.

University of Thessaly, Greece

Despite the wealth of information regarding the effects of exercise on redox status in adults, no study has investigated the effects of chronic exercise on redox status in children. Τherefore, the aim of the present study was to determine the blood redox status of children athletes and compare it with that of age-matched individuals. Seventeen swimmers and twelve non-athletes participated in the present study. All participants were subjected to a maximal oxygen consumption measurement and their diet was recorded for three days before the blood sampling. Reduced glutathione (GSH) was lower by 37% in swimmers compared to non-athletes ($P < 0.01$), oxidized glutathione (GSSG) was not different and their ratio (GSH/GSSG) was lower by 43% in swimmers compared to non-athletes ($P < 0.01$). Thiobarbituric acid-reactive substances concentration was not significantly different between swimmers and controls. Catalase was barely not significantly lower in swimmers ($P = 0.08$). Finally, total antioxidant capacity was found lower by 28% in swimmers compared to controls ($P < 0.05$). In conclusion, we report that children participating in swimming training exhibit increased oxidative stress and less antioxidant capacity compared to untrained counterparts and suggest that children may be more susceptible to oxidative stress induced by chronic exercise.

SALIVARY IGA RESPONSE TO SEVERAL SPORT ACTIVITIES (TREKKING, CANYONING AND ASCENSION TO THE ANETO MOUNTAIN) DURING A WEEK IN THE SPANISH PYRENEES

Teixeira, A.M., Santos, A.M., Oliveira, M., Rosado, M.F., Martins, M., Cunha, M.R.

Faculty of Sport Sciences and Physical Education, University of Coimbra, Portugal

Salivary IgA has been used as a marker for the mucosal immune system status and may decrease after periods of intense exercise (1). Altitude also seems to negatively affect some immunological parameters (2). The aim of this research was to study the salivary IgA (sIgA) response to three different exercise activities at altitude, and to evaluate the recovery time needed to restore the initial sIgA concentration and secretion rate levels.

Eighteen subjects (12 male and 6 female, aged between 20 and 38 years old) participated in the study. Saliva samples were collected as follows: twice on the event day, before breakfast and 2h after the event has finished; a last sample was collected 24h after this collection. Nine collection points were analyzed.

A mountain trekking activity, fulfilled on the 1st day, was accomplished in 4h30min for a 11200m itinerary, with a positive altitude difference of 339m, at an average speed of 2,8Km/h; the mountain climbing activity, fulfilled on the 3rd day, was accomplished in 10h for a 11000m route, with a positive altitude difference of 1340m, at an average speed of 1,1Km/h; the canyoning activity, fulfilled on the 5th day, was accomplished in 6h for a 7000m up itinerary plus the canyon descent, with a positive altitude difference of 230m. On these activities the heart rate registers were as follows: for the trekking activity the average heart beats per minute were 120+14.8hbm-1 and the maximal heart rate average was 181.3+11.1; for the mountain climbing activity the average was 132.7+ 12.9 hbm-1 and the maximal heart rate average was 178.9+2.6; for the canyoning activity the average was 95.8+11.2 and the maximal heart rate average was 155.5+9.9.

Salivary IgA concentration and secretion rates showed statistically significant decreases 2h after the mountain trekking activity, 2h after the mountain climb event (Aneto, 3404m) and 2h after the canyoning descent. 24h hours after these activities sIgA values had not yet recovered, and were still significantly different from the initial values. Recovery was only achieved on the morning of the 3rd and 5th days. This represents a gap of time greater than 40h between the term of the activities and the final collection time points. Day four was a resting day and this caused some differences as higher sIgA values were obtained in the following morning. In the last day, 24h after the canyoning descent, sIgA values were still decreasing and were significantly lower than the ones obtained 2h after that event.

Both the long time duration and high intensity of the activities performed were reflected in the decrease of the sIgA levels. Recovery between tasks took longer than 24h. At altitude, monitoring of the sIgA levels may be of some importance in order to preserve mucosal immunity and to prevent upper respiratory tract infections.

PLASMA PHOSPHOLIPID FATTY ACID COMPOSITION IN SERBIAN ELITE BASKETBALL AND FOOTBALL PLAYERS

Tepsic, J., Arsic, A., Blazencic-Mladenovic, V., Mazic, S., Malicevic, S., Dikic, N., Glibetic, M.

Institute for Medical Research, University of Belgrade, Serbia and Montenegro

Plasma fatty acid (FA) composition reflects dietary fat intake and endogenous fatty acid metabolism. There are no enough data that describe the effects of high impact professional sports activities on endogenous fatty acid metabolism. The aim of this study was to determine plasma phospholipid FA status of the players who are members of two professional teams: 20 basketball (B) and 20 football (F) players, and to compare the results with data obtained from untrained control group (C). All players were lean (BMI< 25), normolipemic and not on any specific diet. Fourteen lean (BMI< 25), normolipemic, untrained male subjects were included in the study as a control group.

The plasma phospholipid fraction was isolated by thin layer chromatography and fatty acid methyl esters were analyzed using gas chromatography. All results were expressed as means ± SD and analyzed using unpaired Student's t- test, accepting an alpha level of significance ($p<0.05$).

Our results showed that the percentage of total polyunsaturated FA (PUFA) and n-6 PUFA is significantly higher ($p<0.05$) in B group compared to C group. Also the percentages of dihomo-γ-linolenic acid (20:3 n-6) and of arachidonic acid (20:4 n-6) are significantly higher ($p<0.05$) in B group compared to C group.

The percentage of 20:3 n-6 is significantly higher ($p<0.01$) in F group compared to C group. There is no significant difference in total PUFA and 20:4 n-6 between F group and C group, nor there is any significant difference in total SFA, MUFA and n-6 PUFA between sportsmen and control group.

Total monounsaturated FA (MUFA) are significantly lower ($p<0.05$), whereas total PUFA, n-6 PUFA and 20:4 n-6 are significantly higher ($p<0.05$) in B group compared to F group.

Alteration in the percentage of dihomo-γ-linolenic acid indicated that the activity of Δ5 desaturase is increased in basketball players and decreased in football players compared to control group. However, low content of MUFA shows decreased activity of

Δ9 desaturase in basketball players compared to football players. Our results suggest that the type of professional physical activity, such as football, may lead to unfavorable changes in plasma phospholipid fatty acid composition. On the contrary, professional physical activity of basketball players appears to have favourable effect on plasma phospholipid fatty acid profile, possible to their high content of PUFA.

EFFECT OF CHRONIC VOLUNTARY WHEEL RUNNING ON LIPIDS INVOLVED IN THE SIGNALING OF APOPTOSIS IN RAT SKELETAL MUSCLE

Tsalouhidou, S. 1, Petridou, A. 1, Bühlmeyer, K. 2, Michna, H. 2, Mougios, V. 1

1 Aristotle University of Thessaloniki, Greece, 2 Technical University of Munich, Germany, Greece

Exercise modulates several factors that may alter apoptosis in a variety of tissues, although little is known about whether it actually affects apoptosis, especially in skeletal muscle. Two phospholipids, cardiolipin and sphingomyelin, and a second messenger in the sphingomyelin-signaling pathway, ceramide, play important roles in the apoptotic process (1,2). However, there are few studies on the effect of exercise on the content of skeletal muscle in these compounds. The purpose of this study was to examine the content and composition of cardiolipin, sphingomyelin, and ceramide after chronic exercise in rat skeletal muscle.

Eight male Sprague Dawley rats exercised ad libitum for 12 weeks in cages equipped with a wheel, while eight counterparts were housed in plain cages. Upon completion of the training period, animals were decapitated and their gastrocnemius medialis muscles were removed. Lipids were extracted and separated by thin-layer chromatography for the analysis of cardiolipin, sphingomyelin, and ceramide. The fatty acid composition of these lipids was determined by gas chromatography. Differences in concentrations and fatty acid profiles were examined through the nonparametric Mann-Whitney U test, because not all parameters displayed normal distribution, as examined by Shapiro-Wilk test. The level of statistical significance was set at 0.05.

The cardiolipin, sphingomyelin, and ceramide contents of gastrocnemius were not different between trained and untrained rats. Linoleate (18:2ω6) was the most abundand fatty acid of cardiolipin, whereas sphingomyelin and ceramide contained mainly stearate (18:0) and palmitate (16:0). The trained group had a lower percentage of cis-vaccenate (18:1ω7) and a marginally higher percentage of docosahexaenoate (22:6ω3) in cardiolipin (P=0.06). Additionally, the trained group had a marginally higher percentage of 16:0 in ceramide (P=0.06) and a marginally lower percentage of the same fatty acid in sphingomyelin (P=0.08).

Our data suggest that chronic wheel running did not affect the muscle concentrations of three lipids involved in apoptosis. This is in accordance with the findings of the relevant studies on cardiolipin (3,4). Data on sphingomyelin and ceramide are mixed, including increases, no differences, and decreases with training (4-6). Also mixed are the data regarding the fatty acid composition of sphingomyelin and ceramide (5,6) whereas there are no data regarding the fatty acid composition of cardiolipin after training. We are currently investigating the relationship of our findings with apoptosis.

THE "DOPING DESIGNER STEROIDS" NORBOLETHONE, DMT (AND THG) ARE ANDROGENS (AND A PROGESTIN)

Michna, H., Selg, P.J., Nishino, T.

Institute of Public Health Research, Germany

The so-called designer steroids were detected in a still growing list of Olympic record holders and prestigious athletes. The compound class belong to the list of forbidden steroids prohibited by the IOC and moreover these compounds have never been marketed as a pharmaceutical. In fact, the biological and toxicological activities are unknown. Thus, we set out to completely endocrine pharmacologically characterize the three steroids.

Besides conceiving various chemical possibilities to access structurally modified steroids like Norbolethone, Desoxymethyltestosterone DMT or Tetrahydrogestrinone (THG), we characterized their hormonal potential using modified industrial standard methods like Hershberger and Clauberg assays. The synthesis of Norbolethone, for example, starts with Norgestrel and its nickel-catalyzed hydrogenation (17α-alkine) resulting in Norbolethone. Norgestrel is a totally synthetic progestational agent used in certain birth control pills. There are various chemical possibilities to access structurally modified steroids like Norbolethone beginning with its total synthesis. Originally developed by a US pharmaceutical company in 1966, the project was abandoned a few years later because of unacceptable adverse side effects. Norbolethone is mainly toxic, caused a lot of bleeding disorders and too many androgenizing side effects.

DMT (17α-methyl-5α-androst-2-ene-17β-ol) is an anabolic steroid, which was initially synthesized and patented in 1961 (Huffman MN 1961). The synthesis of DMT starts with epiandrosterone, a natural reduction product of testosterone that is excreted in urine. Epiandrosterone will be reacted with p-toluenesulfonyl chloride and trimethylpyridine to remove the hydroxyl group at C-3 of the steroid ring system. After elimination of hydrochloric acid, a pair of olefin isomers form: the 3-ene and 2-ene. Reaction of these intermediates with methyllithium adds a methyl group to C-17 and converts the keto group there to a C-17 hydroxyl group, resulting in DMT and its isomer. DMT is a potent anabolic compound and therefore it should be considered as a toxic drug. No (anti-)gestagenic, (anti-)estrogenic or (anti-)glucocorticoid potency could be detected.

The synthesis of THG starts with gestrinone and its nickel-catalyzed hydrogenation (17-alkine) resulting in THG. By modifying the 17-position, THG becomes orally active. THG is a very strong anabolicum with an increased risk of liver damage and the incidence of general side effects usually caused by steroids. THG, like other anabolic steroids, exerts androgenic and progestational effects in the standard assays to predict activity in humans.

Norbolethone and DMT exert mainly androgen-anabolic effects, whereupon THG was identified to additionally induce progestational modulations. Therefore, these compounds may induce severe biomedical side effects and must be considered as perilous drugs, especially when used for doping purposes.

THE RESPONSES OF PROGLYCOGEN AND MACROGLYCOGEN TO EXERCISE AND RE-FEEDING: ARTEFACT OF GLYCOGEN EXTRACTION?

Fournier, P.A., Barnes, P.D., James, A.P.

The University of Western Australia, Australia

Nearly 75 years ago, muscle glycogen extracted with acid was shown to exist as an acid-soluble (ASG) and acid-insoluble (AIG) pool. It was only in the early 90's that these differences in acid-solubility were allegedly explained on the grounds that AIG and ASG correspond to proglycogen (PG) and macroglycogen (MG), respectively. Since then, their responses to exercise and diets have been extensively studied using a homogenisation-free acid extraction protocol to separate these pools of glycogen, with AIG being not only the largest pool, but also the most responsive to changes. Our goals were to determine (a) if it is suitable to use such a homogenisation-free acid extraction protocol, (b) if the AIG fraction corresponds to proglycogen, and (c) if AIG accounts for most of the changes in muscle glycogen content in response to exercise and re-feeding. In order to meet these goals, we have optimised a homogenisation-dependent protocol of muscle glycogen extraction, and compared the effect of extraction protocol on the patterns of response of ASG and AIG to changes in total glycogen levels. To this end, a group of 6 young male participants (24.3 ± 2.5 years) were required to cycle for 60 minutes at 70% peak rate of oxygen consumption on a front access cycle ergometer before being fed a carbohydrate-rich diet (10.9 ± 0.6 g per kg body mass) for the next 24 hours. Before exercise and after 0, 2 and 24 hours of recovery, muscle biopsies were taken for glycogen extraction. We found that the homogenisation-dependent extraction of muscle glycogen resulted in a yield of 75.3 ± 2.8% ASG as opposed to 12.7 ± 1.7% ASG using a homogenisation-free protocol. Moreover, there was little evidence that AIG corresponded to proglycogen, since gel chromatography of AIG and ASG fractions displayed similar elution profiles of high molecular weight glycogen, although a small trail of lower molecular weight glycogen was found in the AIG fraction. Exercise caused a fall in total glycogen levels, which increased significantly within 2 hours of recovery and attained above pre-exercise levels after 24 hours. The patterns of response of ASG and AIG to exercise and re-feeding were markedly affected by the protocol of glycogen extraction, with AIG accounting for most of the changes in total glycogen when muscles were extracted using a homogenisation-free protocol. In contrast, ASG accounted for all the changes in total glycogen using our extraction protocol, with AIG remaining at low and stable levels. In conclusion, this study suggests that (1) the homogenisation-free acid extraction of muscle glycogen underestimates the proportion of ASG, (2) AIG does not correspond to a low molecular weight pool of glycogen, and (3) ASG rather than AIG is the glycogen pool most responsive to changes, thus raising doubts about the physiological significance of the findings of most of the previous studies that have examined the responses of AIG and ASG to exercise and dietary manipulation.

IMPACT OF IN VITRO ANOXIA-REOXYGENATION ON RESPIRATORY PARAMETERS OF HEART MITOCHONDRIA ISOLATED FROM IN VIVO DOXORUBICIN TREATED AND ENDURANCE TRAINED RATS

Ascensão, A., Ferreira, R., Oliveira, P.J., Magalhães, J.

Faculty of Sport Sciences, University of Porto, Portugal

It has been described that endurance training (ET) protects cardiac mitochondria after in vivo treatment with Doxorubicin (DOX), an effective broad-spectrum antineoplastic drug characterized by a dose-dependent cardiotoxicity. ET also limits heart mitochondrial dysfunction induced by in vitro anoxia-reoxygenation (AR) and Ca2+ addition. However, the role of ET against AR effects on mitochondria isolated from previously DOX-treated rats has never been explored so far and is the purpose of the present study.

Twenty-four male Wistar rats were randomly assigned into four experimental groups (n=6 per group): saline control (C), DOX administrated i.p. in a single dose of 20 mg.kg-1, 14wks endurance running trained (T) and trained plus DOX (T+DOX). Respiratory parameters (state 3, state 4, ADP/O and respiratory control ratio- RCR) and oxidative damage markers (carbonyl groups and malondialdehyde) were determined in isolated mitochondria before and after 1 min anoxia followed by 4 min. reoxygenation. Levels of heat shock protein 60 kDa (HSP60) were measured before A-R in isolated mitochondria.

Under basal conditions (before A-R stimulus), DOX per se induced a decrease in state 3 respiration and in the RCR and ET improved state 3 and RCR ($p>0.05$). AR significantly impaired the respiratory rates in state 3 and state 4 as well as RCR and ADP/O in C group ($p>0.05$). However, in heart mitochondria isolated from DOX-treated rats no significant changes were observed after AR in RCR and ADP/O, whereas both state 3 and state 4 decreased ($p>0.05$). State 3 and RCR were significantly impaired after AR in T group. State 3 decreased significantly in T+DOX after AR. Significant oxidative modifications of mitochondrial proteins and phospholipids were found in DOX group before AR and only in C group after A-R ($p>0.05$). Basal levels of mitochondrial HSP60 were significantly higher in DOX, T and T+DOX groups than in C (2.5-fold, 2-fold and 1.9-fold increase, respectively).

We therefore conclude that in vitro AR did not further impair the functional respiratory parameters of heart mitochondria isolated from sedentary DOX-treated rats. Thus, ET did not represent additional advantageous contribution for mitochondrial respiratory function against AR in DOX-treated rats. We hypothesize that probable molecular adaptation associated with DOX treatment may also act to further prevent AR-induced mitochondrial dysfunction.

CELL-FREE PLASMA DNA RESPONSES TO RESISTANCE EXERCISE OVERTRAINING: COMPARISON WITH OTHER INFLAMMATION MARKERS

Margonis, K., Fatouros, I., Destouni, A., Jamurtas, A.Z., Kouretas, D., Mastorakos, G., Vrettou, C., Kanavakis, E., Mitrakou, A., Taxildaris, K.

Democritus University of Thrace, Greece

Introduction

Overtraining or overexertion may lead to performance deterioration (1), various physiological maladaptations, and acute breakdown and repair of skeletal muscle that can be described in terms of an acute inflammatory response (2). Currently there is no single biological measurement that is diagnostic of the overtrained status. Cell-free plasma DNA is altered both quantitatively and qualitatively in a variety of inflammatory conditions (tissue injury, cancer, and trauma) (3) and its concentration has been correlated with the severity of injury in trauma and stroke patients (4). In this study we aimed to investigate plasma DNA response as an inflammation marker to a chronic resistance exercise protocol of progressively increased training volume and compared it with conventional indices used for monitoring and quantification of exercise-induce muscle damage.

Methods

Seventeen men (21.3±2.3 yrs) participated in a 12-wk resistance training consisting of 5 separate training periods (T1 through T4, 3 wk/period) of progressively increased training volume (2 d/wk, 2 sets/exercise, 10-12 reps/set, 70% 1RM in T1; 4 d/wk, 4 sets/exercise, 6-10 reps/set, 75-85% 1RM in T2; 6 d/wk, 6 sets/exercise, 1-6 reps/set, 85-100% 1RM in T3; 2 d/wk 2 sets/exercise, 10-12 reps/set, 70% 1RM in T4). Subjects performed 8 resistance multi-joint exercises. Blood samples, collected at baseline (T0) and 96 hours following the last training session of each period, were analyzed for plasma DNA, C-reactive protein (CRP), creatine kinase (CK), and uric acid (UA). Data were analysed by ANOVA repeated measures ($p < 0.05$).

Results

Plasma DNA (GenEq/mL) increased ($P < 0.05$) following T1 (143.5±22.9), T2 (289.9±41.1), T3 (605.7±116.4) compared to rest (31.4±13.8) and returned to baseline thereafter. There was a difference ($P<0.05$) between periods (T2 vs. T1, T3 vs. T2) in plasma DNA values. CRP (mg/L) increased ($P<0.05$) by 300% and 400% after T2 (3.364±1.07) and T3 (4.8±1.04) respectively compared to baseline (0.84±0.17) with no differences between T2 and T3. CK (U/L) increased only following T3 (368.1±44.0 vs. 102.6±19.1). UA (mg/L) increased following T2 (51.2±3.7) and T3 (66.6±5.8) compared to baseline (39.1±4.0) with T3 being more effective ($P<0.002$). Performance increased after T2 and declined thereafter.

Discussion

Results of the present investigation demonstrate that plasma DNA is increased following chronic excessive resistance exercise stress in proportion to training load suggesting that plasma DNA could be a sensitive marker for monitoring and quantification of overtraining-induced muscle inflammation. Cell-free plasma DNA appears to me a more sensitive marker of exercise training stress compared to other inflammatory markers.

DOSE-RELATED EFFECTS OF PROLONGED NAHCO3 INGESTION DURING ENDURANCE EXERCISE

Fatouros, I., Douroudos, I., Gourgoulis, V., Jamurtas, A.Z., Tsitsios, T., Hatzinikolaou, A., Margonis, K., Mavromatidis, K., Taxildaris, K.

Democritus University of Thrace, Greece

Introduction

NaHCO3 ingestion results in increased plasma bicarbonate [HCO3-] levels, a decline in plasma hydrogen [H+] concentration during exercise (1) as well as in enhanced endurance performance (2). Although several studies examined the ergogenic short-term effects of induced alkalosis following NaHCO3 ingestion during endurance exercise, there is only limited information regarding the effects of prolonged NaHCO3 administration of different dosage levels. Therefore, the purpose of the present study was to investigate the effects of two different levels of prolonged NaHCO3 ingestion on extracellular buffer concentration, acid-base balance and performance during an acute bout of short-term, high-intensity exercise.

Methods

Twenty-four men (22 + 1.77yrs, 77.5 + 7.8 kg, 1.79 + 6.6 cm, and a VO2max of 51.03 + 7.53 ml/kg/min) participated in the present study. Subjects were randomly assigned to one of three groups (8/group): control (C, sugar-free mixed fruit placebo), moderate ΝaHCO3 intake (MI, 0.3 gr/kg/d), and high ΝaHCO3 intake (HI, 0.5 g/kg/d). Participants consumed either placebo or ΝaHCO3 for 6 days. pH, HCO3, PO2, PCO2, and lactate in arterialised blood as well as time to exhaustion were determined prior to and immediately following an endurance exercise test (prior to and following the supplementation period) at 75% VO2max to exhaustion. Data were analysed by ANOVA repeated measures ($p < 0.05$).

Results

Time to exhaustion increased ($p < 0.05$) after supplementation only in HI (53.1 + 12.2 to 64.4 + 9.09). ΝaHCO3 ingestion elicited an increased blood lactate (mM) response ($p < 0.05$) following exercise in MI (5.3 + 0.7 to 6.1 + 0.75) and HI (5.3 + 0.6 to 6.4 + 0.4). Resting pH (7.4 + 0.02 to 7.45 + 0.03 in MI and 7.412 + 0.01 to 7.46 + 0.01 in HI) and [HCO3-] (25.7 + 1.01 to 29.78 + 2.7 in MI and 25.81+ 1.3 to 32.35 + 3.1in HI) increased ($p < 0.05$) following ΝaHCO3 ingestion. However, ΝaHCO3 ingestion did not induce any changes in acid-base balance parameters following exercise.

Discussion

Results of the present study indicate that prolonged ΝaHCO3 ingestion may improve endurance performance as previously shown with ΝaHCO3 ingestion of shorter duration (3). Nevertheless, acid-balance status changed only at rest but not during exercise suggesting that the ergogenic effect of ΝaHCO3 may be related to other physiological adaptations. It appears that this ΝaHCO3 effect on acid-base balance at rest and endurance exercise performance is dose-related with higher intakes being more effective.

ENDURANCE TRAINING IN HYPOXIA HAS A SPECIFIC GENE EXPRESSIONAL TIME-COURSE AND SIGNATURE

Schmutz, S., Däpp, C., Wittwer, M., Vogt, M., Hoppeler, H., Flück, M.

University of Bern, Switzerland

Hypothesis: Ambient hypoxia makes up an additional stimulus to endurance exercise and activates a gene expressional program which supports mitochondrial biogenesis, myogenesis and capillary neo-formation. This would be reflected by differences in the acute adjustments of the muscle transcriptome in response to a single bout of endurance exercise in hypoxia compared to an analogous single bout in normoxia. Similarly, different steady state adaptations of the transcriptome are expected in response to six weeks of training.

Methods: 5 untrained subjects underwent six weeks of endurance training in normobaric hypoxia (4000m above sea-level) on a bicycle ergometer. A 30-minutes near-maximal bout of exercise in normobaric hypoxia was performed in the untrained as well as in the six weeks trained state. Biopsies from the vastus lateralis muscle were taken before and 1, 8 and 24 hours after both single bouts of exercise. The muscle biopsies were processed for morphometric and gene expressional analysis including 220 selected transcripts. Results were compared to the published alterations in response to endurance training in normoxia (Schmutz et al, Pflugers Arch 451(5): 678-87, 2006).

Results: Endurance training in hypoxia increased the mitochondrial density (86%; $p<0.05$). Similar to six weeks of training in normoxia, the transcript levels of genes involved in the mitochondrial respiration and protein turnover were upregulated. Specificity of training in hypoxia was seen on the molecular level by and upregulation of the transcripts involved in angiogenesis and cell regulation inducing a myogenic response. The generalized gene response to a single bout of exercise in hypoxia in the untrained and in the trained state was different compared to the response in normoxia ($p<0.0001$).

Conclusions: The muscle gene expressional response after endurance exercise in hypoxia is different from that in normoxia. Hypoxia provokes additional steady state level adaptations of the transcriptome. These observations are in line with earlier findings concerning specific muscular adaptations to endurance exercise in hypoxia compared to exercise in normoxia (Vogt et al, J Appl Physiol 91(1): 173-82. 2001).

DNA DAMAGE AND OXIDATIVE STRESS INDUCED BY EXHAUSTIVE EXERCISE IN THE ELDERLY: THE EFFECT OF ANTI-OXIDANT SUPPLEMENTATION

Pittaluga, M., Caporossi, D., Morreale, F., de Perini, A., Fantini, C., Sgadari, A., Tavazzi, B., Parisi, P.

IUSM - University of Sport and Movement Sciences, Rome, Italy

Introduction

Increased sensitivity to DNA damage related to aging can be triggered by the oxidative stress caused by exhaustive exercise (EE) (1,2), the extent of which may be influenced by antioxidant diet content. Among exogenous antioxidants, anthocyanins are known as strong ones. Although there exist data on the effects of such supplementation on DNA damage with and without EE (3,4), little is known about the interplay of these factors in the elderly.

Our aim was to investigate the effect of a 4-week supplementation with red oranges (Citrus sinensis, Sanguinello cultivar), rich in anthocyanidine-3-β-glucosyde, on the DNA damage caused by EE-induced oxidative stress in elderly subjects.

Methods

Plasma levels of 8-OHdG and the rate of micronuclei (MN) in lymphocytes, both reflecting DNA damage, as well as some markers of oxidative stress, were evaluated before, 30' and 24hr after a bout of EE in 15 elderly (69.0±5.1yr) healthy and well-trained subjects. EE was performed on a cycle ergometer (initial load of 25W; increments of 15W/3') and was carried out until volitional fatigue was attained or max HR was reached. EE was performed and blood samples were collected at baseline, and after 4 weeks of supplementation with red orange juice (ROJ).

8-OHdG levels were measured by immunoassay method (8-OHdG ELISA kit, JAICA, Japan). MN rates on 1000 binucleated cells were evaluated on Cytochalasin B blocked lymphocytes. Determination of malonilaldeide (MDA), ascorbic acid (AA), oxidized (GSSG) and reduced glutathione (GSH) was performed by HPLC analysis.

Results

At the baseline, we found no significant response to EE, both for 8-OHdG and MN. After supplementation, both basal and 30' levels of 8-OHdG were unchanged, whereas a significant rise was observed after 24hr (1.89±0.43 ng/ml before vs 3.15±0.1 ng/ml after supplementation, $p=0.032$). Conversely, no change after supplementation was observed for MN.

Considering the absolute changes from baseline to 30', ROJ supplementation determined a significantly lower reduction of AA (-1.09 vs -6.551, $p=0.005$), GSH (-1.324 vs -2.735 $p=0.039$) and a much lower increase of MDA (0.007 vs 0.02; $p=0.001$).

Discussion

Our data demonstrate that ROJ supplementation guarantees a higher redox potential, preserving the depletion of AA and GSH induced by exercise, thereby reducing some markers of oxidative stress (i.e., MDA).

Regarding the DNA damage, our results suggest that supplementation could implement the base excision repair activity, as demonstrated by the rise of 8-OHdG, whose plasma level reflects the amount of damage repaired. The lack of a change in MN frequency after EE could also depend on this effective DNA-repair activity, considering that it represents the expression of a stabilized genotoxic damage escaped from the DNA-repair machinery.

NEUROTROPHIC FACTORS AND REGULATION OF THE MUSCULAR SYSTEM: THE EFFECTIVE ROLE OF NERVE GROWTH FACTOR ON PROLIFERATION, SURVIVAL AND DIFFERENTIATION OF MYOGENIC CELLS

de Perini, A., Fantini, C., Pittaluga, M., Bonini, S., Parisi, P., Caporossi, D.

University of Sport and Movement Sciences (IUSM), Rome., Italy

Introduction

The skeletal muscle exhibits a remarkable capacity to adapt to physiological demands such as in growth, training, and injury, largely through to a small population of cells, the satellite cells, that in response to specific stimuli become activated, proliferate, and express myogenic markers.

The satellite cell population not only has a remarkable capacity for muscle regeneration but may have clinical applications in the treatment of devastating and deadly diseases such as muscular dystrophy. Denervation is able to produce a form of disuse atrophy that includes myofiber degeneration and is accompanied by distinctive changes in the myonuclei and quiescent satellite cells. So we focused on the importance that neurotrophic factors could have in the molecular mechanisms that regulate the muscular system.

Lead by a therapeutic purpose, the goal of our study was to verify the effective role that Nerve Growth Factor could have on proliferation, survival and differentiation of myogenic cells in order to improve the clinical course following nervous lesion and chronic muscular atrophy.

Methods

We performed an in vitro protocol utilizing L6C5 rat skeletal myoblasts, which retain a remarkable ability to differentiate in culture and in which the susceptibility to cell death induced by free radicals has been already characterized by our group. L6C5 myoblasts were exposed to different concentrations of exogenous NGF (10, 20, 100ng/ml), with or without the H2O2 pulse treatment (100-400μM for 1hr) in order to analyze the influence of the neurotrophic factor on cell proliferation and survival.

Results and Discussion

Our results show that NGF (100ng/ml) determines an increase in myoblasts proliferation up to 12 hr from the beginning of cell culture (68% increase vs NGF free cultures), while the growth rate seems to decline after 24/48 hr from the seeding.

We demonstrate that NGF does not interfere with the mitogenic effect determined by low doses of free radicals (H2O2 1-10μM), and that it can improve the cellular survival when L6C5 myoblasts are exposed to cytotoxic doses of H2O2,. In the treatment with H2O2 50μM, the number of viable cells is 32% over the control when NGF 20ng/ml is added to the culture.

On the other hand, NGF does not seem to protect skeletal myoblasts from oxidative-stress-induced apoptosis. Since spontaneous apoptosis has a major role during skeletal myoblast fusion and myocyte formation, we will discuss the effect of exogenous NGF treatments on the expression of genes involved in muscle differentiation or resistance to apoptosis.

MOLECULAR SIGNALLING IN HUMAN SKELETAL MUSCLE IN THE RECOVERY PERIOD AFTER ENDURANCE EXERCISE

Mascher, H., Garver, J., Andersson, H., Nilsson, P.A., Ekblom, B., Blomstrand, E.

University College of Physical Education and Sports, Stockholm, Sweden, Sweden

Introduction

Following physical exercise there is an increase in protein turnover. The majority of studies are conducted on resistance exercise, there is less known about the effects on protein turnover following endurance exercise. Most studies are carried out using the stable isotope technique or measurements of arteriovenous balance of amino acids that are not metabolised by muscle. To obtain a better understanding of the mechanisms behind these changes in protein turnover, it is necessary to study the molecular signalling inside the muscle. Components of the insulin signalling pathway including Akt, mammalian target of rapamycin (mTOR) and downstream kinases are believed to be important during initiation of protein synthesis (1,2).

Methods: Six healthy men, mean (+/- SE) age 23 +/- 1 yr and maximal oxygen uptake (VO2 max) 3.9 +/- 0.2 l/min participated in the study. The subjects performed cycling exercise at 75% of VO2 max during 1 h. Muscle biopsies from the vastus lateralis were taken before, immediately after and 30, 60, 90, 120 and 180 min after exercise. Phosphorylation of Akt on Ser 473, mTOR on Ser 2448, p70S6 kinase on Thr 389 and GSK-3 on Ser 21/9 was measured in muscle homogenates with Western blot technique using phosphospecific antibodies.

Results: Insulin levels decreased during the cycling exercise, increased 15 min after exercise but decreased again to 30% below resting value. Muscle glycogen content decreased from 380 to 84 mmol/kg dw during exercise and increased slightly to 134 mmol/kg dw at 3 h recovery. Akt phosphorylation was increased 400% at 1 h after exercise and remained elevated for another hour ($p<0.05$) but returned to initial level 3 h post exercise. The phosphorylation of mTOR was increased approximately 300% directly after, 30 min and 2 h into the recovery period ($p<0.05$). No change in p70S6 kinase phosphorylation was found. GSK-3 alpha phosphorylation at Ser 21 peaked at 1 h (about 250%) and was still elevated 3 h after exercise ($p<0.05$). GSK-3 beta phosphorylation at Ser 9 was increased at all time points after exercise ($p<0.05$).

Discussion: The results suggest a possible stimulatory effect on initiation of protein synthesis in the recovery period following an endurance exercise bout. The increase in phosphorylation of Akt and GSK-3 could be related to an increase in glucose uptake and glycogen resynthesis. However, together with the increase in mTOR this could also lead to an activation of the eukaryotic initiation factor eIF2B and thus initiate translation.

PRACTICAL FEASIBILITY OF SPORTGENOMIC INVESTIGATION IN THE FUTURE

Dekany, M., Gyore, I., Nemeskeri, V., Gogl, A., Ekes, E., Pucsok, J.M

National Institute of Sports Medicine, Hungary

Accomplishing of human genome project have started many studies towards the identification of genetic profile of physical performance. Genetic markers that are exclusively associated with elite athletes have not yet been identified. Potential candidate genes might be found in the renin-angiotensin system, which plays a key role in the regulation of cardiovascular physiology. Further investigation have shown strong association alpha-actinin 3 gene which encodes a protein of the Z disk of myofibers with muscle phenotype in athletes. We have studied the polymorphisms of the ACE (angiotensin I converting enzyme) in endurance athletes and in a well trained control group in some endurance phenotype.

The study population comprised 50 endurance athletes (mountain-bikers, triathletes, rowers, fencers, judo, shooters, karate) as well as 26 well trained control subjects. MVVex (expected maximal voluntary ventilation), VE (expiratory minute ventilation) and VO2max (relative aerobic capacity) were determined at rest and during the exercise test. The exhaustive treadmill or rowing step test was used to measure of the physiological parameters by the Jäger system. The mechanism of breathing was accomplished by Jäger Flowscreen-type spirometer at rest. Concentration of blood lactate was measured on the basis of NAD/NADH transformation by spectrophotometry. Genomic DNA was isolated from white blood cells. A khi-square test was used to compare the ACE I/D allele and genotype frequencies between athletes. Differences in age, body weight, body height and physiological parameters among the groups were tested with Student-type t probe.

Between of two groups arranging according to the VO2max/blood lactatemax ratio were significant differences in ACE allele (1. group: 54% I, 46% D; 2. group: 31% I, 69% D) and genotype (1. group: 31% II, 46% ID, 23% DD; 2. group: 0% II, 63% ID, 37% DD) as well. The ACE I allele is a genetic marker that might be associated with higher endurance efficiency and an adaptation level of the cardiovascular system. At the examination of the genotype besides the measuring of acute physical activity it is worth to take into consideration the long-term efficiency of endurance performance also, in the interest of understanding of the more accurate relationship.

Presumably the traditional examination of exercise physiology can be effectively complete an examination of molecular biology which based on genotype determination. The information of molecular biology and the exercise physiology could refer together to the selection of athletes in the future.

EFFECTS OF GENE VARIANTS ON CARDIOVASCULAR SYSTEM OF ATHLETES

Ahmetov, I., Linde, E., Mozhayskaya, I., Astratenkova, I., Prostova, A., Popov, D., Misina, S., Shikhova, J., Montgomery, H.

St Petersburg Reserch Institute of Physical Culture, St Petersburg, SSC RF Institute for Biomedical Problems, Moscow, Institute for Human Health and Performance, London, UK., Russia

Left ventricular (LV) hypertrophy occurs as an adaptive response to a physiological increase in cardiac work in athletes. Previous studies have shown that exercise-induced LV growth in healthy young men was strongly influenced by the PPARA intron 7 and ACE I/D gene variants [1]. Calcineurin B (CnB) is a regulatory subunit of calcineurin (key mediator of hypertrophic response of the heart) and 5I/5D variant of its gene is significantly associated with the presence of inappropriately high LV mass [2]. Suppression of PGC1 (PPARG coactivator 1) gene expression causes mitochondrial defects in myocytes and predisposition to heart failure [3]. We hypothesized that PGC1A Gly482Ser and PPARG Pro12Ala variants may influence structure and function of the heart of elite athletes. We have tested this hypothesis, together with using PPARA intron 7, ACE I/D and CnB 5I/5D genotypes and some physiological data, in the study of elite Russian athletes.

Eighty Russian athletes (all-round speed skaters and rowers; 43 males and 37 females) of national competitive standard were studied. PGC1A, PPARG, ACE, PPARA and CnB variants were determined by PCR and restriction enzyme digestion. Several physiological tests were performed to assess aerobic and anaerobic characteristics of the athletes.

No association was found between PGC1A and PPARG genotypes and any of cardiologic measures of athletes. However, among female rowers, PGC1A Ser/Ser homozygotes showed the greatest value of maximal voluntary contraction of knee extensors compared to Gly/Gly homozygotes (830±120 N vs 710±30 N; P=0.029). On the contrary, for male Gly/Gly homozygotes the anaerobic threshold occurred at 89±4% of VO2max; for heterozygotes and Ser/Ser homozygotes this value was estimated as 83±7% and 80±7%, respectively (P=0.002). These data suggest that the Gly482 and 482Ser alleles are associated, respectively, with aerobic and anaerobic metabolism. The I allele of ACE gene was associated with shorter duration of QRS complex (P=0.039), vertical position of the heart (P=0.045) and maximal values of resting heart rate (P=0.029) in female athletes. As expected, PPARA GC heterozygotes had the largest LV mass index compared to GG homozygotes both among male (110±21 g/m2 vs 70±12 g/m2; P=0.049) and female athletes (83±16 g/m2 vs 46±10 g/m2; P=0.012). Female GC heterozygotes also exhibited greater ventricular stroke volumes than GG homozygotes (80±4 ml vs 68±3 ml; P=0.033). Furthermore, LV mass was higher in female CnB 5I/5D heterozygotes (254±13 g vs 219±6 g; P=0.039) than in 5I/5I homozygotes. In conclusion, the PGC1A variant was associated with physical performance characteristics of athletes, whilst ACE, PPARA and CnB variants were associated with several cardiologic measures.

ACCELERATED GLIAL REACTIVITY TO STROKE IN AGED RATS CORRELATES WITH REDUCED FUNCTIONAL RECOVERY

Moraru, E., Rusu, L.

University of Craiova, Romania

Background and Purpose: Senescence is both a risk factor for stroke and an impediment to recovery. In the aftermath of cerebral ischemia, peri-lesional astrocytes and activated microglia form a glial scar that hinders the genesis of new axons and blood vessels in the infarcted region. Since glial reactivity is known to be augmented in the normal aging brain, we hypothesized that post-ischemic gliosis would be temporally abnormal in aged rats compared to young rats, and would correlate negatively with functional recovery from ischemic stroke.

Methods: Focal cerebral ischemia was produced by reversible occlusion of the right middle cerebral artery in 3 month- and 20 month-old male Sprague Dawley rats, and the functional outcome was studied at 3-, 7-, 14- and 28 days after surgery using a variety of neurologi-

cal and behavioral tests. At each time point, brains were removed, sectioned and immunostained for the microglial marker ED-1, the astrocytic marker glial fibrillary acidic protein (GFAP), the endothelial cell marker rat endothelial cell antigen (RECA) and the oligodendrocytic marker, chondroitin sulfate proteoglycan, (NG2)

Results On all neurobehavioral tests, aged rats were more severely impaired by stroke than were young rats, and aged rats also showed a diminished capacity for functional recovery. Histologically, in young rats there was a gradual activation of both microglia and astrocytes that peaked by days 14-28 with the formation of a glial scar. In contrast, aged rats showed an accelerated astrocytic and microglial reaction that peaked in the first week after stroke. We also noted a strong activation of oligodendrocytes at early stages of infarct development in all rats that persisted in aged rats. Evolution of astrocytic and microglial reactivity closely paralled the time course of scar formation in both young and aged rats and coincided with the stagnation in the recovery rate of aged rats.

Conclusions: These results suggest that a temporally anomalous gliotic reaction to cerebral ischemia in aged rats leads to the premature formation of scar tissue that impedes functional recovery to stroke. A better understanding of the effects of senescence on the plastic response of the brain to stroke is needed to develop effective new treatment strategies.

INEQUALITIES IN THE USE OF INDOOR AND OUTDOOR SPORT FACILITIES AMONG ADULTS

Serrano-Sanchez, J.A., Sanchis-Moysi, J., Dorado-García, C., Ara-Royo, I., Vicente-Rodríguez, G., Calbet, J.A.

University of Las Palmas, Spain

Background. Different kind of locations, such as natural spaces (beach, sea, mountain, etc), urban spaces (side-walks, city parks, shopping centres, etc), sport-indoor and sport-outdoor facilities, can be used during physical activity (PA). Public institutions spend a lot of money in building and maintaining sports facilities to promote participation in PA and sports. However, few comprehensive studies have been carried out to evaluate the use of different locations for PA. The objective of this study was to explore associations of sociodemographic, geographic, and anthropological variables with the utilisation of different locations for PA. Another aim was to determine the associations of the same variables with the accomplishment of public health recommendations for PA. Methods. A representative sample of the general population of Gran Canaria composed by 3000 adults (18-75 years-old) was interviewed at home. Participants were asked about frequency and duration of use of 8 sport-indoor, 9 sport-outdoor, 7 urban and 6 natural spaces for PA during the last 3 months. PA was assessed using the Minnesota Leisure Time Physical Activity Questionnaire, adapted for Spaniards (1). The use of the four types of locations for PA and the accomplishment of public health recommendations was declared as dichotomous dependent variables. A series of logistic regression analyses adjusted by age, gender, education, occupation, health status, BMI and number of inhabitants were applied. Results. Urban spaces were the most used for PA (64.4%; 95% confidence interval [CI]: 62.6-66.1), followed by natural spaces (26.4%; 95% CI 24.8-28.0%), sport-indoor (20.3%; 95% CI 18.9-21.8) and sport-outdoor (10.9%; 95% CI 9.8-12.1). Age (negatively), gender (male), education (positively), health status (positively) and BMI (negatively) were associated with the utilisation of indoor and outdoor sport facilities, as well as with PA. In contrast, the latter variables were not associated with the utilisation of urban spaces for PA. Associations between characteristics of population and the utilisation of indoor and outdoor sport facilities were stronger than associations between characteristics of same population with PA. Conclusions. Most health-risk groups (obese, elders, lesser education level, etc) of the population had a very low use of sport indoor and outdoor facilities, while these health-risk groups have less difficulty to meet the public health recommendations for PA by using urban spaces. This differential behaviour in the use of locations for PA is likely influenced by the physical design of sport facilities, the policies of access and others unknown factors. This information may be useful to enhance the utilisation of sport facilities and to increase the level of physical activity of the population.

INFLUENCE OF PERFORMING SPORTS IN PUBLIC ON THE IMAGE OF AUSTRIAN POLITICIANS

Hotter, B., Nessizius, K., Kornexl, E.

University of Innsbruck, Austria

Introduction

Even though the sociological phenomenon of advertising various products using the image of amateur and professional athletes already has a long tradition in Austria, little research on this topic has been conducted so far (1). On average, at least once a week the Austrian newspaper Kurier presents an Austrian politician performing a sporty activity in public. Therefore, the subject of this study was to investigate what kind of image Austrian politicians create when using sports as a means of promoting themselves and their political parties.

Method

For this survey 280 students of the University of Innsbruck were interviewed; the random sample reflects the population: 51% (143) of the students were female, 49% (137) were male. The instrument used was the Semantic Differential, a method of a questionnaire always placing two opposite characteristics of a person (e.g. energetic vs. lazy) on the two ends of a scale (-3 to +3) (2). The interviewees were to respond according to their associations when seeing any kind of person – not necessarily a politician – performing sports in public and to choose one position on every scale of each of the 30 pairs of adjectives. Afterwards the results were applied to the image of Austrian politicians.

Results

Taking into account all mean values which are higher than both +1 and -1 and therefore show a clear enough tendency towards one quality, the image of people who are performing physical activity can be characterised as follows: enjoying life, sexy, optimistic, venturesome, funny, open-minded, social, successful, healthy, attractive, energetic, dynamic, powerful. All these qualities can directly be related

to the politician's image when he/she is the person performing sports. However, only if the public acknowledges his/her performance, the politician's image will be enhanced by his/her sportiness (3).

Discussion: In conclusion, the effect on the students of the University of Innsbruck when they see people practicing sports in public is exclusively positive and consequently creates a beneficial image for the active person whether he/she is a politician or not. When sporty appearance becomes part of a politician's image, the social acceptance of his/her political party definitely improves.

THE FITNESS CLUB: A BENTHAM'S PANOPTICON FOR A SELF-CARE?

Pereira, A.L.

Faculty of Sports Sciences - Universtiy Of Porto, Portugal

In his work Surveillance and Punishment, Foucault (1975) described the Bentham's panoptic as a penitentiary structure in which prisoners have a self-monitoring and sense of being always dominated for some invisible power. In this prison, one central tower surrounded by cells, that were kept under permanent observation from the tower, prisoners did not knew when they were being watched, but knew that at any moment that could happened. Thus, they were always in a conscious state of awareness. A few years later, Foucault (1988) developed a theory concerning self-care and self-government, highlighting the importance of technologies of the self: those which permit individuals to effect certain number of operations on their own bodies and souls, thoughts, conduct, and way of being, so as to transform themselves in order to attain a certain state of happiness, purity, wisdom, perfection, or immortality. Along these lines, the aim of our study was to discuss the fitness club: i) as a space that, in some circumstances and ways of inhabit it, may be compared to the Bentham's Panoptic; and ii) as a place in which practices might be included in the technologies of the self. Our data was collected in the course of a fieldwork in a fitness club and through twenty-seven in-depth interviews conducted with fitness activities participants. The interviews were submitted to analysis contents with the following categories: reasons to practice fitness activities, option for the type of fitness activities, frequency, and reasons to continue practicing fitness activities. Our data allows us to assert that fitness clubs are structures that constrain the individual's behavior for their own self-care. Bodies' dispositions are conditioned, turning them into docile-bodies. Indeed, there are some mechanisms in the fitness club that instigate a 'voluntary' action of self-control, i.e., just like in the panoptic, supervision and vigilance are incorporated by the fitness club's layout. Video cameras, glasses and mirrors are some examples of it. Additionally, apparatus like weighing machine, distinct ergometers and mirrors confirm the personal examination that also can be associated to self-governance. Finally, considering the given meanings for practice, fitness activities are able to discipline docile-bodies and also be integrated in the technologies to take self-care. Therefore, we might say that fitness clubs have some elements of the panoptic that allow a metaphor, and are places that instigate continuous and complex self-care, i.e., the Foucault's technologies of the self to a better body.

DECISION-MAKING PROCESSES IN SPORTS CLUBS

Nagel, S.

Technical University of Chemnitz, Germany

In sports clubs, there are a number of trends at the moment, e.g. the differentiation of the sports activities, such as mass or health sports, or the engagement of paid employees. But we find these developments not in all sports clubs. Why do some sports clubs change their organizational structure and others not? As we cannot explain this phenomenon only with structure characteristics (e.g. number of members), it seems obvious to consider strategic decision-making processes, which have been hardly noticed in any research of sports clubs so far. Here, decisions in sports clubs will be analyzed on the basis of behavioural theories of organizational decision-making (e.g.: March, 1994; Simon, 1970). The „Garbage Can Model" seems especially suitable as a heuristic framework. This model has been developed for the analysis of decisions in universities (Cohen, March & Olsen, 1972). Sports clubs as nonprofit-organizations are also distinguished by inconsistent and ambiguous goals, lack of the ability of measuring success, unclear technology as well as fluid participation of members in the decision-making processes. The central idea of the „Garbage Can Model" is the assumption that decision-making processes in organizations are not a sequence of logical steps but consist of four „streams": (1) problems, (2) solutions, (3) participants and (4) choice opportunities. These four streams are more or less independent and the organizational decision-making has a random quality.

How are decisions made in sports clubs? The empirical analysis of this question is based on 20 case studies (Nagel, Conzelmann & Gabler, 2004). 62 strategic decision-making processes in sports clubs were studied in detail. Regarding the „Garbage Can Model" the following results can be emphasized: (1) The reason for decision-making processes in sports clubs are normally not the organizational goals, but often certain problems. Frequently, the interests of some club members are the starting point of an organizational change. (2) Mostly, only a few participants which are involved in the activities of the clubs play an active role. (3) In general, sports clubs try to achieve conjointly solutions which consider the interests of all members. (4) Decisions in sports clubs are especially made in certain committees, but also on an informal level. (5) Decision-making in sports clubs usually last a period of at least several months.

WEB BASED CONTENT MANAGEMENT SYSTEM TO ACQUIRE, STORE AND USE DIAGNOSTIC DATA

Seifriz, F., Mester, J.

German Sport University Cologne, Germany

Introduction

The demand of central data storing requires a right system controlled access on the fastened data holding systems. The advantage of web based systems is the small requirement of software on the client site. Only a web browser is needed. The claim of this project is to develop a web based interface for a content management system (CMS) to use centralised data collections (Bang 2004).

Methods

The base of this project is the content management system of IBM in the version 8.2. The data entry is made with dynamic PDF forms which transfer only the form data over a secure HTTPS connection to the CMS. It is possible to attach to each measurement files of any types (i.e. raw data, graphics or videos). With the help of a C++ application DImport (Ruppert 2005) results of measuring devices can be directly transmitted into the CMS (SFTP). Due to data privacy protection only the diagnostic data are stored in the CMS. Personal data are stored in an external database. The authentication is based by a LDAP system and the authorization is integrated in the web application.

Results

In the first test phase the approach to realise the web based access with PDF forms proves to be advantageous. This is caused by the simplicity to create and the prevalence of the PDF file format. The online and offline entry data is the same so the user needs only a short period of vocational adjustment.

UNDERSTANDING THE BACKGROUND CONDITIONS OF INTENTIONAL MOVEMENTS IN SPORT: A STUDY OF SEARLE'S 'BACKGROUND CAPACITIES'

Moe, V.F.

Sogn og Fjordane University College, Norway, Norway

This paper discusses the problem of how to understand the background conditions that enable and constrain the performance of intentional movements in sport from a philosophical perspective. With background conditions I mean, generally, those conditions that are underlying and sustaining the performance of every intentional movement, and moreover, which remain in the background in the sense that they are not something that the performer is consciously or explicitly aware of while he/she is performing. The aim of the paper is to reveal essential structures of intentional movements' background conditions, and moreover, to reveal how these structures work. To reach this aim I take up the philosopher John Searle's (1983, 1992, 1995) logical analysis of the "Background" and discuss how his account for it can be used to illuminate the background conditions of intentional movements in sport. The Background (with a capital B) names a technical term in Searle's philosophy. It is intended to provide the proper grounding for intentional states in general. Searle defines "the concept of the 'Background' as the set of nonintentional or preintentional capacities that enable intentional states of function" (1995: 129). He divides the structure the Background into a "deep" and a "local" part. The "deep Background" refers to what is common to all human beings, whereas the "local Background" refers to what is characteristic for human beings within a "cultural practice". Also, Searle believes that the distinction between "how to do things" and "how things are" cuts across both the deep and the local Background (1983: 144), and he argues that the Background works in a causal way. I have divided the paper into three parts. First I review the essential characteristics of how the Background is structured. Then I consider some examples that take up how the Background works in relation to the acquisition of skilled motor behavior in sport. Finally, I critically examine how Searle's account for the Background may illuminate essential features of the background conditions of intentional movements in sport.

TECHNIQUE TRAINING IN SPORTS WITH MODERN DIGITAL TECHNOLOGY

Engelmeyer, E., Mester, J., Seifriz, F.

German Sport University Cologne, Germany, Germany

Introduction

Modern digital devices allow new concepts for learning movement skills in sports and technique training. In the spectrum of stand-alone PCs and Laptops on the one hand and powerful server clusters on the other a great number of different presentations modes for improvement of the individual movement skills are available. Looking at this necessity of continuous updating and revising of the curriculum of federations the universities are challenged to offer research based services for the development and digital learning materials. The advantages of e-learning material are used to illustrate play situations, technique training, -analysis, -description and tactics in sport. The digital curriculum in general can cover a wide range of topics including technique/tactics, sports medicine, biomechanics, training and psychology. Whereas traditional printed materials could only be delivered when the last chapter was submitted, in the line of the digital production different modules can be made available as soon as they are ready. The content follows the concept of "blended learning" is represented through different materials: computer based training, interactive images, print version, video pack and interviews.

Method

The method of production is based on the universities true strengths, i.e. the combination of research and education with many skilled students who are already able or can be qualified in using the proper software tools in the area of image and video processing, authoring tools, databases and 3D-animations etc. In cooperation with the scientific staff in the field of training and movement science in the so-

called Sport-el Factory it is possible to consolidate the expertise with the scientific research of training and evaluation. This combination assures a competitive production of high standard learning material.

The wide range of soft- and hardware packages allows for use within the online campus, existing Knowledge Nuggets and Full Web Lectures. Regarding the hardware architecture currently 25 high-end servers with 4.5 Terabytes are in use. It is therefore possible to build up a blended learning concept around the Multimedia Curriculum and enhance the learning material with current, innovative and scientific findings.

For copy protection purposes a sealing program (Sealed Media) is used which enables us to combine document protection and control with the existing applications without detracting from the user experience. To get access to the digital curricula users have to identify themselves to a license server. This makes it possible to define and control the usage of every file on the CD-Rom independently of the acquisition of the material. The admission to the license server and not the property of the material is the key to get access to the material.

TECHNOLOGY ENABLES INTELLECTUAL CAPITAL MANAGEMENT AT THE GERMAN SPORT UNIVERSITY COLOGNE

Wigger, U., Mester, J.

German Sport University Cologne, Germany, Germany

Introduction

Today, it is clear that a university's Internet portal and services are important for its positioning and profile with students, researchers and the larger public. As international leader in its market segment, the German Sport University Cologne (GSU-Cologne) aims to bring its „intellectual capital" closer and more targeted to its various customer groups.

Concept and Methods

To optimize support for research and education, leadership at GSU-Cologne decided to pursue the development of an integrated "Intellectual Capital Management" System (ICM). In addition to Technology Capital – store-and-retrieve technologies – three further types of capital are taken into account: Human – each individual's knowledge and capabilities, Structural – knowledge embodied, internalized, systemized and processed within the organisation, as well as Relational – referring to the university's wide set of economical, political and institutional relationships (Bueno et al., 2002; Leitner, 2004). Large software packages – such as IBM Lotus LearningSpace, Content Manager, WebSphere Portal and Workplace – enable the GSU-Cologne's Online Campus, numerous eLearning products, project rooms, team collaboration, web conferencing, the document and media archive as well as the electronic athlete's record system for capturing, storage, aggregation and statistical analysis of diagnostic data across research departments. A necessary basis for these services is integration of user directories for enterprise-wide identity and access management.

Results and Discussion

In the area of Technology Capital large investments have led to improvements in IT infrastructure and capacities. Since 2001, the growth of Human Capital has been supported by production and access to multimedia eLearning materials. In the future, it shall also be possible to have access to one's own HR and exam data as well as to perform searches across the university's knowledge bases. Structural Capital has been strengthened by the introduction of new organisational units and business models, such as CIO (Chief Information Officer) and CTO (Chief Technology Officer) positions, Sport-eL Factory, electronic athlete's records and ePublishing. Next to implement are the Online Shop and eCommerce models. Relational Capital exists in projects with other research institutions, sports clubs, national and international professional associations and shall be further supported by efficient communication and collaboration technologies.

SPORTS AND COMPETITIVE SPORTS ORGANIZATIONS IN CHINA

Miao, J.

University of Sports, Shanghai, China

The paper presents the sports and competitive sports organizations in China and discusses perspectives for future developments.

The General Sports Administration coordinates and controls all the sports events and sports activities in the coutnry . There are three levels of sports organizations in the Chinese sports systems: state organizations, provincial organizations and regional organizations.

State organizations

The General Sports Administration is responsible for the development of sports in China.

The Pan-Chinese Association is a national organization which is responsible for the develpoment and spreading of mass spaorts.

The Chinese Olympic Committee is an independent organization which aims at promoting the Olympic movement in China.

Since 1998 the various kinds of sports have been organized in China by Administration Centres. However, not every sport can have its own Administration Centre, therefore similar sports are grouped together. This is a temporary ssolution and the plan fot the future is that every kind of sports will have its own Adminaistration Centre. Moreover, there are Special Sports Associations so that single sports kinds can have contact with similar sports associations at an international level more easily.

Provincial and Regional organizations

Every province and every region has its sports administration modelled on the General Sports Administration. The 33 provincial organizations promote the competitive sports as well as mass sports.The teams they maintain form the basis for the national teams. The athletes train in the provinces and they prepare themselves for sports events there. The regional administration functions as a link between leisure sports schools and competitive sports teams.

The perspectives for the development of sports in China are connected with the rapid social and financial development of the country. The change in Chinese polilics is leading to a new sports administration system, which unlike the old one will not be centralized. An additional factor that is going to contribute to the development of sports in China and to arouse the interest of the Chinese people in sports is the fact that China is going to be the host of the 2008 Olympics.

ANALYTICAL HIERARCHY PROCESSING (AHP) AS A MODERN TECHNIQUE FOR GROUP DECISION MAKING IN SPORT MANAGEMENT

Honari, H.

Allame Tabatabaei University, Iran

One of the major responsibilities of managers everywhere is decision making. With respect to bounded rationality of any individual reasoning power perhaps cooperation and participative group work is the only way to achieve a logical, structured comprehensive decision making especially in sport management. To days modern organizations and clubs are so big and complicated that their management is not possible with a single manager so that a manager is obliged to get help from the others in decision making and administration.

Up to now different methods in managing for the effectiveness of group decision making such as brain storming, Delphi method and nominal group technique have certain degrees of short comings in time, costs and intellectual. Meanwhile many techniques have been developed by social scientists to help leaders work with groups to reach decisions. Here are four of them that might introduce useful and wish to experiment with: Affinity diagrams, Interactive diagraphs, Interactive matrices, Collaborative negotiations.

AHP is modern technique which solves this problem to a greater extent. This method not only has the advantages of other techniques but because of its very nature of mathematical logic has the capacity of combining the qualitative and quantitative criterion for multiple choice comparisons.

The essence of AHP is based on the decision hierarchy tree. The group member should at first build the decision hierarchy. In this tree the first level is the level of objectives and the last level is the level of competing choices and the middle level is decision making factors.

In this paper the application of AHP in coordinating the decisions of group members has been introduces. AHP technique will help the top level decision maker to combine and coordinate optimal the decisions of multiple group members.

CHANGES IN SPORT FINANCING BETWEEN 2005 AND 2010 IN PÉCS, THE CAPITAL OF EUROPEAN CULTURE

Papp, G., Vass, M., Prisztóka, G.

University of Pécs, Hungary

In 2004, the Hungarian Parliament passed the Sport Act, and on 1st of May 2004, Hungary joined the European Union. These two events caused Pécs to elaborate its mid-term sport conception. Before the elaboration of the sport conception, by the means of SWOT analysis, we analyzed the sports of Pécs, their weak and strong points, the possibilities of its sports and the dysfunctions of their operation. By applying the results of this assessment, and considering the stance of the leading bodies of the European Union, we elaborated the sport conception of Pécs.

At present, in the European Union, there is no law harmonization related to sports. The Maastricht Agreement (1992) did not include any article on sports. A supplement of the Amsterdam Treaty (1997) included an "EU attitude toward sports". The European Sport Charta (1992) addresses the principles related to sports in a supplement of one of the recommendations of the committee of ministers of the European Council.

Since there are no common legal regulations, there are countries where legal regulations prohibit the government subsidization of professional sport clubs and associations. The measure of government subsidization in all the member countries is 0.4% of the GDP. In Hungary it is 0.2%.

In the European Union, related to the operation of sports, the following priorities can be found:

- The elite professional sports are less subsidized, but the development and maintenance of their institutes are supported by the government budget.
- Junior sport education and student sports, competitions, leisure time sports and sports for disabled are significantly supported.
- The European Union does not wish to introduce a general management of the sports in the member countries, but would like to provide them with the opportunity of preserving their national identity.
- The new member countries have an opportunity of gaining so-called temporary financing for their sports, which makes it possible for the elite sports to maintain their capabilities of functioning efficaciously, and, at the same time, the financing of the other preferred areas is gradually increased.

Our aim is to present the mid-term plans for financing the sports in Pécs by showing the local sport values. We regard it as significant to show Pécs, planned to be the Cultural Capital of Europe, as a model in its sport values and their financing in Hungary.

IS2-11 Blood and performance - "Athene"

BLOOD - THE LIMITING FACTOR OF AEROBIC PERFORMANCE?

Schmidt, W.

University of Bayreuth, Germany

In trained endurance athletes VO2max is essentially (70%) influenced by the O2-transport system which in turn is determined by the heart volume, blood volume (BV) and total haemoglobin mass (tHb). In this review the role of tHb and its particular effect on the O2-transport will be highlighted.

Cross sectional studies show that BV and tHb are increased by up to 80% in elite endurance athletes compared to untrained subjects. Linear regression analysis for tHb and VO2max of 572 differently trained subjects (r=0.864) reveals that VO2max is augmented by 4.3 ml/g tHb. In contrast to tHb no relationship between haemoglobin concentration ([Hb], r=0.171), hematocrit (r=0.094) and VO2max at sea level was found, indicating that under physiological conditions [Hb] is no primary performance limiting factor.

The effect of training on tHb is not yet satisfactorily clarified. After training periods lasting 3-6 weeks different erythropoietic responses have been observed, showing either no changes or augmentations of up to 5-10g/week. During a 9 months training period of marathon runners (3:37 ±0:23h) we found a significant increase in tHb of 7% (62g) which was accompanied by an increase in VO2max of 5%. Considering tHb during a complete training year of elite athletes no changes in rowers and a small increase in triathletes (3459g corresponding to 3.3%) were observed in the competition period. In a group of professional cyclists (n=12), however, we found a heterogeneous behaviour showing small increases (n=6) and strongly elevated values (n=6) after only 3 months of training (+110 12g corresponding to 10.8%). In the group with low erythropoiesis VO2max increased only moderately by 2.5% while the athletes with high red cell production reached 9% corresponding to 3.6 ml/g tHb. As the effect of training on tHb seems to be of relatively low impact, we assume that mainly genetic predisposition is responsible for the extremely high values determined in elite athletes.

Depending on duration and altitude of exposure the hypoxic environment may stimulate erythropoiesis. Major effects were found in elite endurance athletes born and living at altitude (2600m) showing 11% higher tHb values than comparable athletes from sea level. Conventional altitude training camps of 3-4 weeks duration at similar altitudes augment tHb in the mean by maximally 6%, while the live-high train-low concept has no effect on tHb when the daily hypoxic periods are below 10h. Regarding manipulation with blood or EPO the increase in tHb is assumed to be about 12%, which is correlated to an increase in VO2max of 3.3 ml/g tHb.

All data obtained from training and altitude interventions as well as from controlled anti-doping studies show that an increase in tHb of 1g is related to an improvement in VO2max by around 3ml/min.

BLOOD MANIPULATION AND AEROBIC PERFORMANCE

Berglund B., SE

Without abstract submission.

TOTAL HAEMOGLOBIN MASS - A PROMISING PARAMETER TO DETECT BLOOD MANIPULATION

Prommer, N.

University of Bayreuth, Germany

To counteract against excessive blood manipulations haematological upper limits were introduced during the past years in most endurance sports disciplines. Once an athlete exceeds these limits he is suspended temporarily from competition and a doping analysis is performed. This procedure, however, has the big disadvantage that changes in plasma volume can veil manipulations or lead to unwarranted sanctions towards the athlete. As the intention of every kind of blood manipulation is to increase total haemoglobin mass (tHb) it would be important and more reasonable to determine this key parameter directly. The aim of the project presented here was 1) to develop an easy manageable and fast method to determine tHb and 2) to evaluate whether tHb is a valid parameter to detect blood manipulation.

Objective 1: The commonly used and established CO-rebreathing method (Proccom) was optimised by changing the procedure of CO-administration and the breathing pattern.

IMPACT OF BLOOD QUALITY ON PERFORMANCE

Böning, D.

Charité - Universitätsmedizin Berlin, Germany

Gas transport and rheological properties of blood are decisive for performance. Both depend mainly on structure and function of the erythrocytes. Oxygen binding is influenced by hemoglobin type and 2,3-biphosphoglycerate concentration in the red cells; whereas the former only exceptionally is different from HbA1, the latter is slightly increased in endurance-trained subjects. During exercise the rise of temperature and acid concentration (CO2 and lactic acid) in the muscle vasculature attenuates oxygen binding to Hb thus improving O2 transport from blood into the fibres. The acid effect is stronger in endurance athletes than in sedentary subjects by unknown causes. High acid concentrations in the tissues are not detrimental for oxidative metabolism but can act like an oxygen pump from blood to cells; this mechanism is known for the fish swimbladder since long time.

CO2 transport is dependent on content and properties of non-bicarbonate buffers (especially Hb) in blood because the bulk of the substance is transformed to bicarbonate by reaction with the buffers. Only small amounts bind to Hb as carbamate and dissolve as gas. During hard exercise with acidosis caused by lactic acid reducing the bicarbonate content a sufficient arterio-venous CO2 difference can only be obtained by hyperventilation shifting the arterial point to the steep part of the CO2 dissociation curve.

Rheological properties depend on hematocrit, volume and stiffness of the red cells. During exercise a moderate, probably useful increase of hematocrit is caused by water shifts to the tissue. A rise above an optimal value is useless for oxygen transport because the high viscosity hinders blood flow. In athletic animals like horses hematocrit rises markedly during exercise by injecting erythrocytes stored in the spleen into the blood. But they possess very small erythrocytes easily passing through narrow vessels. Volume and stiffness of the red cells change also with cell age. Physical training leads to accelerated destruction of old erythrocytes with functional deficits thereby improving the average quality of red cells with regard to both rheology and gas transport.

Invited symposium (IS)

IS2-12 Nutritional interventions to improve post-exercise protein anabolism (sponsored by Lucozade Sport Science Academy) - "Innsbruck"

OPTIMIZING POST-EXERCISE PROTEIN SYNTHESIS: SPORTS NUTRITION IN ATHLETES

Tipton, K.

University of Birmingham, United Kingdom

The importance of postexercise nutrition has long been recognized. Nutrition following exercise is important, not only for athletes and other healthy exercising individuals, but perhaps even moreso for populations for which muscle hypertrophy is critical for health and function. The elderly, those recovering from illness and bedrest, astronauts and others benefit from information that optimizes nutritional and exercise practices.

The metabolic basis for muscle hypertrophy is the balance between protein synthesis and breakdown. Amino acids are taken up by the muscle and utilized for synthesis of muscle proteins. Muscle hypertrophy results only from positive net muscle protein balance over a given time period, i.e. muscle protein synthesis must exceed muscle protein breakdown. Thus, over a given time of training, periods of increased muscle protein synthesis and/or decreased muscle protein breakdown are necessary for muscle protein accretion due to resistance exercise training. At any given time, net muscle protein balance can be either positive or negative. The balance is determined by the combination of nutrition and exercise. Muscle protein accretion occurs only when the sum of the positive periods exceeds the sum of the negative periods.

Nutrition has been shown to influence the response of muscle protein balance following exercise. Resistance exercise will increase net balance, but ingestion of an amino acid source is necessary before positive balance results following exercise. Amino acid ingestion following exercise stimulates muscle protein synthesis resulting in net muscle protein balance and thus accretion of muscle proteins. The combination of resistance exercise and ingestion of an amino acid source results in greater net muscle protein balance than at rest.

The utilization of the ingested amino acids varies depending on the type of amino acids or protein ingested, other nutrients coingested with the amino acid source and the interaction of the timing of ingestion with the nutrients ingested. Thus, the timing of protein and food ingestion for optimal stimulation of muscle protein balance must be investigated further.

Results from acute studies demonstrating protein accretion are often assumed to indicate that the interventions being investigated would result in long-term gains in muscle mass. Results from longitudinal studies are usually quite difficult to obtain and interpret due to problems with control and design. Evidence that acute results do appropriately represent potential for efficacy in longer time frames is available and will be presented.

These results suggest that ingestion of a specific amount of amino acids may result in differential utilization for protein synthesis depending on the nutritional and exercise situation. Thus, recommendations of a specific protein intake for a group of athletes or individuals with varying diets, training regimens, ages, etc seems nonsensical.

OPTIMIZING SHORT-TERM RECOVERY: POST-EXERCISE PROTEIN INGESTION

Betts, J. A.

University of Bath, United Kingdom

Evidence supports that the ingestion of carbohydrate solutions over the 2-6 hours following prolonged exercise can facilitate the restoration of exercise capacity both through providing the fluid necessary for rehydration and through stimulating carbohydrate storage. The accrual of this evidence has now established many components of the optimal carbohydrate feeding strategy during recovery and further progress has therefore been sought through investigating the potential influence of other macronutrients. Specifically, many authors have reported that the addition of protein to a standard carbohydrate solution might accelerate the rate of muscle glycogen resynthesis when ingested following prolonged cycling. Given that, in general terms, exercise capacity is thought to correlate positively with pre-exercise muscle glycogen availability, there has subsequently been much speculation within the literature regarding a potential application for mixed carbohydrate-protein supplements in the rapid restoration of exercise capacity. While such an ergogenic benefit of specifically designed carbohydrate-protein recovery supplements has received some empirical support, most of the research conducted to date has not evaluated the efficacy of these supplements in comparison with carbohydrate/energy matched controls. However, it has recently been established that running capacity can be restored more completely within 4 hours of prior exercise when a carbohydrate-protein solution is ingested rather than ingesting the carbohydrate fraction alone. Importantly, this benefit did not persist when the carbohydrate concentration of the control solution was increased in order to match the carbohydrate-protein mixture for available energy content. In addition, converse to earlier findings regarding recovery from prolonged cycling, it did not appear that run time to exhaustion in the above study was extended as a consequence of increased muscle glycogen availability. The precise mechanisms through which additional protein might facilitate recovery therefore remain elusive, although it is clear that the capacity for exercise subsequent to recovery is not dictated exclusively by the availability of muscle glycogen. Other potential mechanisms of action include an increased provision of gluconeogenic substrate to the liver and/or an interaction of the ingested amino acids with the central nervous system. In summary, the inclusion of protein in post-exercise carbohydrate supplements would appear prudent, particularly when the time available for recovery is limited. However, the various physiological processes underlying this practical benefit remain poorly understood and therefore warrant further investigation.

NUTRITIONAL INTERVENTIONS TO IMPROVE POST-EXERCISE PROTEIN ANABOLISM

van Loon, L.J.

Maastricht University, Netherlands

Post-exercise carbohydrate and protein ingestion are essential to enable skeletal muscle reconditioning. The latter has resulted in the definition of recovery sports nutrition, but has also important implications for the efficacy of exercise interventions in the elderly and/or in those populations suffering from chronic metabolic disease. Nutritional interventions should be designed to augment the benefits of exercise training. The latter with the intention to prevent and/or treat chronic metabolic disease and impaired skeletal muscle function (insulin resistance, type 2 diabetes, sarcopenia). Main question is how important is nutrition in the post-exercise phase to the proposed benefits of exercise intervention. The role of nutrition in these populations will be underlined based on present literature and on speculations based on our understanding of the importance of recovery nutrition in the athlete.

Invited symposium (IS)

IS2-13 Measuring "real" breath-by -breath gas exchange - "St. Moritz"

BREATH BY BREATH GAS EXCHANGE: GETTING IT RIGHT

Capelli, C., Cautero, M., di Parmpero, P.

School of Medicine, University of Udine, Italy

Breath-by-breath (BB) alveolar VO2 transfer (VO2A) is the sum of the volume of the O2 exchanged at the mouth minus the changes of lung O2 stores: VO2Ai=VO2mi-?VO2si (Eq 1), where: i) VO2Ai and ?VO2mi are the volumes of gas transferred during the breath i at the alveolar and mouth level and; ii) ?VO2si are the O2 stores changes occurring over the same breath. VO2mi is the difference between the volumes of O2 transferred across the mouth and ?VO2si isgiven by: ?VO2si = VAi-1(FAi-FAi-1)O2+FAi?VLi (Eq 2), where VAi-1 is the end-expiratory alveolar volume before the onset of breath i, FAi and FAi-1 are the O2 alveolar fractions in the current (i) and previous (i-1) breaths and ?VLi is the lung volume change over breath i, which can be calculated assuming a net N2 transfer across the alveoli equal to 0: ?VLi = [VN2mi-(FAi-FAi-1)N2 VAi-1]/FAi-1N2 (Eq 3). In the algorithms yielding VO2Ai and ?VLi, only VAi-1 can not measured on a BB basis and it has been usually assumed equal to individual FRC (Auchincloss et al 1966, AU), an unwarranted assumption because it varies from one breath to the next. To circumvent this drawback, Grønlund (1984, GR) defined the respiratory cycle as the interval between equal expiratory FO2 values occurring at t1 and t2 in two succeeding breaths. Since FO2t1 is identical to FO2t2, (FAi - FAi-1)N2 VAi-1 becomes 0 and any assumption as to the value of VAi-1 is unnecessary. Hence, according to Gr, VO2Ai from t1 to t2 is: VO2Ai = ?V'FO2dt-FO2t1?VL (Eq 4), where V' is the respiratory flow whose sign depends on the respiratory phase, FO2t1 is the O2 fraction at t1 and ?VL is the lung volume change over the interval t2 to t1 = ?t. The integral in Eq 4, calculated from t1 to t2, yields VO2mi over ?t and ?VL reduces to: ?VL = VN2mi/FN2t1, where VN2mi is the N2 exchanged at the mouth measured from t3 to t1 and FN2t1 is the N2 fraction at t1 equal to FN2t3. Since t3 may not necessarily concur with t2, also the ?VL occurring from t2 to t3 have to be considered for calculating the total ?VL over ?t. By assuming that the algebraic sum of the CO2 and O2 volumes transferred from t2 to t3 is negligible, ?VL over this interval is obtained by integrating V'E from t2 to t3. Hence, the overall ?VL is given by: ?VL = VN2mi/FN2t1-?V'Edt (Eq 5) and V'O2A is calculated as the ratio of VO2Ai to ?t. AU and GR showed the same accuracy in estimating V'O2Ai; however GR turned out to be significantly more precise. The effects of using different VAi-1 values in estimating the time constant (?2) of V'O2A kinetics at the onset of step exercise were also evaluated by calculating V'O2A by means of GR and of AU with VAi-1 values ranging from 0 to FRC + 0.5 l. ?2 increased linearly with VAi-1 ranging form 36.6 s for VAi-1 =0, to 46.8 s for VAi-1 = FRC+0.5 l, whereas it amounted to 34.3 s with GR. Therefore, when using AU, the obtained ?2 depends on the assumed value of VAi-1.

OPTO-ELECTRONIC PLETHYSMOGRAPHY AS A MEANS TO MEASURE 'REAL' BBB ALVEOLAR GAS EXCHANGE

Aliverti, A.

Politecnico di Milano, Italy

The measurement of the rate of exchange of O2 between alveolar gas and pulmonary capillary blood (V'O2) on a breath-by-breath (BbB) basis is not simply accomplished by measuring the difference between the amount of O2 inspired and that expired at the mouth during a particular breath. This difference includes changes in amounts of O2 stored in alveolar gas that are not transferred to or from pulmonary capillary blood. Lung storage of these gases changes if inspired and expired volumes are different and if alveolar concentrations of these gases change during the course of the breath. To correct for these errors in the BbB measurement of V'O2 and V'CO2, which are not taken into account by commercially available devices, a continuous measure of absolute lung gas volume (VL) is required. In steady state conditions, in fact, the amount of gas remaining in the lung at end-inspiration will, on average, not vary, but this is clearly not the case in non-steady state conditions. At the onset of exercise, for example, expiratory muscle recruitment will lead to a sudden decrease in end expiratory lung volume, which in turn will induce a decrease in end expiratory lung gas stores and thus to an underestimation of alveolar O2 uptake. This problem has been recognized before and several studies have attempted to take into account estimates of changes in pulmonary gas stores. However, all these studies only estimated changes of lung gas stores because until shortly it was not possible to accurately measure actual absolute changes in lung volume on a BbB basis. A new method, Opto-Electronic Plethysmography (OEP) (Cala et al., J Appl Physiol, 1996), now allows measuring changes of the chest wall volume during breathing. By combining chest wall volume changes with measurements of vital capacity (VC) and functional residual capacity (FRC), it has become possible to accurately determine absolute lung volumes at any point during the breathing cycle.

The method has been validated in steady state conditions by comparing it with the gold standard, i.e. measurements of V'O2 by collection of expired gas in a Douglas bag (Aliverti et al, J Appl Physiol, 2004). More recently, we measured in parallel BbB oxygen uptake at the mouth and at the alveolar level in 7 subjects at rest and during on and off exercise transients and we found that by taking into account actual changes in alveolar oxygen stores BbB variability of oxygen uptake is reduced by about 24% (see Wust et al, abstract presend at this Congress).

Obtained data indicate that the proposed method is accurate. With this approach it is possible to partition the uptake of O2 at the mouth into the volumes exchanged between pulmonary capillaries and alveolar gas and changes in alveolar gas stores. It can be therefore very useful for analysing O2 kinetics particularly during non steady-state conditions, like on- and off-transients of exercise.

INTRA-BREATH ASPECTS OF BREATH-BY-BREATH GAS EXCHANGE MEASUREMENTS

Rocker, K.

Med. Clinic, Freiburg, Germany, Germany

Breath-by-breath gas analyses (BbB) usually refer to the balance of metabolic gas exchange. In BbB, oxygen consumption and carbon dioxide release are measured as with the conventional sample bag methods, but with higher temporal resolution. "Intra-breath" analyses go one step further, not only with regard to the temporal resolution, but also to the diagnostic approach. Morphometric and functional diagnostic aspects of the lung can be derived from mathematical interpretation of the exhaled breath gases at mouth within separate breaths. Graphical representative for this exhaled gas concentrations are so-called "expirograms". One prerequisite for the diagnostic use in exercise physiology is the classical subdivision of expirograms into four phases (I to IV). Phase III, the sloping alveolar plateau phase, is the most relevant shape aspect in expirograms if performing intra-breath analyses.

However, the physiological origin of this specific linearity of "phase III" is not clarified unambiguously so far. Thereby, linearity of phase III is crucial for several potentially worthful diagnostic methods. Two contrary and sophisticated principles were recently discussed as origin for the linear sloping characteristic of phase III: A branched-trumpet model of the lungs with sequential representation of a regular stratification to the mouth on the one side, and on the other side a uniform distribution of areas with different ventilation to perfusion ratios over the lungs. In the latter principle, the lung parts with higher ventilation and lower perfusion (and subsequently lower CO2 and higher O2 content) are exhaled systematically earlier than parts with lower ventilation and higher perfusion.

This lecture will revisit and discuss a third and much simpler explanation for the linearity of phase III, once described by Dubois and colleagues in the year 1952. Our results from both physical and mathematical modeling give evidence that this simple principle could be responsible for the course of expirograms on its own. The approach could simplify the diagnostic interpretation of intra-breath measurements especially if applied breath by breath.

IS2-14 Development of interpersonal relations in sport - "Albertville"

PARENTAL SUPPORT AND TALENT DEVELOPMENT

Serpa, S., Barreiros, A.

Technical University of Lisbon, Faculty of Human Kinetics, Portugal

Research in sport psychology has reported the importance of the family influence along the athletes' career. Raising the youngsters in a sports environment, promoting positive emotional experiences, motivating for sports practice, giving emotional support, and adjusting their support to the different developmental phases are important parents' behaviours regarding the athletes' career. Parental support and influence are dynamic processes along the time, determined by the youngsters' developmental needs in what concerns sports participation. It is reported that the most successful athletes received higher levels of support and understanding than the less successful ones. The aim of this research was to study the parents' support to Portuguese young soccer players. Young talents were compared to non-talented players taking into account two phases of sports career (under-17 and under-19). Participants were 82 talented (participation in regional or national teams) and 129 non-talented players aged 13-18. The tool used was the Portuguese version of the questionnaire of parents' support – EMBU, 5-points Likert scale (Perris, Jacobson, Lindstorm, von Knorring & Perris, 1980) administered to the athletes. Results in the talented sample show high values of emotional support (fathers: 3.43; mothers: 3.56) and low levels of rejection (fathers: 1.19; mothers: 1.19), while over-protection has intermediate values (fathers: 2.28; mothers: 2.38). When we compare under-17 with under-19 players in the talented group, the older subjects perceive less rejection behaviours from their fathers and mothers, and more over protection from their fathers. Non-talented subjects reveal a similar distribution in emotional support (fathers: 3.12; mothers: 3.21), rejection (fathers: 1.33; mothers: 1.34), and over-protection (fathers: 2.21; mothers: 2.38). However, general comparison among talented and non-talented players show significant differences in the fathers' and mothers' emotional support (with higher values in the talented group), and lower rejection values in the talented group. When comparing talented and non-talented under-17 athletes, mothers' emotional support is the only variable where we find significant differences (higher values in the talents), while in the under-19 group, fathers' and mothers' emotional support, as well as mothers' rejection, is significantly higher in the talents. Thus, we may conclude that talented players receive more parents' support along the developmental process when compared with the non-talented players, and that perceived parents' influence changes along the years.

THE EMOTIONAL SIDE OF COACH-ATHLETE RELATIONSHIP AS PERCEIVED BY SWISS MALES SWIMMERS

Antonini Philippe, R., Seiler, R.

Swiss Federal Office of Sports Magglingen, Switzerland; University of Bern, Institute of Sport, Switzerland

The relation between coach and athlete is often considered to be a decisive factor for performance in competitive sport. The mutual dependence is manifested in athletes' need to profit from the knowledge, competence and experience of the coach, and in coaches' need to transfer their competences and skills into performance and success. Research employing different methodologies and theoretical frameworks has shown that the quality of the professional and personal relationship between coaches and athletes has an impact on athletes' development and growth. The aim of this study was to investigate the quality of the coach-athlete relationship as perceived by the athletes. Participants were five male swimmers from the Swiss national swimming team who held international titles. A semi-structured interview schedule was employed to obtain qualitative data. The responses of the athletes were content analysed, utilising the three interpersonal constructs of closeness, co-orientation, and complementarity (Jowett & Meek, 2000) as a framework. The results show that the relationship comprised essential coach-athlete requirements and social relationship (closeness), communication and setting of objectives/goals (co-orientation), as well as acceptance and respect of roles (complementarity). It revealed that swimmers placed great importance in maintaining good relations with their coach. Notably, the results highlighted the existence of extremely profound and intimate feelings. The swimmers have come to know their coaches well, appreciate their efforts and respect their opinions,

and in the course of time the feelings were deepened into what some of them described as "more than a friendship". Thus, establishing a relationship based on strong feelings of respect, esteem and admiration seemed to be important to the swimmers. Overall, an "emotional relationship" developed between the coach and the athlete which included strong affective bonds and which can be compared to what Bloom, Durand-Bush, Schinke, and Salmela (1998) called the "human relationship". This part of the coach-athlete relationship may reflect the more personal and humanistic side of coaching in which coaches are perceived by the athletes to care about their welfare, interests, preferences, and needs. The results suggest that the emotional relationship or human relationship is an important facet because it promotes the professional relationship concerned with performance enhancement.

FAMILY INFLUENCES ON CAREER DEVELOPMENT IN SPORT

Alfermann, D.

University of Leipzig, Germany

Scientists and practitioners alike claim that families play a prominent role in an athlete's career development. Likewise, the athletes themselves emphasize that the support and encouragement of their parents were of fundamental importance to their participation and success in sport. And even at the end of their career athletes often mention that the help of their family, particularly their parents, was most important in coping with career termination. Parents are often the primary socialization agents for getting children involved; they may initially act as the child's first coach, and they invest money, time, and emotional support in helping their children to climb the ladder of success. And in many cases, parents of athletes have been active athletes themselves. Besides the parents, siblings may also play an important part in fostering an athletic career.

In studies with adolescent athletes we asked for ways how parents and siblings encouraged the athletes' active involvement into their sport. From a social learning perspective parents' sport activity should have a modelling effect on their kids' activity. And in fact, more than three quarters of both parents were active in the past, and about two third of the parents were still active at the time of study, with fathers still being more often active than mothers. When it comes to introducing their kids into sport, parents and siblings were most often mentioned. Parents were most influential for both, boys and girls, with girls mentioning more often their siblings and less often their parents than boys. And last but not least parents were most important for emotional and instrumental support. Independent from age and skill level, parents gave emotional support, whereas instrumental support was decreasing in the course of an athlete's life. Dropouts from sport perceived less parental support than non-dropouts. And fathers were somewhat more inclined than mothers to put some pressure on their kids, whereas mothers tended more to give instrumental support.

The results of the different studies are summarized and discussed within the framework of the athletic triangle of athlete-family-coach.

Invited symposium (IS)

IS2-15 Eccentric exercise as novel training modality - "Berlin ABC"

THE POSITIVES OF NEGATIVES: ECCENTRIC TRAINING FOR FRAIL ELDERLY

Lindstedt, S.L., Marcus, R., Dibble, L., LaStayo, P.C.

Northern Arizona University and University of Utah, United States

Historically high-force lengthening (eccentric) contractions have been strongly associated with muscle damage and injury. Thus the consensus opinion has been that negative work leads to negative muscle and metabolic outcomes. Owing perhaps to that bad reputation, this mode of muscle use has received scant attention as an intervention to counter muscle wasting and mobility limitations associated with both aging, disease and metabolic abnormalities. In fact, lengthening muscle contractions have two well-documented properties that may make this form of muscle use ideally suited as an intervention. First, the magnitude of muscle force (and hence anabolic stimulus for muscle hypertrophy) is maximized during lengthening contractions. Second, the energy cost to produce these high-force contractions is minimal, a fraction of that required during isometric or shortening contractions. Thus even exercise-limited individuals could, in theory, benefit from high-force eccentric resistance training. We have tested this in several mobility-impaired, high fall-risk elderly populations afflicted with a variety of co-morbid (cardiovascular and neurologic conditions). Compliance is maximized as the training is relatively effortless; there is only minimal and transient muscle soreness. Whole muscle volume increases (15%) and fiber cross sectional area increases (25%-60%) are the result of the high force training along with significant improvements in strength (36%-60%), balance (7%-16%), gait (14%), 6 minute walk distance (8%-17%) and stair negotiating (21%) abilities and importantly at risk individuals improved their fall-risk profile. Additionally, when progressively applied, eccentric exercise amplifies the anabolic response (65% increase in IGF-1) and may improve insulin sensitivity. These data demonstrate that lower extremity eccentric resistance exercise can improve the anabolic mileau by increasing muscle size, function and performance without worsening metabolic impairments, and these muscle changes are accompanied by improved mobility in vulnerable elderly individuals plagued by physical inactivity and a limited exercise tolerance. Funding from NIH.

SLIMMER AND STRONGER - THE EFFECT OF ECCENTRIC EXERCISE IN THE ELDERLY

Däpp, C., Vogt, M., Klossner, S., Popp, A., Lippuner, K., Hoppeler, H.

University of Bern, Switzerland

Introduction

Loss of muscle strength and coordination is a consequence of aging and increases the risk for falling. Conventional heavy resistance training improves muscle strength but represents a safety risk for people with limited cardiovascular exercise tolerance. By contrast, eccentric muscle work (lengthening contractions) allows high-load muscular exercise training with low cardiovascular stress as com-

pared to shortening contractions. We hypothesized that eccentric ergometer training is superior to conventional strength training for gain in leg strength, muscle mass and muscular coordination in elderly subjects >75 years.

Methods

Forty-six elderly subjects (age 81.3±3.2 years, 30 females, 16 males) were randomized to an eccentric (ECT), a resistance (RET) training and a control (CTL) group. Each group followed two guided trainings per week for 12 weeks; each session lasting 45 min. ECT trained on an electronically braked eccentric ergometer where appropriate dosage of the eccentric target load had to be self-monitored on a screen by the subject. RET performed a high-intensity heavy resistance training (4 exercises with 2 sets of 8-10 repetitions each) on weight machines. CTL did not train physically but followed guided cognitive training sessions of the same duration. Pre- and post-intervention testing assigned the risk for falling (Timed Up&Go (TUG), Berg Balance Scale (BBS)), maximal voluntary contraction (MVC) of the legs and eccentric muscle coordination (dosage of the target load), while dual X-ray absorptiometry (DXA) determined the subjects' body composition.

Results

The training intervention caused a significant improvement for TUG in ECT (-0.5±0.1s) and RET (-0.7±0.1s), but not in CTL. BBS score was not changed in any group. Significant increases were recorded for MVC (+7.1±2.0%) and for eccentric muscle coordination (+66±11%) exclusively in ECT. Thigh muscle mass was not changed in any group, but interestingly, body and thigh fat were decreased exclusively in ECT by 5.3±1.7% and 8.0±2.0%, respectively.

Discussion / Conclusion

Eccentric ergometer training in elderly outperformed conventional resistance training concerning gain in leg strength and muscle coordination which resulted in comparable improvements in functional tests assessing the risk for falling. Unexpectedly, eccentric ergometer training positively influenced the subjects' body composition lowering their fat proportion. However, the cellular or molecular mechanisms behind this metabolic phenomenon remain speculative. Our results suggest that eccentric ergometer training may be a well-suited type of exercise for elderly to become slimmer and stronger, and to reduce the risk for falling.

THE IMPACT OF ECCENTRIC EXERCISE ON SELECTED COGNITIVE MEASURES IN THE ELDERLY

Buschkuehl, M., Hutchison, S., Daepp, C., Hoppeler, H., Perrig, W.J.

Institute of Psychology, Switzerland

There is a whole body of research showing that cardiovascular exercise has positive effects on cognitive performance measures in the elderly. However, little is known about the impact of eccentric exercise on cognition. In order to investigate this issue, we conducted an eccentric training study with 15 healthy elderly participants (Age: M = 81.2 years; SD = 3.5 years). Training took place twice a week for a period of 12 weeks; each session lasted 45 minutes. Before and after the training, several cognitive measures were administered, including tasks on memory, speed, executive functions and semantic knowledge. Furthermore, quality of life, daily activities, and locus of control were assessed with questionnaires. Besides a subjectively experienced improvement in quality of life, which was especially pronounced in the physiological domain, we also found enhancements in cognitive tasks that required abilities that were comparable to the ones used while performing the eccentric exercise, such as monitoring. These results show that eccentric training, like cardiovascular training, has a positive impact that goes beyond the improvement of physiological performance measures in the elderly.

OP2-11 Physiology 7/10 - "Oslo"

THE EFFECT OF NSAID INGESTION ON SATELLITE CELL PROLIFERATION IN HUMANS IN RESPONSE TO A 36KM RUN

Mackey, A., Mikkelsen, K., Jørgensen, S., Kadi, F., Kjær, M., Langberg, H.

Institute of Sports Medicine, Denmark

It has been shown that exercise can enhance the satellite cell pool in humans, after both acute bouts of exercise (Crameri et al., 2004) and periods of long term training (Kadi et al., 2004). Satellite cells are critical for hypertrophy and the successful repair of damaged muscle. Consumption of nonsteroidal anti-inflammatory drugs (NSAID) is common practice among individuals participating in various sporting activities in order to continue training when faced with muscle soreness or injury. It has however been demonstrated that NSAID consumption can suppress the normal increase in muscle protein synthesis observed following exercise (Trappe et al., 2002). The aim of this study was to investigate the effect of NSAID consumption on the satellite cell response to an acute bout of exercise.

16 healthy well-trained men volunteered for the study which involved a 36km run and 4 muscle biopsies, obtained before the run and on days 1, 3 and 8 afterwards. Volunteers were randomly assigned into two groups to receive either NSAID (indometacin 100mg/day) or placebo from 4 days before the run until the final samples had been collected. The mean age of the NSAID group was 25 +/- S.D. 1 yr, and 26 +/- 4 for the placebo group. Satellite cells were visualised by immunohistochemical staining of microthin muscle cross-sections with a monoclonal antibody against neural cell adhesion molecule and counterstained with Mayer's Haematoxylin. Satellite cells were counted from a minimum of 200 fibres and expressed relative to the number of myonuclei.

VO2max testing showed similar aerobic capacities for the NSAID and placebo groups (59 +/- 6 and 63 +/- 6 ml/kg/min, respectively). Satellite cell analysis revealed a small but significant increase (from 4.10 +/- 0.79 to 5.13 +/- 1.08; p = 0.042, Friedman test) in the number of NCAM-positive cells in the placebo group on day 8 after the run, whereas no change was observed in the NSAID group (4.46 +/- 0.97 to 4.07 +/- 0.86). Using the Kruskal-Wallis test on normalised data, a significant group effect was observed on day 8.

The main finding in this study was an increase in the number of satellite cells (NCAM-positive) in vastus lateralis muscle following a 36km run in endurance trained men, and furthermore that this response was not observed in the group taking NSAID, suggesting that this type of medication may attenuate the proliferation of satellite cells in fit, healthy individuals under moderate muscle loading conditions. Given the prevalence of NSAID consumption among individuals participating in a wide range of sports, further work is warranted in this area in order to elucidate the precise function of NSAID with regard to muscle metabolism.

THE DOSE-RESPONSE OF INHALED BETA2-AGONISTS ON ATHLETIC PERFORMANCE IN NON-ASTHMATIC COMPETITIVE ATHLETES

Sporer, B.C., Brooks, J., McKenzie, D.C.

University of British Columbia, Canada

Introduction

Salbutamol use in elite sport is increasing and there are concerns of over-use by non-asthmatics in order to gain a competitive edge. Although the majority of research suggests there is no performance enhancement in non-asthmatics, the dose-response effect on performance has not been evaluated in a homogenous group of trained athletes with a sport specific performance test. The purpose of this study was to determine the dose-response effects of inhaled salbutamol on time trial (TT) performance in competitive athletes.

Methods

Non-asthmatic, competitive, male cyclists and triathletes (n=37) came to the laboratory on 5 separate occasions. On day 1, athletes were screened for airway responsiveness using a eucapnic voluntary hyperpnea test (EVH). This test is commonly used to determine eligibility for use of a B2-agonist in international competition1. An incremental exercise test was performed to determine VO2max. During the last four visits, athletes performed a 20km TT on the Velotron Pro cycle ergometer 15 minutes post-inhalation of placebo, 200mcg (D2), 400mcg (D4), or 800mcg (D8) of salbutamol. All conditions were randomized and double blind. Metabolic data was collected during each TT. Repeated measures ANOVA was used to determine effects of dose on performance and physiological va1riables with post-hoc analysis done using Tukey's HSD test. For all statistical procedures alpha = 0.05. All values are mean (SD).

Results

Seven subjects had a positive response to the EVH test resulting in a 19% incidence. These subjects were excluded from the remainder of the analysis. The remaining subjects (n=30) had a VO2max of 67.1 (4.3) ml/kg/min with a peak power (PP) of 457 (31) watts (W). Three subjects were unable to complete at least one TT. There was no effect of dose on time (PT) (Pl=30.72 (1.06) min; D2=30.55 (1.03) min; D4=30.67 (1.06) min; D8=30.70 (1.04) min; p=0.16), mean heart rate (Pl=172 (9) bpm; D2=173 (10) bpm; D4=171 (9) bpm; D8=171 (10) bpm; p=0.52), or mean power output (Pmean) (Pl=306 (29) W; D2=310 (30) W; D4=307 (29) W; D8=307 (30) W; p=0.12). No differences were found with respect to mean VO2, VE, or ventilatory equivalent for oxygen (VE/VO2).

Discussion/Conclusions

The primary finding was that inhaled salbutamol, in doses up to 800mcg, has no performance enhancement effect in a 20km cycling time trial. This coincided with no observable difference in metabolic or ventilatory parameters during exercise. Additionally, incidence of exercise-induced bronchospasm in athletes not having previously been diagnosed with asthma was 19% when measured using an EVH test.

This study was funded by the World Anti-Doping Agency.

THE EFFECT OF A BRIEF SPRINT INTERVAL EXERCISE ON GROWTH FACTORS AND INFLAMMATORY MEDIATORS

Meckel Y., Nemet D., Seraev M., Sagiv M., Eliakim A.

Zinman College of Physical Education, Wingate Institute, Netanya. Child Health & Sport Center, Pediatric department, Meir General Hospital, Sackler School of Medicine, Tel-Aviv University. , Israel

Introduction: The efficiency of exercise training depends on the intensity, volume, duration, and frequency of training, as well as on the athlete's ability to tolerate it. Recent effort to quantify the effects of exercise training on the athletes hormonal response suggest that exercise leads to a simultaneous changes of antagonistic mediators. The aim of the present study was to evaluate the effect of a brief sprint interval exercise session (four repetitions of 250m run at 80% of the maximal speed) on the balance between anabolic hormones [growth hormone (GH) IGF-I (insulin-like growth factor-I) axis], catabolic hormones (cortisol), and circulating pro-inflammatory cytokines like Interlukin-6 (IL-6).

Methods: Twelve healthy elite Israeli junior handball players (age range 17 - 20 years) participated in the study. Exercise consisted of four 250m runs on a treadmill, at a constant work rate of 80% of the maximal speed (calculated from the maximal speed of a 100m run), with three minutes rest interval between each of the 250m runs. Therefore, each participant ran in the same relative speed.

Results: Exercise led to significant increases in GH, IGF binding protein-3 (IGFBP-3) and testosterone, and to a significant decrease in IGFBP-1 levels. There were no significant effects of exercise on IGF-I and cortisol levels. In addition, exercise led to a significant increase in the testosterone/cortisol ratio. Exercise was associated with a significant increase in IL-6 levels. IL-6 remained elevated one hour after the end of exercise.

Conclusions: Changes in the anabolic-catabolic hormonal balance were found following a brief sprint interval exercise indicating that these markers may be used to gauge the training intensity of anaerobic-type exercise. Changes in the GH-IGF-I axis and testosterone/cortisol ratio suggested exercise-related anabolic adaptations, while increases in IL-6 may indicate its important role in muscle tissue repair following anaerobic exercise. The clinical use of these markers in the assessment of longer periods of anaerobic-type training still needs to be explored.

THE EFFECT OF LEUKOCYTE ACCUMULATION IN EXERCISED MUSCLES ON RECOVERY OF MUSCLE FUNCTION AFTER HIGH-FORCE ECCENTRIC EXERCISE IN HUMANS

Raastad, T., Paulsen, G., Fjeld, J.G., Hallén, J.

Norwegian School of Sport Sciences, Norway

We have previously shown a close relation between leukocyte infiltration in exercised muscles and recovery of muscle function after normal strength exercise and extreme high-force eccentric exercise (Raastad et al., 2003; Paulsen et al., 2003). The initial muscle damage during exercise seems to determine the number of infiltrating leukocytes which in turn seems to control the following recovery process. The recovery process may involve a secondary loss of force-generating capacity 1-3 days after exercise if a large infiltration is mani-

fested (Paulsen et al., 2003). Therefore, manipulating the inflammatory response by anti-inflammatory drugs could affect the recovery after exercise-induced muscle damage. The purpose of this study was to investigate the effect of a COX-2 inhibitor on leukocyte infiltration and recovery of muscle function after high-force eccentric exercise.

Seventeen students performed 70 unilateral maximal eccentric repetitions with the elbow flexors. The subjects were divided into a Celebra group (n = 8); receiving celecoxib (an anti-inflammatory drug; COX-2 inhibitor; 2 x 200 mg pr day for ten days), and a Placebo group (n = 9); receiving lactose pills. Medication started 1 hour before exercise. Infiltration of radioactive leukocytes was measured with a gamma camera, six and 20 hours after exercise. Maximal, voluntary, isometric torque was measured before and regularly for ten days after exercise.

Immediately after exercise isometric force-generating capacity was reduced by 48±4% in the Celebra group and 52±4% in the Placebo group (no significant difference between groups). The workout resulted in a gradual accumulation of labelled leukocytes in exercised from six to 20 hours after exercise, but the COX-inhibitor had no effect on the amount of infiltrating cells (82±29 % over control muscle in the Celebra group and 82±27 % over control muscle in the Placebo group, 20 h after exercise). Independent of groups, subjects experiencing large infiltration (more than 100% over control, n=5) had no recovery of force-generating capacity from 6 h after exercise to 72 h after exercise while subjects with moderate infiltration (42±5% over control, n=12) recovered by 45%. On individual level we observed a strong correlation between accumulated leukocytes 20 h after exercise and the force reduction observed in the placebo group ($r=0.85$, $p<0.01$) and in all subjects ($r=0.58$, $p=0.01$) 72 h after exercise.

Although the accumulation of leukocytes into exercised muscle not was reduced by the anti-inflammatory drug, we observed a tight relation between the extent of infiltration and the recovery of force-generating capacity the first days after exercise.

20-HZ WHOLE BODY VIBRATION TRAINING FAILS TO COUNTERACT NEGATIVE EFFECTS OF 14 DAYS OF BED REST ON MUSCLE PERFORMANCE

Liphardt, A.M., Zange, J., Schmidt, A., Kleinöder, H., Heer, M., Mester, J.

DLR-Institute of Aerospace Medicine, Cologne,, Germany

The absence of mechanical loading e.g. in microgravity (µG) or immobilization leads, amongst others, to a decreased muscle performance (1). Bed rest in 6°-head-down-tilt (HDT) is a well-established model to simulate some of the physiological effects astronauts experience in µG (2). Similar to µG, immobilization in 6°-HDT bed rest leads to a lack of mechanical loading in the lower extremities. Although the negative effects on the muscular-skeletal system are known, training methods during space flight still need optimization.

Vibration training (VT) has been shown to improve muscle performance in training studies (3;4) with little time effort. Thus, it is hypothesized that VT will change the response of the body to bed rest with respect to skeletal muscle performance.

8 healthy male subjects (78.1 ± 9.5 kg; 179 ± 9.6 cm; 26 ± 5 years) performed 14-days of bed rest in 6°-HDT in the DLR-Institute of Aerospace Medicine. The study was carried out as a cross-over-design, consisting of two phases, each lasting 23 days. Each subject received VT in one phase and a control intervention in the other phase. Study phases were divided into three periods: a 4-day adaptation period, a 14-day intervention period in 6°- HDT bed rest and a 5-day recovery period. During the intervention period, all activities including eating, showering and weighing were carried out in the 6°-HDT position. Subjects were mobile in the adaptation period and the recovery period. Study phases were identical with respect to environmental conditions, study protocol and diet. The VT consisted of 5 x 1 minute whole body vibration twice daily on the Galileo 900 vibration plate (20 Hz / 2-4 mm). Isometric (maximal voluntary contraction (MVC)) and dynamic (power) muscle performance of the knee extensors and the knee flexors was measured at the last day of the adaptation period (day -1), the first day of the recovery period (R1) and the last day of the recovery period (R5).

MVC decreased significantly ($p < 0.001$) for the knee flexors during the bed rest intervention. However VT failed to counteract this effect. For the knee extensors no changes in MVC due to bed rest or VT could be observed. Power in both muscle groups decreased due to bed rest but the response did not change with the VT. MVC and power did not recover to baseline after the recovery period for both muscle groups.

The results indicate that loss in muscle performance after 14 days of immobilisation of healthy subjects in 6°-HDT with controlled diet is muscle specific. The applied training protocol failed to counteract negative effects on muscle performance. The chosen training regime may not have been intense enough to cause changes in the response of the body to bed rest.

EFFECT OF CONCENTRIC AND ECCENTRIC RESISTANCE TRAINING, AND DETRAINING, ON THE RATE OF FORCE DEVELOPMENT OF HUMAN SKELETAL MUSCLE

Blazevich, A.J., Cannavan, D., Coleman, D., Horne, S., Aagaard, P.

Brunel University, United Kingdom

The ability of an athlete to achieve a high rate of force development (RFD) in the early phase of muscle contraction is important in sports where force application times are shorter than those needed to reach maximum. As the adaptations elicited by concentric and eccentric modes of resistance training are different, we hypothesised that they would have dissimilar effects on RFD; quantification of these differences is important for the optimisation of physical training interventions. Based on previous reports, we also expected that training-related increases would be greatest in the first few weeks of training and, perhaps paradoxically, that RFD should increase after training

cessation. Twenty-one subjects (10 men and 11 women, 18–32 yr) completed 10 wk (3/wk) unilateral concentric or eccentric maximal isokinetic knee extension training through 90 deg at 30 deg/s. Before (0 wk), during (5 wk) and after (10 wk) training, and after 14 wk of detraining, the subjects performed an isometric knee extensor test aiming for a maximal rate of force increase. The maximum RFD, relative RFD (to MVC; rRFD) and the integral of the force-time curve (contractile impulse) were measured in the epochs 30, 50, 100 and 200 ms after the initiation of contraction. The relative RFD was also calculated to the level of 1/6, 1/2 and 2/3 of MVC. Repeated measures MANOVA was used for analysis after log transformation of non-normally distributed data (alpha=0.05). Our results revealed an effect of training mode on only one of the 19 RFD variables (concentric group > eccentric group for RFD to 30 ms: 38% vs 12%); there was no effect of gender or pre-training isometric strength on RFD changes. When all subjects were pooled, there was a significant increase in RFD, rRFD and impulse in the first 30 ms, and an increase in impulse measured to 50 ms at 5 wk. After 10 wk, there were significant increases in MVC, RFD, rRFD and impulse calculated to 30, 50, 100 and 200 ms, as well as a reduced time to reach RFD to the level of 1/6 MVC. These improvements remained unchanged through 14 wk of detraining. Interestingly, subjects with less-than-median rRFD at 0 wk improved in all RFD measures (with most increases occurring by 5 wk; $p<0.01$), while subjects who had greater-than-median rRFD showed decreases in rRFD at 50, 100 and 200 ms and to 1/2 and 2/3 of MVC ($p<0.05$). In conclusion, our data provide further evidence that maximal strength training improves early-phase RFD irrespective of training mode, but also show that improvements occur largely in the first few weeks of training and are maintained through a prolonged (14 wk) period of detraining. A unique finding of the present study was that the increases in RFD were limited to those subjects who had the slowest rRFD prior to training, with those subjects with faster rRFDs showing no change, or a reduction, in RFD. Thus, the use of heavy resistance training to improve RFD might be best limited to individuals who have a slower rRFD.

LOADING CONDITIONS AND NEUROMUSCULAR ACTIVITY DURING "TURN MOVEMENTS" IN ALPINE SKIING AND IN A NEW SKI SIMULATOR

Pozzo, R., Consuelo, P., Casasola, S., Rejc, E., Canclini, A.

University of Medicine Udine, Italy

Introduction In alpine skiing the loading constrains make the legs to resist to high level of peak forces and vibrations. This loading conditions are not easy to be reproduced by means of standard strength exercise used in training protocols. The aim of this study is to verify the affinity of the turn movement carried out in a real giant slalom (GS) and on a new simulator (SS). The simulator used has two breech footboards which can rotate around their longitudinal axis and can vibrate with a frequency between 0 to 50 Hz. The athlete is tied with a waist belt from which two lateral cables and one directed to middle line of the feet are connected to a traction lever which is controlled by an external operator.

Methods Different methods have been used during GS and SS situation.3D-Kinematics: two videocameras (50 Hz) and dedicated SIMI-software. Dynamics: insoles with pressure cell sensors (PEDAR 100 Hz). Muscle activity: EMG by MEGA-electromyographer (1000 Hz) with 8 channels. In GS testing session, vertical and lateral forces acting on the subject's belt were recorded (100Hz) by means of load cells.

Results On the SS the joint variations show the same time phase for both legs, whereas in the GS the curves are time shifted. This is due by the different external constrains affecting the flexion phase. In GS the ski move laterally from each other causing the external leg to be much more extended with respect to the SS situation where the can only rotate in the frontal plane. Maximal knee flexion are consistent in the vibration exercise and reach a mean value of 110 deg and 85 deg for external and internal knee, whereas in GS the value are 96 deg and 60 deg respectively. Internal and external reaction forces show similar curve patterns in both situations GS and SS. Peak forces in GS and during SS, when the lateral traction cables are omitted and under different vibratory condition, were: highest values, 2500 N external and 1300 N internal, occurred during the 30 Hz vibration, while in the GS they reach 1400 N and 500 N respectively. Using traction cable, forces on the feet are 1100 N external and 300 N internal while lateral force acting on the hip is 700 N. So, lateral force constrains allows the typical distribution of the forces between legs. The EMG showed high similarity between the GS and SS conditions. For the BF, VM, and RF there is a linear tendency to increase the RMS values according to the augmented frequency of vibration. Maximum RMS values are observed during GS. Analogues considerations are founded for IEMG parameter.

According to these results new assumption can be made in order to improve the constrains of the simulator and make it more useful in training or in the rehabilitation.

BLOOD LACTATE CONCENTRATION AFTER SLALOM COURSE OF DIFFERENT LENGTH

Dolenec, A., Tomazin, K., Jereb, B., Strojnik, V.

University of Ljubljana, Faculty of Sport, Slovenia

In alpine skiing, most of the required energy for slalom skiing comes from an anaerobic glycolytic system (Andersen and Montgomery, 1988; Tesch, 1995). This causes that fatigue appear very soon. Following a race, blood lactate concentration averages 9 to 13 mmol/l (Andersen and Montgomery, 1988) so the fatigue is beyond anaerobic threshold. Fatigue beyond anaerobic threshold disturbs body balance (Nardone et al., 1997) and consequently slow-down learning processes. For technique training, fatigue should be kept at low level. Therefore the aim of this experiment was to find the level of fatigue that appears in slalom skiing after 15, 30 and 45 gates respectively to establish the proper distance for technique training. Eight alpine skiers (age 19 ± 1.3 years; height 182.4 ± 3.6 cm; weight 81.5 ± 4.4 kg) from the Slovenian national team volunteered in the experiment and gave their written consent. After the warm-up, the participants perform three runs on the same course. In random order they performed courses with 15, 30 and 45 slalom gates respectively. The end of the course was always in the same place. The rest between runs was at least 30 minutes. Before each run and three minutes after skiing we took blood samples from the ear lobe for blood lactate concentration analysis. T-test for dependent samples was used for testing differences. Before runs the lactat concentrations were 2.5 ± 0.88 mmol/l for 15 gates, 1.6 ± 0.58 mmol/l for 30 gates and 1.8 mmol/l ± 0.71 for 45 gates. The lactate concentration after skiing on 15 gates course was 2.6 ± 0.57 mmol/l and was significantly lower than after skiing on 30 gates course (4.5 ± 0.52 mmol/l). The highest lactat concentration was after skiing on 45 gates course (6.7 ± 0.99 mmol/l). Only skiing on 15 gates course caused fatigue that is under anaerobic threshold. Such a low level of blood lactate concentration should not significantly interfere neuromuscular function. Since the body balance is very important in learning process we can speculate that skiing on 15 gates course is suitable for learning skiing technique. Skiing on 30 and 45 gates course caused fatigue that is beyond anaerobic threshold and may not provide good physiological basis for learning skiing technique.

EFFECTS OF COLD WATER IMMERSION ON MARKERS OF RECOVERY, PERFORMANCE AND TRAINING QUALITY IN WELL-TRAINED TRIATHLETES

Rowsell, G., Coutts, A., Reaburn, P., Halson, S., Toone, R.

South Australian Sports Institute, University of Technology - Sydney, Central Queensland University, Australian Institute of Sport, South Australian Sports Institute, Australia

The use of ice baths and other forms of cold water immersion (CWI) has become a common practice with high level athletes who train regularly. It is thought that the use of CWI immediately post-training promotes faster restoration of performance capabilities and enhances subsequent training performance. However, to date, few studies have examined specific changes in performance and capacity to train following CWI. This study investigated the effects of CWI on submaximal and maximal performance, ability to complete a quality training set, perception of recovery, and changes in various biochemical markers of physiological stress and muscle damage. Seven male triathletes (age 28.6 ± 7.1 y, VO2 max 71.2 ± 4.6 mL/kg/min, mass 73.4 ± 10.2 kg) completed two trials in a counterbalanced cross-over design: an intensive running training session in the morning immediately followed by either CWI or CONTROL immersion and then an incremental cycling test and quality interval training set 9 h later. The morning run training session consisted of 7 x 5 min running intervals on the treadmill at 105% of their individually determined anaerobic threshold running speed with 2.5 min active recovery between each interval. On completion of the run session subjects consumed a recovery drink prior to immersion in either cold (10 ± 1° C) or control (34 ± 1 °C) for 5 x 1 min 'in' / 1 min 'out'. 9 h after the morning run session, subjects completed a series of cycling performance trials: 5 min at 1.5 W/kg, 5 min at 3 W/kg, 5 min maximal effort bout and 6 x 5 min with 1 min recovery as a high quality training set. Power output, heart rate (HR), blood lactate (BLa), rating of perceived exertion (RPE) and VO2 were monitored throughout. Resting plasma concentrations of interleukins 1, 6 and 10, fatty acid binding protein, myoglobin, lactate dehydrogenase and creatine kinase were also determined. Subjects also completed questionnaires to assess their perception of recovery. Subjects kept a training and diet log during the study and followed the same training and nutrition plan the day prior and the day of testing for both trials. Results demonstrated improved training quality and an improved perception of recovery in all subjects with CWI. We also observed practically meaningful positive changes (1) in mean power output and percentage of goal power, HR and BLa during the quality interval training set following CWI. There were also significant improvements in the work-RPE, HR-RPE, and BLa-RPE relationships during the quality training set following CWI ($p<0.05$). These results show that between-session CWI augments subsequent training effort. The improved training performance appears to be linked to higher perception of physical recovery and reduced perception of fatigue and leg soreness.

OP2-13 Health and Fitness 3/4 - "Berlin DE"

"TO GET GERMANY MOVING"- AIMS, TARGET-GROUPS, PROGRAMS, EVIDENCE OF HEALTH-SPORT

Brehm, W., Bös, K.

Universität Bayreuth, Germany

Introduction

As in most industrialized countries the majority of the German adults (90%) do not follow the recommendation of the American College of Sports Medicine. In order to improve the compliance with these requirements more intervention strategies that focus not only on health but even more on the behavior are needed and evaluated with regard to the evidence of the effectiveness.

Concept

Since about 1995 in Germany a field of health-Sport is created, besides the established fields of competition-sport, fitness-sport and fun-& nature-sport. On the basis of the "New Public Health Concept" of the WHO the German Sports Federation (DSB) and the German Gymnastics Federation (DTB) decided, that this field should be health and behavior directed and that this field demands – as a "bridge" to the medical system – specific qualities and a special quality management (evidence based approach).

Together with the sport organizations and cooperating with Health-Insurance Companies in Germany, we developed a concept of six specific aims of Health Sport. Two main target groups were defined:

- Sedentary persons who often have not been exercising for a long time.
- Persons with risk-factors and/or problems in metabolism and the heart circulation system, in the muscle-skeleton-system, in psy-chic and somatic areas.

In order to reach the above-mentioned aims a "seven sequence intervention" was developed for Health Sport programs. Every exercise session in this intervention – normally with a duration of 90 minutes – consists of seven sequences: 1. Preparation, 2. Warm-Up, 3. Endurance, 4. Strength & Flexibility, 5. Relaxation, 6. Stimulation, 7. Information (integrated in 1 – 6).

Programs and Evaluation

On the basis of the outlined concept in the last years several Health-Sport-Programs were developed and evaluated within different working groups. Especially the German Gymnastics Federation (DTB) is integrating these programs in the health sport offers of the clubs. The evaluations are showing that over all a behavioral change could be reached for about three quarters of the participants by the means of the intervention. Participants who were in a negative fitness- and health condition before the intervention had the greatest benefit from the pro-gram while other participants stabilized their status. The results emphasize the importance of a well-structured physical activity program as a bridge in non-medical therapy and the prevention especially of the metabolic syndrome.

Introduction: Valid measurement of physical activity level is essential, when exploring the association between physical activity and different health aspects, when monitoring interventions aimed at increasing physical activity and when estimating the balance between dietary energy intake and energy expenditure. Physical activity is often measured by self-report in large study populations and it is therefore important to establish how self-report methods relate to objective measures of physical capacity.

Aim: To assess the validity of a new self-report physical activity questionnaire in relation to maximum oxygen uptake.

Material: 102 volunteer men and women between 35 and 65 years of age, recruited from the 5-year follow-up of an on-going population-based intervention study, the Inter 99 study.

Methods: Participants filled out a self-report questionnaire on 24-hour physical activity on an average weekday and aerobic capacity was measured on an electrically-braked Krogh bicycle- ergometer. Oxygen uptake and heart rate was measured continuously during the test and the peak value was regarded as max V02. Relationship between physical activity level and max V02 was explored by linear regression.

Results: Data from 47 women and 53 men were analysed. Total amount of physical activity was not significantly associated with max V02 (p=0.098), whereas amount of vigorous physical activity was significantly associated with max V02 (p=0.0001).

Conclusion: The self-report questionnaire used in this study provides a reasonably valid measurement of physical activity, since vigorous, but not total amount of physical activity is associated with maximal oxygen uptake, corresponding to findings in similar validation studies.

WHICH ENVIRONMENTAL VARIABLES SUPPORT/INHIBIT PHYSICALLY ACTIVE COMMUTING IN URBAN AREAS?

Schantz, P., Stigell, E.

The Research Unit for Movement, Health and Environment, The Åstrand Laboratory, Sweden

Introduction

The understanding of how environment may stimulate or hinder physically active commuting in urban areas is meagre. The aim of this study is therefore to scrutinize environmental factors related to existing behaviours of bicycling between home and work/study place in the inner urban part of Stockholm. For this purpose physically active commuters rated their perceived experience of 13 environmental variables along their self-chosen commuting routes. They also expressed whether the overall route environment stimulated or inhibited their commuting.

Methods

The subjects volunteered to participate in the study after being contacted through advertisements in two large morning newspapers in Stockholm. They live in the County of Stockholm and cycled the whole way to work/study place at least once a year. The minimum age for inclusion was 20 years. A questionnaire was sent to 1950 persons in May 2005. The response frequency was 93 %. 847 of the respondents bicycled in the inner urban area of Stockholm and constitute the basis for this study. Semantic differential 15-point scales for responding were used. The variables studied were exhaust fumes, noise, flow and velocities of motorized vehicles, respectively, velocities of other bicyclists, congestion of all vehicles in non-separated traffic environments, congestion of bicyclists in bicycle lanes/paths, incidence of conflicts between the individual and other road-users (including pedestrians), the extent that the route consisted of paths/lanes specifically separated for bicyclists and apart from car traffic, feeling of unsafety/safety, the extent of green elements (nature, parks, trees, plantings), aesthetics, the extent to which route complexity hampered the commuting, hilliness, number of red lights, and the perceived distance. Whether these variables could explain the ratings of to what extent the overall route environment stimulated or inhibited their commuting was tested with multiple stepwise regression analysis.

Results

The following variables were statistically significant in explaining variations in the ratings of whether the overall route environment stimulated or inhibited the respondents commuting: 1) aesthetics, 2) unsafety/safety 3) exhaust fumes, 4) route complexity hampering the commuting and 5) green elements (nature, parks, trees, plantings). The multiple regression analysis built a regression equation of the form: Y = 5.90 + 0.32 x aesthetics + 0.19 x unsafety/safety – 0.17 x exhaust fumes – 0.11 x route complexity + 0.12 x green elements.

Discussion/Conclusion

The present findings are in part clearly unexpected and of distinct interest in understanding how existing behaviours of commuting can be understood in relation to the surrounding environment. On this basis the analysis will be furthered through e.g. analysis of what the important constituents of the feeling of unsafety/safety are. Also the dimensions of aesthetics and route complexity need to be understood in depth.

MOTHERS ARE KEY DETERMINANTS OF PHYSICAL ACTIVITY IN YOUNG CHILDREN

McKee, D.P., Boreham, C.A., Murphy, M.H., Nevill, A.M.

Stranmillis University College, United Kingdom

Aim: To examine the relationship between parental and child physical activity.

Methods: Physical activity (PA) measurement using a uniaxial pedometer was simultaneously assessed for six days in 38 (14 male) three and four year old children and their parents. The relationship between parental and child PA was assessed using an ANCOVA for both weekdays and the weekend.

Results: Weekdays showed mothers' PA was positively related to child PA (partial Eta squared 0.140), whilst paternal activity was negatively associated with child activity (partial Eta squared 0.257) and that girls were more active than boys (partial Eta squared 0.173, all P ≤ .05). These factors combined to explain 42% of the observed variance in weekday child physical activity. Child weekend PA was only associated with maternal PA (partial Eta squared 0.256, P ≤ .05) with no difference in PA by gender. Maternal PA explained 26% of the variation in child PA. The mothers and fathers of the girls in this study took 30% and 27% more steps per day than the parents of the boys. This may partially explain the observed higher level of female PA.
Conclusion: These results suggest that different factors influence the PA levels of young children during weekdays compared to the weekend, and that maternal PA is likely to be a key determinate of PA in young children at all stages of the week. However, a large proportion of the variance in PA in young children remains unexplained.

DETECTION OF SHORT WALKING EPISODES IN DAILY LIFE BY MEANS OF A NEW ACCELEROMETRIC APPROACH

Terrier, P., Chalokh, M. Schutz, Y.

University of Lausanne, Switzerland , Switzerland

The energy expenditure induced by spontaneous non-structured activities called Non-Exercise Activity Thermogenesis (NEAT) has been shown to play a key role in the regulation of energy balance. NEAT comprises fidgeting, posture changes, short discontinuous walking bouts and static work. Among these activities, walking is an energy demanding exercise and it may constitute a major component of NEAT.
The aim of the present work was to objectively assess walking activities during daily life with a new method using a motion sensor optimized for walking recognition. The technical challenge was to offer increased specificity, sensitivity and accuracy as compared to classical pedometers/accelerometers.
The tri-axial accelerometer was a Leica Vectronix DMC-SX Digital Magnetic Compass. The unit contains 3 accelerometers and signal processing capabilities: the acceleration is measured in a -2 G to +2G range, and sampled at 60Hz with signed 16bits words, for an accuracy of 0.003G. This small sensor (31x33x13.5mm, 28g) was attached to the low back (L4-L5). A programmable logger (prototype) received the digital acceleration data through a serial interface, compressed them "on the fly", and stored the file onto a Compact Flash data card. This device (20x10x5cm, 100g) was worn on the side, attached with a belt.
In order to specifically track walking activities, the accelerometric signals were analyzed to detect the repetitive acceleration pattern of the gait. Hence, the duration and frequency of walking episodes were specifically assessed. The hypothesis was that a substantial part of the daily walking activities was due to short walking "bouts".
The physical activity level of 29 healthy young subjects with variable Body Mass Index (18-41kg/m2) was assessed during their habitual occupation typically over 8 hours. The results showed that during daytime the subjects performed 151±77 (SD) very short walking episodes (<60s) of an average duration of 11second each (6-17s). The subjects spent 18.7% of their day-time in walking activities. Long duration walking (>60s) accounted for about two third of the walking duration, whereas short walking episodes (<60s) accounted for about one third (respectively 12.9 and 5.8% of the total time).
Although intermittent short walks are rarely considered in the analysis of daily walking pattern, we found that they were spontaneously performed by all the subjects. Because intermittent short walking bouts are relatively high energy demanding movement among sedentary activities, they should not be neglected, due to their repetitive pattern, for a more appropriate assessment of total daily physical activity and energy expenditure.
The use of new objective methods to assess physical activity level by taking into account movements performed during everyday activities (including short walking bouts) is probably a new opening area to a better understanding of energy balance dysfunction leading to obesity.

OP2-14 Motor Learning 2/2 - "Turin DE"

CONTEXTUAL-INTERFERENCE-APPROACH VERSUS DIFFERENTIAL-LEARNING-APPROACH

Birklbauer, J., Haudum, A., Müller, E.

University of Salzburg, Austria

Shea and Morgan demonstrated that in motor learning performance improved more in a randomized order of exer-cises than in a blocked one (Contextual-Interference-Effect, CI). Schöllhorn developed the thesis of differential learning, based on the coordination dynamics approach. The aim of this study is to examine the efficiency of random-ized variable practicing on the one side and of variable practicing according to differential learning on the other side. This paper should prove that not only the choice of exercises, but also their methodically guided order are crucial for success in learning.
The skills to be learned were slalom dribbling and target shooting in indoor hockey. 57 sport students participated in the study. All subjects were parallelized into 4 groups: Control (CG, n=14), CI (n=15), Randomized differential learn-ing (RD, n=14) and Goal-oriented differential learning (GD, n=14). Each of the 3 intervention groups performed 12 training units within 5 weeks. The CI-group had to complete 5 x 5 randomized target shooting and 4 x 4 dribbling exercises per training unit. In the other two intervention groups no exercise was repeated. Both differential learning groups performed the same exercises. The RD had to execute exercises in random order, while those in the GD were arranged according to certain methodical criteria. The pretest (accuracy in target shots; movement time in slalom dribbling) was repeated immediately, 3 weeks, and 6 months after the training intervention.
4 X 4 ANOVA showed significant interaction for slalom dribbling, $F(9,147)=6.01$, $p<0.001$, $eta2=0.27$. All groups except CG improved significantly ($p<0.01$) by an average of 23.2% (±10.4%) in their performance after training and by another 3.7% (±7.2%) after 6 months. No significant difference between the 3 training methods was revealed. The results for target shooting were similar to the ones in slalom dribbling. But unlike the performance in cyclic dribbling, the accuracy in target shooting of the RD group between the first and the second retention test decreased by 29.4% (±55.9%), whereas the GD and CI groups improved their accuracy by an average of 6.3% (±27.7%). During this last retention interval, changes in motor behavior differed between RD and GD, RD and CI ($p>0.05$), while GD and CI did not ($p>0.05$).

The results cannot show differential learning's supremacy to randomized variable practice. The comparison of the two types of differential learning did not indicate significantly different performance improvements, but both groups showed significantly differing retention performances in the long term interval. It is remarkable that the choice of exercises for both methods was identical. Since the only difference was the order of exercises, great importance should be attached to the goal-directed use of exercises, in consideration of a temporally persisting change of motor behavior.

ERRORLESS LEARNING AND TRANSFER TO NOVEL TASK VARIATIONS: A SWITCH FROM IMPLICIT TO EXPLICIT CONTROL?

Maxwell, J.P., Masters, R.S., Lam, G.

University of Hong Kong, Hong Kong

Maxwell, et al (2001) examined the role of errors in the implicit acquisition of motor skills. They reported beneficial effects for settings that reduced error execution during acquisition of a golf putting skill. Specifically, relative to training that involved a high rate of error committal, errorless learning reduced performance costs associated with imposition of a cognitively demanding secondary task load, and optimised performance during retention and novel distance transfer tests. However, previous research has uniformly demonstrated poor transfer to novel task variations for errorless learners, relative to discovery learning (e.g. Prather, 1971; Singer, 1977). Maxwell et al. suggest that previous results are confounded by the presence of artificial movement controls (e.g. physical restraints) that critically alter task parameters when removed. The present experiment examined the effects of transfer from a flat to sloped putting surface following errorless training that involved no artificial change in movement constraints during the transfer test. It was hypothesised that the performance of errorless learners would remain superior to that of errorful learners. The effects of secondary task load were also examined to confirm Maxwell et al's previous finding of robust performance for errorless learners, but not for errorful learners. A 400 trial learning phase, in which two groups (Errorless and Errorful) performed a putting task on a flat artificial grass surface at varying distances from the hole, was followed by a 50 trial retention test and a novel task (sloped surface) transfer test. The novel transfer test was followed by a second 50 trial retention test and a 50 trial secondary task transfer test, both performed on the flat surface. The performance of the Errorless group was uniformly superior to that of the Errorful group in the testing phase. In addition, the Errorless group suffered a smaller drop in performance during the novel task transfer test. However, both groups suffered an equivalent drop in performance when required to perform the secondary task transfer test, contrary to previous findings. The data support the novel task transfer hypothesis, but suggest that altering task requirements may cause the performer to adapt their cognitive strategy from a largely implicit to an explicit mode in order to overcome performance decrements. Continued employment of explicit cognitive activity may explain the subsequent inability of the Errorless group to cope with the secondary task load.

NEUROMUSCULAR TRAINING MAY DECREASE THE RISK OF ACL-INJURY DURING SIDECUTTING MANOEUVRES BY INCREASING MEDIAL HAMSTRING ACTIVITY

Zebis, M.K., Bencke, J., Magnusson, S.P., Døssing, S., Kjær, M., Aagaard, P.

Bispebjerg Hospital, Denmark

Introduction

In the recent years increasing focus has been directed on the prevention of anterior cruciate ligament injury (ACL-injury). Dynamic lower extremity valgus has been identified to predict ACL-injury risk in female athletes (Hewett et al. 2004). Different neuromuscular training regimes have been shown to effectively decrease the incidence of ACL-injuries in female sports like handball and football. However, little is known about the specific neuromuscular adaptation mechanisms elicited by these types of neuromuscular training.

In the present study we investigated the neural pre-activation pattern of the hamstring and quadriceps muscles, in a movement associated with non-contact ACL-injury, before and after the implementation of neuromuscular training.

Material and methods

A neuromuscular training program (Myklebust et al. 2003) was implemented (1/wk) during a full handball season (47 wk). Neuromuscular activity (EMG; biceps femoris, semitendinosus, vastus lateralis and medialis, rectus femoris) was recorded during a sidecutting manoeuvre in 8 female elite handball players pre and post the intervention period. Neuromuscular activity in the prelanding phase was obtained in time intervals 10 and 50 ms prior to foot strike on a force plate (AMTI). Neuromuscular activity was normalized to the peak EMG amplitude recorded during the standardized sidecutting manoeuvre.

Results

Pre-activation EMG of the medial hamstring was significantly altered after the period of neuromuscular training. Pre-activation of the semitendinosus in the pre-landing phase increased from 32 ± 11% to 46 ± 18% in time the 10 ms time interval before foot strike ($p<0.05$). No changes in neuromuscular activity were observed for any of the other examined muscles.

Conclusions

During rapid movements like sidecutting, which involves substantial eccentric quadriceps forces, substantial neural pre-activation of the hamstrings just prior to ground contact may be highly important in the control and dampening of ACL shear forces at toe down. Contraction of the medial hamstring muscle is important to medially compress the knee joint and thereby limit the risk of excessive valgus movement. It therefore seems important for dynamic knee joint stabilization that the ratio between semitendinosus and biceps femoris activity is optimally 'tuned' to avoid excessive valgus movement, and to control rotation of the tibia. The observed increase in semitendinosus activity and the unchanged activity of biceps femoris in the present study may result in more compression of the medial knee joint and greater control of tibial rotation just prior to landing, thereby reducing the risk of dynamic valgus, and the risk of ACL-injury.

ARE WEIGHT AND SIZE OF THE FOOTBALL CRUCIAL FOR DEVELOPING GOOD KICKING SKILL?

Loftesnes, J.M., Buvik, P., Hansen, R.V.

Sogn og Fjordane University College, Sogndal, Norway

Children are more able to develop active play and get a better understanding of the football game as such if they have a high mastery of the relevant properties of the ball (Araūjo, 2004). These properties could be crucial for the acquisition of a good kicking action, but the study of how such a skill is acquired has not been extensively investigated (Haywood and Getchell, 2001). Both theory and the associated physical laws are discussed in this research in order to underline the importance of understanding the way ball size influences the development of the ability to kick a football. As novices children tend to all go for the ball rather than maintaining an appropriate position on the pitch, with the result that it looks like bees! Such behaviour could be due to the use of balls that are too large and heavy. When using a ball that is too heavy, inappropriate kicking actions may be acquired, leading to a static, and not a dynamical kick that is needed to kick with both temporal and spatial precision.

Methods

Forty Norwegian children served as subjects, with a mean± (SD age of 8.5± 0.8 yr). They were tested on a National Football Association test, kicking the ball 12 m in the air and hitting a 5x5 m square. Three different balls were used: internationally approved 4" and 3" footballs, and a beach volleyball.

Results

The children hit the square significantly more often with the beach volleyball than the other two balls ($p<0.01$). The 3" football was also better than the 4" football ($p<0.01$).

Discussion

In light of the results, we argue that the ball used for inexperienced football players of age 8-9 years, should be lighter than the normal 4" ball, but not smaller. This will enable such players to acquire a more appropriate kicking action by ensuring the ankle is not locked in order to achieve a successful outcome. We also argue that in using the beach volleyball the play becomes more open, and that the children will be able to make both short and long passes with better spatial and temporal precision.

TRUNK STABILITY TRAINING IN CHRONIC LUMBAGO

Sarabon, N., Palma, P., Strojnik, V.

Faculty of Sport, University of Ljubljana & Institute of Clinical Neurophysiology, MC Ljubljana, Slovenia

Introduction

Low back pain is one of the most common orthopedic problems. Etiology can be very diverse, if only the patients share many deficiencies of their locomotor system. The aim of our study was to check the effectiveness of the sensory-motor trunk stability training in chronic low back pain patients.

Methods and Materials

10 subjects (3♂, 6♀; 48+8 yrs) volunteered for the study. After the initial measurements had been done, the experimental group was exposed to 8-week trunk stability training. Training sessions supervised by a professional staff have been carried out two times a week, for 50 to 75 min (10 min warm-up, 35 to 60 min stability training, and 5 min warm down). The subjects performed circuit training that consisted of 8 stations. Intensity as well as quantity of the exercises has been progressively modified. To test the training effects on flexibility, strength, reflex stabilization of the trunk, and individual self satisfaction, final measurements were done using the same diagnostic battery as at the beginning. We measured maximal isometric force (trunk flexion and lateral flexion, hip flexion and extension), flexibility (hip flexion and extension, Schober thoracic and lumbar, lateral flexion), m. multifidus reaction time to sudden external disturbance, Oswestry questionnaire, visual pain scale. Paired t-tests have been carried out in order to test statistical significance of the differences.

Results, Discussion and Conclusion

The general satisfaction of the subjects with the exercise program was very high (average 8 out of 10). After the training intervention, Oswestry total as well as pain level decreased significantly (7.0+2.1 to 4.0+2.5; P<.01 and 3.8+0.7 to 2.3+0.5; P<.01 respectively). The strength tests showed significant effects of the training program on trunk flexors and lateral flexors (41.7+15.1%; P<.001 and 33.3+25.2%; P<.05 respectively) while no significant changes were identified for the strength of hip muscles. Inversely, the flexibility tests indicated improved maximal range of motion for hip flexion and extension (10.4+12.8%; P<.05 and 34.4+26.1%; P<.01 respectively), while trunk flexibility remained unchanged. Multifidus reaction times to sudden perturbation was significantly decreased (98+12 ms to 87+14 ms; P<.05) after the trunk stability training.

Our data suggest that a changed neuro-muscular control in patients with chronic lower back pain can be affected by the use of systematic trunk stability training. Combining both basic situations that require trunk stability ("legs-to-center" and "arms-to-center") is a promising kinesioterapheutic approach.

MUSCLE STRENGTH AND FUNCTIONAL PERFORMANCE IN PERSONS WITH HEMIPARESIS: EFFECT OF HEAVY-LOAD RESISTANCE TRAINING

Andersen, L.L., Zeeman, P., Jørgensen, J., Andersen, J.L., Kjær, M.

Institute of Sports Medicine Copenhagen, Denmark

Stroke is the third leading cause of disability in the Western world. Hemiparesis is common after stroke, affecting more than 40 % of the stroke survivors chronically. Muscle strength is reduced and the gait cycle is altered causing walking speed to be drastically decreased. We investigated the effect of rehabilitation training consisting of heavy-load strength training combined with treadmill training on muscle strength and walking speed. Methods: 13 hemiparetic, poststroke subjects participated in the study (47±13 yrs, 180±6 cm, 86±7 kg). Training was performed for 12 wks with 5 training sessions (1-1½ hour) each week. Heavy-load strength training was performed only with the affected side of the body in resistance training machines that provided bio-feedback with regard to power-output and ROM (leg press, knee extension and knee flexion, 3-4 sets/exercise, 4-12 RM). Treadmill training was performed with partial bodyweight support to allow a progressive increase in walking speed. Before and after the training period eccentric (30 degr/s) and concentric isokinetic strength (30, 240 degr/s) for the quadriceps and hamstring muscles was measured in a KinCom dynamometer, with simultaneous recording of EMG amplitude in the agonist and antagonist muscles. Explosive muscle strength was measured as isometric rate of force development (RFD). Maximal walking speed over a 10 m distance and average walking speed over a 6 min period were also determined. Results: Before the training period all parameters of strength was markedly reduced in the affected side compared to the non-affected side, especially in the hamstrings (slow isokinetic strength: hamstrings 0-20% and quadriceps 56-69 % of the non-affected side). After the training period isokinetic strength increased in the quadriceps (e.g. slow concentric: from 92±45 to 127±52 Nm, $P<0.01$), with a similar increase in EMG amplitude. However, no significant change was seen in the hamstring muscles (slow concentric strength: from 21±15 to 29±10 Nm, $P>0.05$). RFD increased in the quadriceps from 277±176 to 329±170 Nm/s, $P<0.05$. Maximal and average walking speed increased 53 and 48 %. Discussion: In the present group of hemiparetic persons strength training combined with treadmill training increased muscle strength as well as walking speed. The relative increases in maximal and explosive strength in the quadriceps muscle were comparable to those previously observed in healthy persons undergoing strength training, which indicates that trainability of the quadriceps is not impaired. However, in the hamstring muscles where a greater pre-training deficit was observed no significant change occurred in response to the training intervention. This could indicate that a certain threshold of voluntary muscle activation is necessary to induce effective gains in response to training. The observed increase in walking speed is an important finding, since this may enhance many daily living functions in persons with hemiparesis

INTRAMENISCAL TEARS IN SPORTS MEDICINE - COMPARISON OF PRE-OPERATIVE CLINICAL AND MRI FINDINGS WITH ARTHROSCOPIC FINDINGS AND RELATIONSHIP TO THE CLINICAL OUTCOME AFTER ARTHROSCOPY –

Baraliakos, X., Meyer, O., Heikenfeld, R., Follrichs, E., Godolias, G.

St. Anna Hospital Herne, Germany

Introduction: Intrameniscal tears occur mostly in the medial meniscus with an incidence of about 3%. While a meniscal tear Grade III (with damage of the meniscal surface) in combination with the localization of the damage (meniscus basis of periphery) is an absolute indication for meniscectomy, intrameniscal tears are difficult to manage. This is also the case, if preoperative MRI shows suspicious signs of meniscal damage and clinical symptoms are also uncertain, but indicating meniscal damage.

Objectives: This study presents the results of our experience with the pre- and intraoperative management of intrameniscal tears in athletes and discusses these results with data from pre-operative MRI and postoperative clinical follow-up examinations in athletes where meniscectomy was performed in comparison to athletes where a decision against meniscectomy was failed.

Material and Methods: Overall, 37 young athletes (mean age 19.7 years, range: 15-27 years) were included in this study. All of them had a positive history of knee injury and also positive clinical findings indicating a meniscal damage, as also positive MRI examinations with signs of intrameniscal lesions. All patients underwent arthroscopic surgery because of their symptoms and positive preoperative MRI.

Results: In 31/37 athletes (84%), the preoperative diagnosis of intrameniscal tear was confirmed during arthroscopy. On the other hand, 4/37 (11%) showed a meniscal tear Grade III and in 2/37 patients (5%) we did not find any pathological finding during arthroscopy. Meniscectomy was only performed in patients with a meniscal tear Grade III. All 31 patients with intrameniscal tears were re-examined after a postoperative follow-up period of 4 months (range 2 – 7 months). During this period, intensive conservative care was performed to all patients. Loading of the knee could be performed shortly after the arthroscopy and sports activity was also possible with a very short time period (mean 14 days). At follow-up 20/31 (65%) athletes reported significant improvement of their clinical symptoms, as compared to the individual preoperative situation. However, 11/31 athletes had to be re-treated by arthroscopic meniscectomy due to remaining clinical symptoms. Finally, 10/11 athletes (91%) recovered successfully short time after meniscectomy, the remaining patient complained recurrent knee swelling, which recovered after intensive physiotherapy.

Conclusion: Intrameniscal lesions are a challenge for failing the correct treatment decision in arthroscopic surgery of the knee in sports medicine. Although many of the athletes can benefit by conservative treatment, some may require arthroscopic meniscectomy. Thus, decision for arthroscopy must be failed only after combination of excellent clinical examination, positive MRI signs preoperatively and failure of conservative treatment.

THE ROLE OF CONFIDENCE IN REHABILITATION FROM ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

Waters, A., Hardy, L., Gleeson, N.P., Rees, D.

University of Wales Bangor, United Kingdom

Whilst confidence has been identified as a potentially important factor in sports injury research, very little is known about its precise role within the athletic injury experience. For surgical treatments (such as anterior cruciate ligament (ACL) reconstruction) that involve considerable investment of time, effort, and money, establishing whether or not a significant relationship exists between confidence and recovery rates could have important implications for both injured athletes and medical teams. The aim of this study was to investigate whether certain facets of confidence early in the rehabilitation period following ACL reconstruction, could predict physical recovery later on. A non-experimental field study design was employed. Participants were 30 athletes (24 male & 6 female) with a mean age of 29.3 (SD = 8.4), of varying abilities from a wide range of sports undergoing ACL reconstruction. Six facets of confidence specific to injury rehabilition were measured using the Self-Evaluation Inventory. Measures of neuromuscular and musculoskeletal factors, including: peak force (PF), rate of force development (RFD), electromechanical delay (EMD) and joint laxity were taken. The PF, EMD & RFD performance measures

were assessed on both the knee extensors (quadriceps) and knee flexors (hamstrings). Performance Profiles (Butler & Hardy, 1992) were employed to measure self perceived recovery rates. Data for all measures was collected at pre-surgery, and 6, 12 and 24 weeks post-surgery. Results analysed using quadratic regression analysis demonstrated support for quadratic relationships between certain facets of confidence and physical outcome measures. Specifically, higher confidence in the body, higher confidence in the injured body part, less fear of re-injury at re-entry into sport and smaller lossses of self-esteem were significantly related to better susequent electromechanical delay and rate of force development outcomes, as well as self-perceived recovery rates. Inspection of the scatterplots indicated that these quadratic effects were plateau effects rather than inverted 'U' effects. The results provide some support for a positive relationship between confidence and recovery progress. They show no evidence of over-confidence effects. The findings suggest that interventions designed to augment certain facets of confidence in patients rehabilitating from ACL reconstruction might have a favourable effect on rehabilitation outcomes.

ADAPTATION OF THE MUSCLE TENDON JUNCTION TO EXERCISE: REACTIONS OF THE COLLAGEN FIBRILS

Michna, H., Selg, P.J., Kühnel, W.

Institute of Public Health Research, Germany

Introduction

The collagen fibrils of the muscle tendon junction substantially contribute to the fact that a rupture between both tissues of the (muscle tendon) junction never appears: there is not one clinical report indicating a rupture of the muscle-tendon junction. Therefore, we set out to analyze the adaptation of the muscle tendon junction to exercise in an experimental model using high power transmission electron microscopy and stereological procedures. The collagen fibrils of the tendon play a significant functional role in transferring the stress to the muscle. Understanding the functional properties of the tendon it seems expedient to apply some of the concepts of material science to elucidate the adaptation of the muscle tendon junction. In materials the mechanical properties of the components and their geometric organization determine its characteristics.

Methods

Five segments of the tendon in the area of the muscle tendon junction of the flexor digitorum longus muscle were taken from the hind limbs, from mice of control groups (n= 20) and "exercised" mice (n=20). "Exercised" mice were trained in running wheels over a treatment periods up to one, thee, five and ten weeks. The tissues were prepared for electron microscopy (using a Zeiss EM10) and morphometry (using an IBAS II system)

Results

The principal structural features of the muscle tendon junction of exercised and controlled mice are indistinguishable: the plasmalemma of the muscle fiber is folded into fingerlike extensions and invaginations; and these folds increase the interfacial area between the tendon and the muscle fiber. The differences of trained and non-trained muscle tendon junctions can only be revealed by use of morphometrical procedures. The morphometric analysis of the collagen fibrils indicate that exercise stimulates the growth of thin collagen fibrils in the range of forty nm and thick collagen fibrils in the range of 250 nm, displaying a bimodal distribution pattern of the collagen fibril diameters. Growth of extremely thin and thick collagen fibrils enhances the volume fraction of collagen fibrils in up to 10 to 20% with a raise of the mean collagen fibril diameter up to 20%. Ultrastructural analysis of the muscle tendon interface indicate that, in exercised animals, the "interfacial ratio" (Trotter and Baca, 87) (the ratio of the surface area of force – transmitting membrane to the cross-sectional areal force – generating tendon fibrils) is significantly enhanced up to 30%.

Conclusion

It becomes evident, that the tendon tissue is not a "bradytrophic" tissue but that is lively reacting to functional loading. We present data indicating the pathways in which collagen fibrils responde to functional loading. We will also present data indicating, that collagen fibrils adapt dynamically to the loading regime they experience.

TRUTH AND SPORT SCIENCE RESEARCH: PROBLEMS WITH THE RELATIVIST TURN

Bailey, R.

Roehampton University, United Kingdom

Truth has had a hard time in recent social scientific writing, and this has started to be felt in some work in the sport and exercise sciences. The rise of relativism, or the view that conceptions of truth are not absolute but are relative to the persons or groups holding them, can be witnessed in the work of those influenced by post-modernism, radical social constructivism, pragmatism, and other schools of thought. Although such relativism reveals itself in many different ways, certain characteristics are common, which deserve questioning. It is suggested that a fully-fledged relativistic stance towards research is inherently self-contradictory, and is harmful to the research enterprise. A partial solution to the problems that relativists raise about the nature and growth of knowledge is suggested that seeks to balance a recognition that the truth is hard to come by, but matters, nonetheless.

THE TRUTH ABOUT OBESITY AND CHRONIC DISEASE: THE MEDICO-DARWINIAN PARADIGM

Batterham, A.

University of Teesside, United Kingdom

"Nothing in biology makes sense except in the light of evolution".
(Theodosius Dobzhansky).

In this talk, I present a thumbnail sketch of the Darwinian Medicine approach to health promotion research and practice, with an emphasis on obesity and the chronic 'diseases of civilization'. Historically, the limited impact of health promotion may relate to four key factors. First, there has been a lack of an overarching paradigm to guide interventions. Secondly, the target audience often perceives health messages as controlling and coercive. Thirdly, contradictory research findings and health messages have affected public confidence in health professionals. Fourthly, individual-level interventions have been over emphasised. Adoption of an evolutionary biology perspective may help surmount these barriers.

The central premise of the Darwinian Medicine approach to understanding the aetiology of chronic disease is a mismatch between our Stone-Age genes and the modern environment. This argument is founded on a key principle of natural selection applicable to human health - that genes are selected in particular contexts and consequently that our genes function optimally in the environment and lifestyle to which we have been most exposed, that is, a hunter-gatherer existence. Evidence suggests that the current human genome has remained essentially unchanged since the Late Palaeolithic era, and was selected in an environment in which a high level of physical activity was tightly coupled to food procurement. In industrialised societies physical activity is no longer obligatory, as pleasant tasting, energy dense foods are widely available. In short, food is plentiful and physical activity is optional.

Apparently, the prevalence of obesity and related conditions in developed countries has increased rapidly in just a few decades. Using Darwin's Razor, an explanation for this disturbing trend is that humans are not well adapted to modern environments. In brief, we are hard-wired to prefer sweet, salty, and energy dense foods, and to curtail physical activity whenever possible to conserve energy. These behaviours were adaptive in the Stone Age but now render many susceptible people with thrifty genes vulnerable to obesity and its pathological consequences. Humans are adapted to cycles of rest/ feast and physical activity/ famine, but this process has been interrupted. Today, physical inactivity and poor diet may result in abnormal gene expression and consequent clinical disease.

Evolutionary explanations of chronic disease represent an example of non-deductive reasoning in an 'inference to the best explanation', and a plausible and parsimonious way of accounting for the available data. Conventional health promotion approaches encouraging voluntary health behaviour changes may be doomed to failure – a losing battle against our own biology. The Darwinian Medicine paradigm may inform a research agenda and the development of more effective, translatable interventions.

GENDER DIFFERENCES IN MUSCLE METABOLISM DURING EXERCISE

Kiens, B.

Copenhagen Muscle research Centre, Institute of Sport and Exercise Science, University of Copenhagen, Denmark

From the literature it seems reasonable to conclude that there is a small gender difference in relation to fat oxidation during submaximal exercise in the favour of a higher relative fat oxidation in women than men.

The mechanism(s) behind the higher relative fat oxidation seen during exercise in women compared to men is not known. Recent findings suggest that an improved muscle cellular energy balance during exercise in women than men, plays an important role (Roepstorff et al, 2006).

Besides a gender difference in relative fat oxidation during exercise, there seems also to be gender differences in substrate utilisation. Thus females use intramuscular located triacylglycerol to a larger extent than males.

It could be speculated whether the differences in energy substrate utilisation during exercise between gender could play a role in nutritional recommendations for athletes as well as for the population

Roepstorff, C.,Thiele,M.,Hillig,T.,Pilegaard,H.,Richter,EA.,Wojtaszewski,J and Kiens, B. J Physiol, April,2006. Epub Ahead of print.

QUANTITY OF CARBOHYDRATE INGESTED AFFECTS EXOGENOUS AND ENDOGENOUS CARBOHYDRATE UTILIZATION DURING EXERCISE IN TRAINED WOMEN

Wallis, G.A., Yeo, S., Blannin, A., Jeukendrup, A.E.

The University of Birmingham, United Kingdom

The effect of different quantities of carbohydrate (CHO) intake on CHO metabolism during prolonged exercise was examined in endurance trained females. On four occasions, 8 females performed 120 min cycling at ~60% maximal oxygen uptake with ingestion of beverages containing low (LOW, 0.5 g/min), moderate (MOD, 1.0 g/min) and high (HIGH, 1.5 g/min) amounts of CHO, or water only (WAT). Test solutions contained trace amounts of [U-13C] glucose. Indirect calorimetry combined with measurement of expired 13CO2 and plasma 13C enrichment enabled calculation of exogenous CHO, liver-derived glucose and muscle glycogen oxidation during the last 30 min of exercise. The highest rates of exogenous CHO oxidation were observed in MOD, with no further increases in HIGH (peak rates of 0.33±0.02, 0.50±0.03 and 0.48±0.05 g/min for LOW, MOD and HIGH respectively; $P<0.05$ for LOW vs. MOD and HIGH). Endogenous CHO oxidation was lowest in MOD (0.99±0.06, 0.82±0.08, 0.70±0.07 and 0.89±0.09 g/min; $P<0.05$ for MOD vs. all other trials). Compared to WAT, CHO ingestion reduced liver glucose oxidation during exercise by ~30% ($P<0.05$ for WAT vs. all CHO). Differential rates of

muscle glycogen oxidation were observed with different CHO doses (0.57±0.07, 0.53±0.08, 0.41±0.07 and 0.60±0.09 g/min for WAT, LOW, MOD and HIGH respectively; P<0.05 for MOD vs. HIGH). In endurance trained women, the highest rates of exogenous CHO oxidation and greatest endogenous CHO sparing was observed when CHO was ingested at moderate rates (1.0 g/min, 60 g/h) during exercise.

IS2-18 Physical activity and the elderly - "St. Moritz"

CHANGES OF PHYSICAL ACTIVITY HABITS AMONG ELDERLY POPULATION

Schena, F., Lanza, M.

University of Trento, Italy

Exercise prescription represents a main step in the strategy to increase the amount of daily physical activity in order to improve the life quality and reduce the chronic pathologies in elderly people. The individualised progression of ageing process and the need to consider the elderly motivation and expectation related to exercise reinforce the role of a correct prescription to reach the higher success rate in promoting physical exercise among aged people. The optimal prescription for an elderly individual is determined by an proper evaluation of: 1- Subject goal(s) The final targets to reach with exercise; 2- Physical Capacity (determined by applying an appropriate physiological and performance evaluation); 3- Psychological profile (the individual attitude or fears towards exercise); 4- Social environment helps and barriers (probably the most important in reaching the changing in life style). Following medical tradition, exercise programs for elderly up to ten years ago was generally defined on the basis of a reduction in intensity in order to increased safety without any control on the efficacy of the intervention. Recently an increasing amount of evidences coming from the literature strongly suggested that elderly can exercise to a moderate and sometimes also hard intensity and these levels of effort produce the larger positive health effects while the risks remain low. Following these principles also exercise prescription for elderly can take advantage by using these five steps: 1- Appropriate mode(s) of exercise, 2-Intensity, 3-Duration, 4-Frequency, 5- Progression. We apply this strategy to the project "Health is in the Movement" developped in Italy as a model of health promotion through exercise in the elderly, actually involving es more than 7000 individuals aged 60 and more. The project includes actions which are targeted to the whole old people (healthy, diseased, frail) living in communities as well as in nursing homes.

HOW TO ASSESS PHYSICAL ACTIVITY IN ELDERLY ?

Vuillemin, A.

University Henri Poincare, France

There is evidence to suggest that reduced physical activity (PA) plays a major role in age-related decline, particularly in energy expenditure. PA guidelines have emphasized the importance of and the need to promote PA for health throughout life. Accordingly, accurate measures of PA are necessary to study the relationship between PA level and health outcomes in research practice; and to facilitate early initiation of appropriate intervention in clinical practice, thus reducing health problems. Nevertheless, there is a considerable problem to obtain reliable assessment of PA partly due to the difficulties to assess under free-living conditions. Assessing PA is a challenge because of the need to consider many activities of various duration, frequency and intensity that may occur as part of daily life in varying context (transportation, school, occupation, household chores, recreation, and sport). Many instruments are available in the literature but there is no single current instrument able to assess all aspects of PA. Each instrument has its own utility and limitations and some may be complementary. Simple field techniques for assessing usual PA are difficult to develop. The greatest obstacle to validating field methods of assessing usual PA is the lack of adequate comparison criteria. Doubly labelled water (DLW) is considered as a gold standard for validating methods to measure energy expenditure (total daily or PA-related energy expenditure) but it doesn't provide information on PA patterns. PA can also be objectively measured by wearable monitors that can record heart rate and/or movement. Accelerometer sensors are currently used mainly in a research setting; however, they can be used in clinical practice but they don't capture the type and context of activity (e.g., occupation, transportation, household, recreation). At present, self- or interview-administered questionnaires are also widely used, all the more in large population studies (surveillance, risk factor epidemiology). One of the limitations of these questionnaires is the definition of PA and the dimensions covered. Compared to DLW, PA questionnaire and accelerometry may significantly underestimate free-living PA in older adults. For example, Minnesota Leisure Time PA recall and Caltrac uniaxial accelerometer appear to significantly underestimate (by 50-55%) free-living PA in older adults. Inability of recall methods and accelerometers to detect every movement may partially contribute to this underestimation. The use of recall questionnaire as a proxy measure of individual energy expenditure is limited in older women and men. Despite their limitations, recall questionnaire are relatively easy to administer, relatively inexpensive, acceptable for the subject and of interest when studying the influence of lifelong physical activity.

CHALLENGES IN IMPLEMENTATION OF PHYSICAL ACTIVITY PROGRAMS FOR THE ELDERLY

Hopman-Rock, M.

TNO Quality of Life, Netherlands

During the last 10 years a lot of scientific effort has been put into the development and evaluation of effective physical activity programmes for older adults. Many programmes have been launched, but less is known about their fate. What happened to them after their introduction? Did they reach the intended public? What were the enabling factors and what were the barriers?. In this presentation it is explained why innovation processes often fail, why it is important to carry out research in this area, and what we can learn of earlier experiences in introduction of physical activity programmes for the elderly. We call this the 'Implementation challenge'.

First, attention is paid to the definition of some widely used concepts and what is known about the implementation challenge, using the review by Fleuren et al. After that, the pathway from basic research to implementation is viewed from the perspective of the researcher and from the perspective of the practitioner, illustrated with examples of own research.

- The researcher's perspective

A framework for evaluating health (education) programmes was proposed by Nutbeam et al., including:

- Basic research and theory
- Experimental studies (especially Randomised Controlled Trial)
- Demonstration studies (especially Community Intervention Trial)
- Dissemination studies (especially Monitoring)
- Operational management (Implementation)
- The practitioner's perspective

The practitioner works "opposite" the researcher. He or she may use the usual programmes in everyday practice and may be unwilling to change to a new programme. Orlandi et al. identified this as a potential problem for the dissemination and implementation of innovations. They proposed the "intermediary linkage system" as an efficient method to ensure the transfer of innovations from the source to the users. The idea is that researchers and practitioners exchange information and communicate with each other from the start of an innovative project onwards. In this way collaborating partners can provide each other with training, technical support, and feedback.

Finally, some basic principles of the diffusion theory of Rogers are given and the RE-AIM framework of Glasgow is introduced to support research on innovation processes.

SKEET SHOOTING ATHLETES' PSYCHOLOGICAL PREPARATION: AIMS AND CONTENT OF THEIR MENTAL IMAGERY USE

Psychountaki, M.

University of Athens, Greece

The mental imagery is an intervention strategy which is usually included in psychological programs for athletes. Applied sport psychologists suggest that imagery use -combined or not with other strategies- can influence athletes in a variety of ways. For example, in improving psychological skills (e.g., self-confidence, self-control, coping with stress etc.), as well as in improving the techniques and tactics of the sport and the athletes' performance (Moritz et al., 1996; Orlick, 1990; Suinn, 1996; Vadocz et al., 1997).

The purpose of this presentation is to describe indicative applications of mental imagery focusing on the aim, the content, the phase in which they were applied and the way they were evaluated. More specifically, the presentation includes the application of mental imagery in the case of four athletes of the Cyprus National Team (2 male athletes aged 27 and 36 and 2 female athletes aged 22 and 31).

For the formation of the mental imagery programs, the following were taken into consideration: (a) the psychological preparation phase (training and application phase), (b) the previous experience (primary or high) in the psychological preparation program, (c) the physical preparation phase (pre-competitive and competitive), and (d) the needs of each individual athlete. The presentation will provide examples of how the content of mental imagery is adapted to the intervention goals for each individual athlete.

After the teaching and training in mental imagery, each athlete used a specific program once or twice a day for 10 – 15 minutes. The mental imagery training took place before, during or after the physical training, or at another moment during the day. Each practice was evaluated by the athletes by filling in a relative evaluation form so that they would get aware of their ability for visualization.

Psychological service to skeet shooting athletes was evaluated at the end of each competitive year by taking interviews from the athletes. It was also informally evaluated by the officials of the team and by the fact that more and more athletes from the same federation every year asked for psychological support. Throughout the last six years, in which the program is in use, the athletes were able to achieve their goals: they got a lot of medals in European, World or Commonwealth competitions and one of them has equaled the world record. The program is still in use and has been planned to last until the 2008 Olympic Games.

PERFORMANCE ENHANCEMENT ISSUES IN SPORT PSYCHOLOGY CONSULTING: SEVENTEEN CASES SUMMARY

Johnson, U., Stambulova, N.

Centre for Sport and Health Research, Sweden

Address of Institution(s): Centre for Sport and Health Research, Halmstad University, Sweden

The study aimed at cross-case comparison and synthesis of final reports about implementation of individualized intervention programs. Clients were 17 Swedish competitive athletes (11 females and 6 males) between 14 and 35 years old, representatives of individual (e.g., boxing, golf, tennis) and team (e.g., soccer, floor ball) sports. Consultants were students under applied sport psychology course at Halmstad University who collected information, identified individual needs, planned and then implemented individualized intervention programs with athlete-clients during six months under supervision of the authors who were the course leaders. Inductive analysis of primary working issues showed that 35 (72%) of them across 17 cases related to performance enhancement and 13 (28%) to career development/transitions. In total performance enhancement issues were among the athletes' dominant individual needs in 16 cases. Five high

order themes representing the performance enhancement category were identified: a) performance-related mental skills, e.g., imagery, self-talk, relaxation, concentration, communication, etc. (40%); b) pre-performance routines (11%); c) self-confidence/efficacy in performance (11%); d) goal setting (9%); e) other, e.g., optimal recovery, self-image, high quality practice, attitude to failure, attributions, etc. (29%). All the consultants used educational approach based on a combination of sport specific and general theoretical frameworks, including e.g., the model of a seven-phase performance enhancement process, the pyramid model of peak performance (In Hardy, Jones & Gould, 1996); the IZOF-model (Hanin, 2000); the psychological preparation for a competition model (Puni, 1969); the sport self-confidence model (Vealey, 2001), but also social cognitive theory and attribution theories. The intervention programs involved education, counselling goal setting sessions, mental training, practical implementation of learned skills, homework, athletes' diary, analysis of video, after performance debriefing. Each consultant developed and employed an individualized assessment map that included both monitoring instruments (e.g., self-made scales, DART-notes, performance results, IZOF-profiles) and also pre-post intervention assessment (e.g., PSPP, TEOQS, Sport Imagery Evaluation form, CSAI-2, individualized self-made scales). Advantages and limitations of the synthesis undertaken will be discussed, and recommendations on how to improve applied sport psychology education will be suggested.

A DEVELOPMENTAL APPROACH TO MENTAL SKILLS TRAINING OF TALENTED YOUNG TENNIS PLAYERS

Wylleman, P., Kahan, N.

Vrije Universiteit Brussel, Belgium

Applied sport psychology literature provides insight into, and descriptions of techniques and approaches for sport psychologists on how to work with elite athletes and players (e.g., Hardy, Jones, & Gould, 1996; Taylor & Wilson, 2005). However, at present little information is available on the needs of, and approaches for mental training with talented young athletes and players. Using a combination of a qualitative and quantitative research methodology, 14 tennis coaches working on a daily basis with 12 to 18 year-old players in the elite tennis school of the Flemish Tennis Federation (VTV) were questioned on (a) their knowledge on mental coaching, (b) the mental functioning of their players in function of age and level of performance, (c) the learning and training of mental techniques with young players, and (d) the role and influence of significant others on the mental functioning of young players. Results showed, amongst others, that the coaches had a good basic knowledge of sport psychological techniques and mental coaching. Furthermore, coaches advocated the need to specify mental training and mental coaching not only in function of specific mental skills and/or attributes (e.g., being motivated and showing effort, being able to concentrate and focus, being able to manage stress) but also in function of specific age-groups. Finally, coaches also indicated that mental training of young players should not only be conducted on a day-to-day basis but also be integrated, as fully as possible, in young players' daily on-court training provided by the coaches themselves rather than via a sport psychologist or mental consultant. On the basis of these data, a developmental framework for teaching, training and using six mental skills (motivation, self-control and self-discipline, self-confidence and mental strength, concentration, relational and communication skills, lifestyle management skills) with tennis players in three age-groups (9-11 yrs, 12-14 yrs, 15-18 yrs) was tentatively formulated. In conclusion, the use of this developmental framework in working with coaches, players and parents in elite-level tennis will be illustrated, while recommendations for further research will be formulated.

TENDON ADAPTATIONS TO LONG-TERM DISUSE

Narici, M.V., Reeves, N., Maganaris, C.N.

Manchester Metropolitan University, United Kingdom

Prolonged disuse is associated with a substantial decline in muscle mass and strength (1). Despite the importance of human tendons for the transmission of force to bones enabling movement, and for their influence on the behaviour of the contractile element in static and dynamic contractions, scanty information existed on their adaptations to prolonged disuse. Recently, however, we had the opportunity to study the changes in tendon mechanical properties in two disuse paradigms, simulated microgravity (long term bed rest, LTBR) and spinal cord injury.

Tendon stiffness, length and cross-sectional area were measured in 18 young healthy males (aged 25-45 years) before and after 90 days of bed rest (ESA LTBR 2001-2 study) (2). Nine subjects performed resistive exercise (BREx group), and nine underwent bed rest only (BR group). Calf raise and leg-press exercises were performed every third day using a gravity-independent flywheel device. Isometric plantar flexions and ultrasound imaging were used to determine the tensile deformation of the gastrocnemius tendon during contraction. At the end of the 90-day bed rest period, in the BR group, tendon stiffness and Young's modulus decreased by 58% (P 0.01), and 57% (P 0.01), respectively. Despite the intensive resistive exercise of the BREx group (4 sets of 7 leg-press, and 4 sets of 14 calf raise exercises), tendon stiffness and Young's modulus decreased by 37% (P 0.01), and 38% (P 0.01), respectively. These findings showed that unloading causes a decrese in tendon stiffness due to a change in tendon material properties, but not in tendon dimensions and that a very large volume of resistive exercises is needed to protect the tendon from disuse.

In the second paradigm of prolonged disuse (3), we compared the mechanical properties of the patellar tendon in six men who were spinal cord-injured (SCI) and eight age-matched, able-bodied men. Measurements were taken by combining dynamometry, electrical stimulation, and ultrasonography. Tendon stiffness and Young's modulus were lower by 77% ($P < 0.01$) and 59% ($P < 0.05$) in the SCI than able-bodied subjects. The cross-sectional area (CSA) of the tendon was 17% smaller ($P < 0.05$) in the SCI subjects, but there was no difference in tendon length between the two groups. These results indicate that paralysis causes substantial deterioration of both structural and material properties of tendon.

Hence the results of these two studies provide evidence of marked alterations in tendon mechanical properties in response to prolonged disuse. These alterations are expected to play a significant role in the loss of muscle function induced by this condition.

INFLUENCE OF EXHAUSTIVE FATIGUE ON STRETCH RESPONSE OF THE MUSCLE-TENDON UNIT

Nicol, C., Ishikawa, M., Cronin, N., Avela, J., Komi, P.V.

1 University of the Mediterranean, France, 2 University of Jyväskylä, Finland, France

Stretch-reflex changes are of particular interest in stretch-shortening cycle (SSC) exercises (such as jumping and running) where stretch loads are high and muscle stiffness must be regulated to meet the external loads (1). However, the exact contribution of stretch-reflexes to force and stiffness regulation needs to be quantified, especially in fatigue situation. As the stretch reflex mechanical response takes place in SSC actions while the muscle is actively stretched, the question arises about the potential fatigue effects on the resistance to stretch of the reflex mechanical response. Based on results with high speed ultrasonography (US) the entire fascicle-tendon interaction must be also considered (2).

Exhaustive SSC exercises are typically associated with ultrastructural muscle damage, delayed onset muscle soreness and with a bi-modal trend of decline of the neuromuscular function that may not recover for a few days. The stretch reflex EMG response follows a bimodal pattern when measured either in passive or active stretching conditions. Although sensitive to SSC fatigue, this does not apply to the contractile tissue (fascicle length and orientation) recovery (4). The follow-up of the mechanical response to fatigue of the muscle-tendon complex is critical as it requires repeated measurements of the Achilles tendon force (ATF).

The present report deals, first, with the reliability and limits of the torque signal to record passive stretch reflex responses of the triceps surae muscle group when compared with the simultaneous optic fiber signal of the ATF. Further comparison was then made with the US signal pre- and post-SSC exercise as well as 2h, 2 days and 7 days later. The reflex test included a series of passive double dorsiflexion stretches ranging from 0.1 to 3.1 rad.s-1 induced by a powerful ankle ergometer. Each mechanical stimulus consisted of 2 identical dorsi-flexions in both amplitude (.05 rad) and velocity. The 2nd stretch timing was varied to occur at different force levels during the contraction and relaxation phases of the reflex mechanical response.

The increase in torque at the slowest velocity followed well the pedal displacement, reflecting the pure passive resistance to stretch. This parameter was not influenced by SSC fatigue. At faster velocities, the magnitude of the reflex mechanical response confirmed the substantial role of the stretch reflex for force and stiffness enhancements. SSC fatigue resulted in a bimodal drop of the mechanical reflex response that recovered in parallel with the EMG response. The active resistance to the 2nd stretch (ARS) was found to be much influenced by the contraction-relaxation state of the muscle. It is noteworthy that this trend was preserved all along the SSC recovery period, and despite a large ARS reduction until day 2.

CURRENT ISSUES IN THE TREATMENT OF TENDINOPATHY

Kjær, M.

Institute of Sports Medicine, Denmark

Treatment of chronic tendon pain has advanced, and attempts include eccentric training, anti-inflammatory drugs and sclerosing tendon vessels. However, mechanisms behind the effect of treatment modalities are far from solved. It is clear that even in injured tendon mechanical loading can increase collagen formation in the Achilles tendon. Furthermore, both concentric and eccentric training results in an upregalation in procollagen type I expression of tendon. Interestingly, the exercise stimulated increase in collagen synthesis is less pronounced in women than in men and furthermore gender differences in tendon fasicle tensile strength exists. This could have implications for a gender specific time frame of training and rehabilitation. During exercise tendon blood flow and metabolism increase, and blockade of prostaglandin release in relation to exercise reduces the blood flow in tendon.

DIFFERENCES IN INTRAMYOCELLULAR LIPIDS UTILIZATION IN THIGH AND CALF MUSCLES DURING ENDURANCE EXERCISE DETERMINED BY 1H-MR SPECTROSCOPIC IMAGING

Zehnder, M., Saillen, P., Kreis, R., Boesch, C., Vermathen, P.

University and Inselspital Berne, Switzerland

Introduction Intramyocellular lipids (IMCL) are important fuels during prolonged moderate-intensity exercise. However, little is known about specific IMCL usage in different muscles. Based on a previous feasibility study [1] we performed muscle specific analyses of metabolite changes in thigh and calf muscles using a standardized exercise protocol.

Methods 8 trained cyclists (6 males, 2 females, 31y, 8 training h/week) and 8 trained male runners (29y, 8 training h/week) exercised 3h on a cycle ergometer (at 49% of max workload = 69% of max heart rate) or on a treadmill (at 52% of max speed = 75% of max heart rate), respectively. The subjects added supplementary 0.75 g fat/kg bw to their diet during 2 days prior to exercise to ensure full IMCL stores. In 2 cyclists right and left thigh as well as in 4 runners right and left calf were examined. IMCL concentration was determined before and after endurance exercise in m. rectus femoris (RF), vastus intermedius (VI), medialis (VM), lateralis (VL1, VL2) and adductor magnus (AM) for the cyclists and in m. soleus (S), gastrocnemius (G), tibialis anterior (TA) and extensor digitorum (ED) for the runners.

MR-spectroscopic-imaging (MRSI) measurements were performed at 1.5T using a 2D-MRSI sequence in transverse orientation. Parameters: TR=1200ms, TE=35ms, Matrix=36×36, FOV=20cm. Processing included spatial zerofilling, lipid-extrapolation, receive profile correction and spectral fitting using TDFDFIT.

MRSI voxels were assigned to specific muscles using image segmentation and their metabolite content subsequently averaged to yield one value for each muscle and subject. Bone-marrow lipid served as reference for quantification.

Results a) a good correlation of IMCL before and after exercise in thigh and calf muscles ($R2=0.75$, $p<0.0001$), b) higher resting IMCL concentration in S than in G and TA for calf and higher resting IMCL in vastus muscles than in RF for thigh, c) strongly reduced IMCL after exercise by ~50%, d) stronger absolute IMCL depletion in muscles with high IMCL resting concentration. Beside absolute also relative

IMCL depletion differences between muscles (relative to resting IMCL) were detected with higher reductions in "slow" than in "fast" muscles, e.g. between S (slow) and G (fast) for calf, and between vastus muscles (slow) and RF (fast) for thigh. An additional finding was that trimethyl-ammonium (TMA) increased significantly with exercise.

Discussion The results showed muscle specific reductions of IMCL after exercise. In general, resting IMCL and absolute as well as relative IMCL depletion after exercise was higher in slow compared to fast muscles. The TMA increase may be related to acetyl-carnitine increase with exercise and differing MR-visibility between carnitine and acetyl-carnitine [2].

KINETICS OF MUSCLE PHOSPHOCREATINE AND PULMONARY OXYGEN UPTAKE DURING MODERATE INTENSITY EXERCISE IN CHILDREN

Armstrong, N., Barker, A.R., Fulford, J., Welford, D., Welsman, J.R., Williams, C.A.

University of Exeter, United Kingdom

Despite the influence of transit delays and utilization of O2 body stores, the rise in phase II pulmonary oxygen uptake (VO2) during a step-transition to moderate intensity exercise has been demonstrated to closely reflect (~10%) muscle O2 consumption (QO2) in adults, using phosphocreatine (PCr) as its proxy (Rossiter et al., 1999). However, as large inter-breath fluctuations and low response amplitudes complicate the child's VO2 response, the derived parameter estimates have low confidence, which may limit physiological inference to changes in QO2. To indirectly explore this association in children, this study compared the kinetic changes in quadriceps PCr and cycling VO2 during moderate intensity exercise.

Following habituation, 14 children (mean age 9.8 y, height 1.36 m, body mass 32.4 kg) completed a unilateral knee-extensor incremental exercise test to exhaustion whilst lying prone in a whole body scanner (Philips, 1.5T) for determination of muscle energetics using 31P-magnetic resonance spectroscopy. Subsequently, the dynamic changes in quadriceps PCr were resolved every 6 s during at least 4 constant rest-work transitions, corresponding to 80% of the previously determined intracellular threshold for Pi/PCr. Cycling VO2 was measured throughout no fewer than 4 work transitions from unloaded pedaling to 80% of the previously determined ventilatory threshold. Breath by breath responses were interpolated to 1 s intervals. Each subject's PCr and VO2 responses were time aligned and averaged to enhance the response profile. A mono-exponential model with no delay term was used from exercise onset for characterization of PCr kinetics, whereas for VO2, a mono-exponential including a delay term was used to determine phase II following deletion of phase I (>15 s). Values are reported as means ± standard deviation (SD).

A paired samples t-test revealed that at the onset of exercise PCr decreased with a mean time constant of 22.4 ± 4.4 s (range 13.9 - 32.2 s), which was non-significantly different (P=0.678) to the phase II VO2 mean time constant of 21.9 ± 3.8 s (range 14.5 – 26.5 s). The 95% confidence intervals for the estimated PCr and VO2 time constants were 5.5 ± 1.3 s and 5.3 ± 1.7 s, respectively.

These results suggest that during the child's on-transient response to moderate intensity exercise, the temporal rise in cycling phase II VO2 reflects that of the fall in PCr during knee-extensor exercise, and therefore provides an estimation of QO2. The measurement of VO2 kinetics during cycle ergometry rather than during knee-extensor exercise is a limitation of this study, but was necessary to obtain acceptable confidence (~±5 s) in the estimated VO2 time constant, that would be compromised if determined during knee-extensor exercise due to its associated low response amplitude.

CAN WE MEASURE MAXIMAL VOLUNTARY MUSCLE ACTIVATION?

Kooistra, R., de Ruiter, C.J., de Haan, A.

Institute for Fundamental and Clinical Human Movement Sciences, Netherlands

Voluntary activation (VA) is often quantified using the interpolated twitch torque technique (ITT) and high levels of VA (>90%) are frequently reported, e.g for isometric knee extension. Generally, the superimposed 'twitch' torque increase on the highest MVC is expressed as a percentage of the resting twitch torque, subtraction from 100% results in a value for VA. The maximal torque capacity (MTC) is generated when activation is 100%. However, recent experiments and observations of non-linear evoked–voluntary torque relationships indicate that this ITT technique may represent a substantial overestimation of VA. Conversely, the calculated MTC will be a severe underestimation of true muscle capacity. This may have implications for clinical practice (e.g. the detection of central vs. peripheral strength deficits in the elderly and patient groups) and basic research related to muscle fatigue. The aim of the present study was to use a new method of several high force contractions with superimposed nerve stimulation to accurately quantify VA and MTC of the knee extensors and compare this method with the ITT method that is usually applied.

Seven male subjects, with previously confirmed very high ability for maximal VA, were tested at 30, 60 and 90° knee angles (full extension=0°) on a custom-built ergometer on two experimental days. On each day, at each angle, high force level isometric knee extension contractions (70, 80, 90 and, 100%MVC) were performed with supramaximal superimposed nerve stimulation (three 100ms pulses; 300Hz) to assess VA and MTC. The torque increment from the superimposed triplet was plotted as a function of the torque reached prior to stimulation. Following linear regression, the intersection with the x-axis yielded MTC and VA was defined MVC/MTC*100%. Paired t-tests were used to test for significant ($p<0.05$) differences between methods used and intraclass correlation coefficients (ICC) for reliability.

Results for 90° (shown) were very similar to 30 and 60° knee angles. Linear extrapolation of the torque increment from superimposed nerve stimulation on high intensity (>70%MVC) contractions provided high R2 values (0.85±0.11[SD]). MTC using the present method (204.6±38.7Nm) was reliable across days (ICC:0.97) and not significantly different from using the 'usual' ITT technique (192.7±22.3Nm). However, applying the 'usual' ITT technique to ~80%MVC contractions, lead to a substantial and significant overestimation of VA (94.8±1.1%) compared to the presented method (79.1±6.6%). Note that at this activation level, the torque increment was small (2.1±0.6%MTC) despite a substantial triplet torque on the resting muscle (39.7±4.0%MTC). Moreover, the overestimation of VA using the traditional ITT technique can only be demonstrated in subjects with a very high ability for maximal VA.

Thus, high levels of VA (~95%) obtained using the 'usual' ITT method represent a substantial overestimation of VA (~16%) when compared to the presented method.

THE ISOMETRIC KNEE EXTENSION TORQUE AT WHICH MUSCLE REOXYGENATION STOPS

de Ruiter, C. J., Goudsmit, J., van Tricht, J., de Haan, A.

Institute for Fundamental and Clinical Human Movement Sciences, Vrije Universiteit, Amsterdam, The , Netherlands

In skeletal muscles the intramuscular pressure, caused by the contraction of muscle fibers, rises with force. At a certain force blood flow may be hampered and with a further increase of contraction intensity it may even completely stop. This will cause a rapid decrease of tissue oxygenation and the active muscle fibers will largely depend on anaerobic energy supply, which will accelerate muscle fatigue. For the knee extensors complete occlusion of blood flow was reported at 64±12 % MVC in vastus lateralis muscle (VL) and at 50±6.5 % MVC in rectus femoris muscle (RF) (1). Clearly, reoxygenation of muscle (inflow of arterial blood, saturated with oxygen) during a submaximal contraction will postpone fatigue during daily activities. The goal of the present study was to investigate at which isometric torque knee extensor reoxygenation during the contraction would stop.

Fifteen healthy male subjects (20-30 years) signed informed consent and the local ethics committee approved the study. Isometric knee extension torque of the dominant leg was measured using a custom made dynamometer with 90° angles in hip and knee. Maximal voluntary activation, established with superimposed nerve stimulation upon MVC, was >90% in all subjects. Near infrared spectroscopy (NIRS) was used to measure changes in muscle oxygenation of the m. vastus medialis (VM), RF and VL during submaximal isometric contractions at intensities (based on pilot experiments) ranging from 20 – 45 % maximal torque capacity (MTC) with 5% increments. Torque levels were randomly assigned and divided over two days. At each torque, a contraction with inflated pressure cuff (450 mmHg), inducing full arterial occlusion, was followed (10 min rest) by a second contraction without pressure cuff. Both contractions lasted until maximal deoxygenation was reached (all oxygen consumed) during the contraction with cuff. It was assumed that if blood flow was occluded by internal muscle pressure during a contraction without cuff, tissue reoxygenation would not occur and maximal deoxygenation would be similar to that obtained during the contraction with cuff at the same torque. ANOVA repeated measures ($p<0.05$) followed by simple contrasts showed that maximal deoxygenation was independent of torque during the contractions with cuff but not without cuff. During contractions without cuff maximal deoxygenation became similar ($p<0.05$) to maximal deoxygenation reached with cuff from 25%, 25 % and 35% MTC in the VM, VL and RF muscle respectively. It was concluded that knee extensor reoxygenation stopped at lower torques than previously reported for blood flow (1). The higher torque at which reoxygenation stopped in the RF may be due to differences in anatomy among the muscles and/or because the biarticular RF is less active than the VM and VL at submaximal torques.

WHY DOES VO2MAX NOT INCREASE WITH ACCLIMATIZATION TO HIGH ALTITUDE

Lundby, C., Boushel, R., Robach, P., Sander, M., van Hall, G., Møller, K., Calbet, J.A.

Copenhagen Muscle Research Center, Denmark

When arterial oxygen content (CaO2) is increased by hyperoxia or erythropoietin administration maximal oxygen uptake (VO2max) is increased. Conversely, when CaO2 is reduced acutely by hypoxia, VO2max is reduced proportionally to the degree of hypoxia. Thus, there seems to be a tight relation between CaO2 and VO2max. However, with acclimatization to high altitude CaO2 is normalized to sea level values without concomitant normalization in VO2max, and thus the tight relation between arterial oxygen content and VO2max at sea level is diminished with altitude acclimatization. The present data are gathered from two independent high altitude studies and focuses on oxygen delivery to the locomotor muscles during exercise with acclimatization. In study I six Danish lowlanders were studied at sea level, and with acute exposure to 4100 m altitude, and again after 2 and 8 weeks of acclimatization to this altitude. With acclimatization CaO2 was normalized, but VO2max remained unchanged compared to the acute hypoxic situation. This could be explained by a gradual reduction in maximum leg blood flow, and thus resulting in unchanged O2 delivery to the working muscles with acclimatization. Therefore it is also clear that VO2max should not be increased with acclimatization to high altitude. In study II 8 Danish lowlanders were studied after 7-9 days of exposure to 4559 m altitude. The aim of this study was to increase leg blood flow by arterial infusion of the vasodilator ATP, however, although the artery was dilated, leg blood flow, and therefore O2 delivery remained unchanged, and thus also leaving VO2max unchanged, as compared to the control situation. As a result of the two studies we conclude 1) VO2max does not increase with acclimatization since maximum leg blood flow is reduced with acclimatization, 2) as at sea level, VO2max at altitude is a function of oxygen delivery to the exercising muscles, and 3) Vasodilation of the femoral artery does not increase leg blood blow, suggesting that the limitation to maximal exercise in hypoxia is related to the failure of cardiac output to increase leg blood flow.

NO DIFFERENCE IN TIME TO EXHAUSTION AT MAXIMAL LACTATE STEADY STATE BETWEEN CYCLING AND RUNNING

Fontana, P., Boutellier, U., Knoepfli-Lenzin, C.

ETH-University of Zurich, Switzerland

Introduction: Heart rate (HR) and blood lactate concentration (Lac) in cycling and running are different, at exhaustion as well as at a comparable submaximal intensity (Roecker et al., 2003). The purpose of the present study was to investigate if the above mentioned results lead to differences in time to exhaustion at maximal lactate steady state (MLSS) between cycling and running. Methods: 15 moderatly endurance trained men (age: 30 ± 6 years, height: 180 ± 5 cm, weight: 77 ± 6 kg, maximal oxygen uptake: 50 ± 4 ml/kg/min, exercise activity: 2-6 h/week) performed a lactate minimum test to determine anaerobic threshold and several constant load tests (CLT) until criteria for MLSS were fulfilled [Lac in a CLT is constant (≤ 1 mmol/l) over 20 min after initial 10 min for reaching steady state and increases (> 1 mmol/l) in a second CLT in the same time when power (5 W) or speed (0.25 km/h) are elevated]. MLSS was determined on a cycle ergometer and a treadmill, respectively. During the CLT Lac and rate of perceived exertion (RPE) were measured every 5 min, oxygen uptake and ventilation were recorded continuously, HR every 5 s. Results: Time to exhaustion (37.5 ± 8.6 vs. 38.3 ± 5.9 min) and RPE (7.5 ± 1.5 vs. 7.4 ± 1.4) were equal in cycling and running. Oxygen uptake (3.1 ± 0.3 vs. 3.4 ± 0.3 l/min, $p < 0.001$), ventilation (95 ± 13 vs. 105 ± 17 l/min, $p < 0.01$) and HR (166 ± 8 vs. 176 ± 9 min-1, $p < 0.01$) were lower, Lac (5.6 ± 1.6 vs. 4.4 ± 1.3 mmol/l, $p < 0.05$) was higher in cycling than in running. MLSS parameters referred to maximal values (%) showed no difference in ventilation (70 ± 11 vs. 76 ± 8 %), HR (92 ± 4 vs. 94 ± 3 %), Lac (57 ± 17 vs. 48 ± 12 %) and RPE (79 ± 17 vs. 82 ± 14 %) between cycling and running, only oxygen uptake (86 ± 5 vs.

89 ± 5 %, $p < 0.05$) was slightly lower in cycling than in running. Conclusions: No difference in time to exhaustion at MLSS between cycling and running was found. Absolute differences in ventilation, HR and Lac disappeared when compared relatively with the exception of oxygen uptake, which was absolute as well as relative slightly lower in cycling than in running.

Roecker K., H. Striegel, and H.-H. Dickhuth: Heart-rate recommendations: transfer between running and cycling exercise? Int J Sports Med 24: 173-178, 2003.

LACTATE-MINIMUM AND LAKTAT TURN POINT

Hofmann, P., Hartleb, C., Wonisch, M., Schwaberger, G., Pokan, R., von Duvillard, S.P.

Universiities Graz and Vienna, Medical-University Graz, Austria, Texas A&M University-Commerce , Austria

The lactate minimum (Lamin) method was described to give the maximal lactate steady state and to be independent of the status of glycogen stores (1). A modification of the method was described repeating two incremental tests with only a short active break between (2). The method is discussed controversially in the literature (3). Aim of the study was to compare the Lamin threshold to the first (LTP1) and the second (LTP2) lactate turn points and the first (VETP1) and second (VETP2) turn points in ventilation (VE). METHODS: Young healthy students (N=16; age: 28.7±4.6 yrs, height: 178.2±8.3 cm; weight: 74.4±11.3 kg) performed two incremental exercise tests (T1, T2) with an active break between tests until La decreased to 5 mmol.l-1. Lamin was determined as exercise performance at the nadir of La during T2. The first increase in La above base level was defined as LTP1 and the second abrupt increase between LTP1 and Pmax was defined as LTP2. Turn points in VE were defined as the first (VETP1) and the second (VETP2) increase in VE accompanied by turn points in the equivalents for O2 uptake and CO2 output. TP˝s were determined in T1 and T2 and compared to Lamin by ANOVA and /or t-test where appropriate. Correlation coefficient was calculated to prove the relationship between TP values. RESULTS: VO2max (3.5±0.7 / 3.4±0.7 l.min-1) Pmax (298±54 / 288±55 W) but not HRmax were slightly but significantly lower in T2. Power output and VO2 were found at 127±34 W and 1.7±0.4 l.min-1 (LTP1-T1), 127±29 W and 1.7±0.4 l.min-1 (LTP1-T2) and 219±46 W and 2.7±0.5 l.min-1 (LTP2-T1) and 210±44 W and 2.6±0.6 l.min-1 (LTP2-T2) were TP˝s in La were not significantly different between T1 and T2. However, Lamin (146±33 W, 1.9±0.4 l.min-1) was significantly different from TP˝s in La from both T1 and T2.

Power output at Lamin was significantly related to LTP1 (T1: 0.836, $P<0.01$; T2: 0.921, $P<0.001$) and LTP2 (T1: 0.851, $P<0.001$; T2: 0.886, $P<0.001$). Power outputs at TP˝s for La from T1 were significantly related to TP˝s from T2.

Turn points in VE were not significantly different from turn points in La in T1 and T2 and they were significantly related.

CONCLUSIONS: The Lamin was significantly different from both TP˝s in La and VE from both T1 and T2 whereas TP˝s in La and VE were highly reproducible. As T2 and the Lamin did not give any additional information, T1 is suggested to be sufficient to describe exercise performance in healthy young subjects.

DETECTION OF AN ANAEROBIC THRESHOLD USING NEAR INFRA RED SPECTROSCORY IN CHF PATIENTS

Karatzanos, L., Gerovassili, V., Renieris, P., Karaseridis, A., Dimopoulos, S., Georgiopoulou, V., Nanou, V., Mansolas, G., Roussos, C., Nanas, S.

University of Athens, Greece

Near infrared spectroscopy (NIRS) has been recently introduced as a non-invasive methodology providing measures of tissue oxygen saturation (StO2) (Boushel et al., 2001). This study was designed to evaluate different methods of detecting a threshold employing NIRS and correlate them to ventilatory threshold in patients with chronic heart failure (CHF).

Ten stable CHF patients, 2 males and 8 females [(M±S) age: 55.2±9.4 years, VO2peak: 14.2±2.5 ml/kg/min], performed a symptom-limited exercise test to exhaustion on a cycle ergometer. The test was consisted of 1-min stages and the increase in workload was individualised according to the Wasserman norms. The NIRS probe was placed on the vastus lateralis muscle. Power output at the NIRS threshold was evaluated with StO2-workload plots, employing three different models: linear (NTlin), log-log transformation (NTlog) (Beaver et al., 1985) and Dmax (NTD)(Cheng et al., 1992). Ventilatory threshold was assessed with the V-slope method (VCO2-VO2 plots), while the corresponding power output (VT) was calculated by the gas analysis system software.

Mean ± SD values for VT, NTlin, NTlog and NTD were 66.5±25.0, 69.3±23.0, 69.3±23.4, and 74.6±25.8 watts respectively. VT was significantly correlated ($p<0.05$) to NTlin ($r=0.84$), NTlog ($r=0.83$), and NTD ($r=0.90$). The 95% limits of agreement of VT with NTlin, NTlog and NTD were from -15.11 to 22.91 watts, from -16.21 to 24.01 watts, and from -6.31 to 21.71 watts respectively.

NIRS methodology seems to provide a useful means of detecting a threshold in CHF patients. All models employed were highly correlated with VT, with Dmax model showing higher correlation and narrower limits of agreement than linear and log transformation models. These findings, as well as the appropriateness of the NIRS methodology in prescribing exercise training in CHF patients, need to be further investigated.

THE RELATIONSHIP BETWEEN SELECTED CARDIOVASCULAR VARIABLES AND EXERCISE INTENSITY DURING CONTINUOUS AND DISCONTINUOUS INCREMENTAL ISOMETRIC EXERCISE TESTS

Allum, S.R., Wiles, J.D., Coleman, D., Swaine, I.L.

Canterbury Christ Church University, United Kingdom

Introduction: It has been reported that there is a linear relationship between heart rate (HR) and exercise intensity during a continuous incremental isometric exercise test using bilateral knee extensions. However, it is unknown whether this relationship remains the same if

the exercise is performed in a discontinuous manner. Therefore, the aim of this study was to compare the relationship between selected cardiovascular variables and exercise intensity during continuous and discontinuous incremental isometric exercise tests.

Methods: 9 healthy male subjects (age 27.8± 4.1years) performed seated maximal bilateral isometric knee extensions, using an isokinetic dynamometer, in order to assess their maximum voluntary contraction (MVC). From this, the associated peak electromyographic activity (EMGpeak) was determined. Subjects then performed a continuous and discontinuous incremental isometric exercise test, in a randomly assigned order. These tests were commenced at 10% EMGpeak and increased by 5% EMGpeak every two minutes until 30% EMGpeak or voluntary exhaustion. During the discontinuous protocol, each exercise intensity was separated by a two minute rest period and the tests were performed within 72hrs of each other. HR was recorded continuously via electrocardiogram and values averaged for the last 30s of each two-minute intensity. Blood pressure (BP) was recorded every minute throughout each test.

Results: The results revealed a linear relationship between %EMGpeak and HR for both the continuous (r at least 0.92) and discontinuous (r at least 0.98) incremental tests. Analysis of covariance (ANCOVA) revealed no significant differences in the slopes of the EMGpeak versus HR relationships for the continuous and discontinuous tests (slope F= 3.16; P=0.13). However there was a significant difference between the elevations of the EMGpeak versus HR relationships for the continuous and discontinuous tests (slope F=16.8; P=0.005). In addition, there was no statistically significant difference (P >0.05) between the peak HRs achieved during the continuous and discontinuous protocols.

Conclusion: It would appear that for a given EMG, HR is higher with a continuous versus a discontinuous incremental isometric exercise protocol. However, there was no difference in the peak HR achieved in either test (P>0.05). It is therefore concluded that there appears to be no advantage in using a discontinuous versus a continuous incremental isometric exercise test to establish exercise intensity. However, it was found that a number of subjects were unable to complete the continuous test, whereas all subjects completed the discontinuous protocol.

VO2 RESPONSE TO EXERCISE INTENSITIES ABOVE VO2MAX IN TRAINED MIDDLE-DISTANCE RUNNERS

Duffield, R., Bishop, D.

Charles Sturt University, Australia

INTRODUCTION

Previously we have reported an association between faster VO2 kinetics (tau) and faster starting speeds with faster subsequent race performance in trained middle-distance runners during simulated on track 800-, 1500- and 3000-m races. However, only a single trial was analysed and the races were not constant exercise intensities. While this data fits with previous reports of faster tau values for higher exercise intensities, not all studies have reported faster tau values for higher intensities. Therefore, the aim was to determine whether faster running speeds were associated with faster VO2 kinetics at running speeds encountered in middle-distance track events.

METHODS

Seven male, trained middle-distance runners; VO2 max 60.6 (2.5) mL/kg/min, performed 5 testing sessions at the same time of day and separated by 48 h. Following an incremental graded exercise test of 1-min stages until volitional exhaustion to determine VO2max and velocity associated with VO2max (v-VO2max), the athletes twice performed runs to fatigue (RTF) at 100% and 110% v-VO2max. During the RTF, VO2 and heart rate (HR) were continuously measured on a breath-by-breath basis; lactate (La) was measured pre and post run and integrated electromyographic (iEMG) measures of the Rectus Femoris, Vastus Lateralis and Biceps Femoris muscles were recorded during the first and last 10 s of each run. VO2 data was smoothed using standing 5 s averages and along with HR data fit to a mono-exponential model. iEMG data was full wave-rectified and movement artefacts removed using a high (15Hz) and low (5Hz) pass Butterworth filter.

RESULTS

Time to fatigue was significantly longer in the 100% v-VO2max run (223(49) v 136(24) s: p=0.01). However, no significant differences were present between 100% and 110% v-VO2max for the baseline, primary amplitude, total amplitude or %max reached for either VO2 or HR data or for post-run La (p>0.05). Significant differences were present (p<0.05) between 100% and 110% speeds for tau values in both VO2 (29.3(1.8) v 26.3(2.7) s) and HR (31.8 (5.0) v 24.0(3.6) s). However, no significant correlations were observed between either VO2 or HR tau values and time to fatigue. EMG analysis indicated larger iEMG activity in the 110% run and an increase in iEMG activity as the run progressed at both speeds.

DISCUSSION

Faster running speeds during constant-speed treadmill runs were associated with faster VO2 and HR responses, with no difference evident in the amplitudes or %max of either run at the end of exercise or by 2min. iEMG activity indicated a greater muscle recruitment in the 110% run, however the association with VO2 response was weak to moderate and not correlated with performance. A combination of previous on-track and current treadmill data suggest the potential benefit of faster starting speeds at the commencement of a race to invoke faster VO2 and HR responses.

WALKING AND CYCLING BEHAVIOUR OF CHILDREN AND YOUNG ADULTS IN SWITZERLAND: RESULTS FROM THE TRAVEL SURVEY 2000

Martin-Diener, E., Sauter, D.

Federal Office of Sports, Magglingen, Switzerland

At least one hour of physical activity a day is recommended for children and half an hour of moderate intensity activities for adults. Active transport can contribute substantially to meet these recommendations. As in many industrialized countries, there is public concern in Switzerland about an increasing number of children not walking or biking but being brought to their destinations by car. For this paper, travel survey data were analysed focussing specifically on children's travel behaviour.

The travel behaviour of 5030 individuals aged 6 to 20 years was assessed in a telephone interview in the context of a national representative travel survey. Basis for the results presented below are 1) the 6737 trips to school accumulated by those 2130 individuals reporting

at least one trip to school on the day preceding the interview, and 2) the 7889 trips during leisure time accumulated by those 3204 individuals reporting at least one trip on the day of interest.

In the year 2000, 76.8% of the 6-9 year old children walked to school, 3.6% used their bicycle, 8.1% were brought by car, 6% walked and used public transport and 5.4% other forms of combined mobility. The respective numbers for the other age groups were: 10-12 years: 61.6%, 18.7%, 4.6%, 8.4%, 6.7%; 13-15 years: 30.9%, 27.6%, 6.3%, 24.5%, 10.8%; 16-17 years: 18.7%, 20.0%, 9.8%, 32.0%, 19.5%; 18-20 years: 19.6%, 12.0%, 21.5%, 33.8%, 12.9%. In a logistic regression model, determinants for the choice of different modes of transport were assessed. Distances up to 1km increased the chance of walking compared to longer distances, while medium distances increased the use of a bicycle. Living in the German part of Switzerland was associated with a higher probability of walking or cycling to school than living in the French part of the country, where on the other hand the chance of being brought by car was higher. With an increasing number of cars in the household the chance of walking to school decreased.

During leisure time, 38.8% of 6-9 year olds walked to their destinations, 8.8% used their bicycle, 37.0% were brought by car, 3.7% walked and used public transport and 11.7% other forms of combined mobility. The respective numbers for the other age groups were: 10-12 years: 35.0%, 14.4%, 32.8%, 6.4%, 11.4%; 13-15 years: 33.7%, 21.7%, 23.8%, 9.2%, 11.6%; 16-17 years: 29.9%, 13.3%, 30.3%, 14.6%, 12.1%; 18-20 years: 21.1%, 7.6%, 44.2%, 11.1%, 15.9%.

A comparison with the 1994 survey data revealed that for school trips as well as for trips during leisure time, for trips up to 3km and overall, the shares of walking did not change between 1994 and 2000, whereas the shares of cycling decreased and the shares of individual motorized transport increased.

For trips to school the share of active transport was high, whereas for trips during leisure time the potential was not used. The development from 1994 to 2000 suggests that the use of the bicycle for short distances should be encouraged and facilitated.

PREVALENCE OF METABOLIC SYNDROME IN GREEK ADOLESCENTS

Bouziotas, C., Koutedakis, Y., Christodoulos, A., Ageli, E., Nikolaou, A., Nakou, A., Gara, S.

Consultant of Physical Education, Greece

Introduction

Childhood metabolic syndrome (MetS) promotes the development of premature atherosclerosis and significantly increases cardiovascular disease risk early in life (Kohen-Avramoglu et al. 2003). Hence, early identification of the syndrome is essential, so that appropriate interventions can be targeted to children, minimizing thus the risk of developing metabolic-related diseases later in life. Although research indicates an alarmingly high prevalence of cardiovascular risk factors among Greek adolescents, such as dyslipidemia, high blood pressure and obesity (Bouziotas et al. 2001), to our knowledge, there is a paucity of data examining the clustering of these disorders and the prevalence of MetS in Greek paediatric populations. In view of the dearth of such data, the present study was conducted to determine the prevalence of the MetS among Greek adolescents.

Methods

A population of 102 boys and 85 girls, 17.2±0.5 years of age, participated and had a physical examination to measure height, weight, and a useable fasting morning blood sample drawn after providing assent and informed consent from a parent. Paediatric MetS was defined using criteria analogous to ATP III (Alberti and Zimmet 1998, De Ferranti et al. 2004) as 3 or more of the following criteria: (1) fasting triglycerides ≥ 150 mg/dL; (2) HDL-C < 50 mg/dL (girls), < 45 mg/dL (boys); (3) fasting glucose ≥ 100 mg/dL; (4) BMI ≥ 90th percentile for age and gender; and (5) systolic blood pressure ≥ 130/85 mm Hg. Descriptive statistics and simple contingency table analyses were performed with SPSS Version 11.0 software.

Results

Low HDL-C was the most prevalent metabolic abnormality in this population (31.6%), followed by hyperglycemia (18.7%) and obesity (14.4%). The prevalence of elevated blood pressure and hypertriglyceridemia was 11.8% and 2.7%, respectively. Prevalence estimates indicated that 5.3% of these teenagers had MetS, according to the set criteria. Male adolescents had a greater prevalence of MetS compared with females (7.8% vs 2.4%, respectively), though, this difference did not reach statistical significance (chi-square=2.76, p<0.097).

Discussion/Conclusion

In the present cohort of adolescents, MetS prevalence was 5.3%. Since obesity and other cardiovascular risk factors originate in childhood and tend to track into adulthood (Andersen et al. 2003), the present data suggest that the prevalence of MetS among adolescents will increase, unless effective prevention efforts will be implemented early in life.

GENDER-RELATED DIFFERENCES IN PERCEIVED ENVIRONMENTAL AND PSYCHOSOCIAL CORRELATES OF CYCLING AMONG YOUNG ADULTS

Titze, S., Stronegger, W.J., Janschitz, S., Oja, P.

Institute of Sport Science, University of Graz, Austria , Austria

Introduction

Non-motorized transport has been recognised as an ideal setting for regular health-enhancing physical activity. Bicycling, in particular, could be a feasible alternative for car to commute distances less than 5 km. Yet bicycling as a means of transportation makes up only a small percentage of such journeys in most European countries.

Recent studies suggest that several personal, social, and environmental variables are correlated with cycling for transportation. Furthermore, gender has been identified as a consistent predictor of travel pattern. The purpose of this study was to identify whether psychosocial and environmental variables are differently associated with bicycle use for transportation among young female and male adults.

Methods

In a cross-sectional sample of university students in Graz, Austria (n= 538; mean age 23.8 years SD = 3.5; female 43.9%) we applied a questionnaire to assess perceived personal, social and environmental attributes of cycling from home to university. Responses were given on a 4-point scale ranging from "strongly agree" to "strongly disagree". Participants were classified as non-cyclists (43,5 %), irregular cyclists (15,1 %) and regular cyclists (41,4 %). Two multi-nominal regression analyses, for men and women, were conducted to identify associations between independent variables and cycling behaviour. The comparison group for irregular and regular cyclists were non-cyclists.

Results

The proportions of no cyclists, irregular cyclists and regular cyclist were similar among men and women. Overall, more environmental and psychosocial factors were associated with cycling among women than among men. While high mobility and little physiological effort of cycling were positively correlated with irregular and regular cycling among both genders, among women, quickness of travel, enjoyment of cycling and convenience for errands correlated positively with cycling, but among men only no danger of bike theft did so. Paradoxically, no hills en route to university and car parking problems around home showed negative correlation with cycling among women, and high traffic safety among men.

Conclusions

Although no differences in the commuting pattern from home to university were found among male and female students the findings show divergences between men and women in the number and type of factors that are associated with cycling to university. These findings suggest that gender-specific strategies may be needed in order to successfully promote transport cycling among young adults.

AEROBIC FITNESS IN PATIENTS WITH CHEMICAL DEPENDENCE

Mamen, A., Martinsen, E.W.

Sogn og Fjordane University College, Norway

Introduction

Few investigations have assessed the aerobic fitness of people with substance dependence. These studies indicate that chemically dependent patients have a reduced level of fitness compared to non abusers of the same age. However, none of the previously reported studies have used direct measurements of VO2max, only indirect methods have been used. We wanted to test such a population's aerobic fitness using direct measurement of VO2max and the lactate profile test.

Methods

A total of 54 patients admitted to the psychiatric clinic for substance abuse or dependence served as subjects, 17 were females. Mean ± SD age for the group was 31±9 yr.

They performed a lactate profile test on either a cycle ergometer or a treadmill and a Bruce treadmill test for maximal aerobic capacity.

Results

VO2max for males, 39.2±10.3 ml kg-1min-1 (mean±SD), and females, 30.1±7.5 ml kg-1min-1, were significantly different, $p< 0.01$. The cycling load at lactate threshold was 92±25 W for males and 70±16 W for the females. The speed at threshold was 7.8±1.0 km h-1 for males and 7.2±0.8 km h-1 for females. Heart rate at threshold reached 72±7 % of HRmax for males and 70±3 % females when cycling. When running, the males had a threshold heart rate of 76±6 %, whereas the females reached 79±8 %. The difference between cycling and running was significant for the females, $p<0.05$.

Discussion

The VO2max in relation to body mass was somewhat higher than in most previous studies. Our results were on the same level as was found by Murphy et al. (1986) in a study of college students with excessive alcohol consumption, but our subjects were ~10 yr older. Compared to a normal population, the men are in the normal range for their age, whereas the women are somewhat lower than normal. As far as we know, testing of lactate threshold has never been done in such a group of subjects, but the values seem to be lower than the results of the aerobic capacity would indicate. This indicates a low training state, enabling them to use only 45-70 % of their maximal aerobic capacity before lactate elimination is reduced. The especially weak results on cycling indicate that this is a little used exercise modality. The discrepancy between the best and the least fit was great, indicating that people with chemical dependency represent a diverse group with large variations in aerobic fitness. This fact must be taken into consideration if physical activity is to be used as a part of a rehabilitation programme, so that level and intensity of the physical activity can be optimal.

SINGLE MOTOR UNIT IDENTIFICATION IN HIGH ACTIVATION LEVEL USING A NEW SELECTIVE MULTI-WIRE ELECTRODE

Linnamo, V., Kallio, J., Søgaard, K., Komi, P.V.

University of Jyväskylä, Finland

Introduction

With low activation level in isometric condition the identification of single motor units (MU) is generally successful. As the recruitment and firing rate increases the process becomes more challenging. With decomposition and quadripolar needle technique it is possible to identify the MUs up to higher activation levels even if they are overlapping with each other (e.g. De Luca et al 1982). Although there is some data about the MU behavior also from high level dynamic conditions (Del Valle & Thomas 2005, Søgaard et al. 1998) the identification of single MUs near maximal force levels is difficult. The purpose of the present pilot study was to examine if single MUs could be identified even up to maximal level of activation using a new selective multi-wire electrode with larger number of channels to help identification and decomposition. If successful, this technique could then be utilized later also in dynamic conditions.

Methods

The new multi-wire electrode consists of four 50µm polyurethane insulated wires glued parallel together so that one of the wires was ¼ mm shorter than the other three. The insulation was then mechanically removed from the shortest wire over ½ mm distance from the tip.

A hook was formed to the end of the wires to ensure the fixation during the measurements. The electrode was inserted into the soleus muscle of a 20-year old subject. He was instructed to increase steadily the plantar flexion torque from 0 to 100% (ramp). Activities of one MU, whose recruitment threshold was at 17 % MVC, were then analysed in the following force ranges: 20-40%, 40-60%, 60-80% and 80-100% using Daisy software (Olsen et al. 2001).

Results and Discussion

The mean firing rate of the MU that was analysed was more than two times higher in maximal compared with lowest activation (20-40%) condition. At 20-40% the mean firing rate was 9,1 Hz, at 40-60% 10,1 Hz, at 60-80% 13,5 Hz and at 80-100% 18,5 Hz. This particular MU was recruited at 17% MVC threshold and derecruited at 58% MVC in the relaxation phase. It has been suggested with biceps muscle that at higher force levels the increase in force is mainly due to increased firing rate of the fast (phasic) MUs, which may increase almost linearly up to 100% MVC while slow (tonic) MU:s reach a saturation frequency of discharge at lower force levels of approximately 60% - 80% MVC (Gydikov & Kosarov 1974). Since soleus muscle consists mainly of tonic MUs, this indicates that also a tonic MU (with high threshold) is able to increase its firing rate up to maximal MVC. In conclusion, the present pilot test showed that with a selective multi-wire electrode it is possible to identify single motor unit activity even up to 100% MVC.

SOLEUS MUSCLE SPINDLE SENSITIVITY AFTER 1 HOUR OF ELECTRICALLY EVOKED ECCENTRIC EXERCISE

Peltonen, J., Kanervo, M., Komi, P.V., Avela, J.

University of Jyväskylä, Finland

It has been shown that soleus muscles fascicles fall shorter even after such a low load stress as 1 hour of passive repetitive stretching (Avela et al., 2004). This is associated with reduced MVC, twitch response, stretch and H-reflex responses. Most probable explanation for reduced reflex sensitivity is disfacilitation of alpha motor neuron pool either because of 1) lower static firing frequency at shorter muscle length; or 2) lower dynamic response to length changes because of increased compliance of muscle-tendon unit. This study was aimed to identify the changes in static or dynamic spindle firing frequency after SSC exercise. 11 healthy males volunteered for the study. Their MVC torque and H-reflex responses at three different muscle pre-conditioning as well as corresponding soleus muscle fascicle lengths were measured before and after the exercise. Exercise consisted of 5200 cycles of electrically evoked eccentric contractions of the right leg triceps surae muscle group at frequency of 1,5 Hz. Exercise was performed in ankle dynamometer. Pre-conditioning was done by contracting muscle slightly at certain muscle length, holding it there for 10 seconds, then stretching it rapidly (pre-Fast), slowly (pre-Slow) or not stretching at all (Control) before H-reflex stimulation. Preliminary results show that, while H-reflex amplitude was not altered in control situation, it was reduced in both pre-Fast and pre-Slow conditioning. Important difference was that H-reflex amplitude diminished more in pre-Slow than pre-Fast conditioning after fatigue. Soleus muscle fascicles were shorter after exercise in both pre-Slow and pre-Fast conditions. Exercise was not associated with changes in MVC. This study confirmed the earlier observations of Avela et al. (2004) that soleus muscle fascicle length is shorter even after exercise containing relatively low tensile muscle and tendon forces. Since control H-reflex amplitude remained unchanged after exercise, it's unlikely that disfacilitation caused by lower static firing frequency of muscle spindles (if there is any) is adequate to alter H-reflex response. Explanation has to be found from changes in dynamic activity of muscle spindles. Smaller H-reflex reduction in pre-Fast, compared to pre-Slow, might suggest that fast pre-stretch-induced spindle activity is lower after exercise. Lower spindle activity presumably leads to a diminished release of neurotransmitter which, as a consequence, is not depleted from axon terminal and therefore allows better transmission of following action potentials (Hultborn et al., 1996). Lower dynamic spindle activity was also supported by lower reflex response, both neural and mechanical, to fast pre-stretch after exercise.

SEX SPECIFIC DIFFERENCES IN MECHANICAL PROPERTIES OF ISOLATED COLLAGEN FASCICLES FROM THE HUMAN PATELLAR TENDON

Haraldsson, B.T., Aagaard, P., Krogsgaard, M., Alkjaer, T., Kjær, M., Magnusson, S.P.

Institute of Sports Medicine, Copenhagen, Denmark

It is well known that women are much more likely to sustain certain connective tissue injuries than men during physical activity, for instance is the incidence of anterior cruciate ligament (ACL) tears several fold higher in women (1). The reasons for the sex specific predisposition to injury are unknown, however, it has been suggested that estradiol may reduce fibroblast proliferation, collagen synthesis, fibril diameter and collagen content, which may weaken the mechanical properties of connective tissue and make it more susceptible to injury (2-4). To our knowledge, there is no available information to what extent there is a sex specific difference in the mechanical properties of human tendon tissue in young persons.

The purpose of the present study was to examine and compare the mechanical properties of single isolated collagen fascicles from the anterior portion of the patellar tendon obtained from young males and females.

Thin collagen bundles (~ 35 mm long and ~ 3.5 mm in diameter (ø)) were obtained from the anterior portion of human patellar tendons from healthy young males (mean±SD, 29.0±4.6 yr., n=6) and females (mean±SD, 27.0±5.7 yr., n=6) that underwent elective anterior cruciate ligament reconstruction. A single individual collagen fascicle was dissected from each bundle under a stereoscopic microscope. The male (ø 320±33 µm) and female (ø 350±18 µm) fascicles were tested for tensile strength in a mechanical rig, placed under a stereoscopic microscope equipped with a digital camera that recorded elongation of the specimen.

The following parameters were obtained: fascicle ultimate stress, fascicle yield stress and strain, and tangent modulus. Fascicle stress (σ) was calculated as the tensile force (N) divided by the cross-sectional area (m2) of the fascicle and reported as MPa. Fascicle strain (ε) was defined as the length change divided by the initial length and was expressed as a percentage ((∆L / Lo) x 100)). The tangent modulus (E) was calculated in the linear portion of the stress-strain curve.

Ultimate stress was greater for male fascicles (76.0±9.5 MPa) than for female fascicles (44.1±1.9 MPa), P<0.05. Yield stress did not differ for male (56.6±10.4 MPa) and female fascicles (32.7±1.3 MPa, P=0.06). There was no significant difference in yield strain between male (6.8±1.0 %) and female fascicles (8.7±1.3 %). The tangent modulus was significantly greater for male fascicles (1231±188 MPa) than female fascicles (576±86 MPa), P<0.05.
These preliminary data suggests that the collagen fascicles from the patellar tendon of male subjects were stronger than that of females as indicated by the greater ultimate stress and tangent modulus in male fascicles, which may reflect a sex specific difference in mechanical properties. However, the effect of gender and training on the material properties of isolated collagen fascicles are not fully understood, or to what extend this influences the rate of collagen tissue injurie.

TIBIAL SAFETY FACTOR IN EXTREME IMPACT LOADING AMONG PHYSICALLY ACTIVE MALES AND FEMALES

Rantalainen, T.J., Heinonen, A., Linnamo, V., Kyröläinen, H., Sievänen, H., Komi, P.V.

University of Jyväskylä, Finland

INTRODUCTION: Extreme impact loading demonstrates considerable influence of mechanical loading on human bone strength (1). Bones have an intrinsic safety factor to sustain loads in strenuous activities (2). The safety factor is described as the strength of the bone compared with the stress imposed on it during extreme activity, usually fast locomotion (3). Safety factor is reflected as the ability of bone to adapt within boundaries to imposed loads. The present study was designed to examine the safety factor in cross-sectional study with males and females.
METHODS: Eight triple jumpers and eight age, height and gender matched nonathletic controls participated in the study. Neuromuscular performance was measured with walking test at normal pace (maximal ground reaction force [GRF]). Bone variables were measured with peripheral quantitative computer tomography (pOCT) from the tibial mid-shaft and from the distal end of tibia. Total density (ToD, mg/cm3) and total area (ToA, mm2) were calculated from the measured variables. To characterize the bone bending strength, bone strength index (BSI, 4) was determined as the density weighted section modulus. Safety factor (SF) at mid-tibial shaft (SFs) was calculated as BSI/(GRF*height) and at distal tibia (SFd) as ToD2*ToA/(GRF). Independent samples t-test was used for statistical analysis.
RESULTS: In tibial mid-shaft, SFs was significantly (P= 0.009) higher (15.7±0.5) in triple jumpers than that in the controls (12.9±1.8). No intergroup difference was observed in SFd (104,0±18,0 vs, 91,2±11,1, P = 0.132).
DISCUSSION: Present results indicate that the safety factor in normal locomotion (walking) can be greater in subjects imposed to regular high skeletal loads. The built of the long bones is actually determined by the forces imposed during locomotion to secure reasonable safety factors. The athletes demonstrated a high safety factor in sedentary locomotion as compared to nonathletic counterparts. Impact loading seems to increase the factor of safety towards normal loading and thus has clinical importance in preventing fractures from occurring.

CHAIN WHEEL SHAPE AFFECTS BLOOD LACTATE CONCENTRATION DURING SUBMAXIMAL CYCLING

Hansen, E.A., Jensen, K., Hallén, J., Pedersen, P.

The Norwegian School of Sport Sciences, Norway

Introduction
Two decades ago the Shimano Corporation introduced a non-circular chain wheel (Biopace) to optimise the human engine for bicycling. It was reported that in comparison with the circular chain wheel, the Biopace (at a fixed pedal rate) reduced peak joint torques, calculated from pedal forces.
Unfortunately, only data from one subject was shown (Okajima, 1983).
Reduced peak pedal force or peak crank torque (Tpeak) with the Biopace, may lower sensory feed back from mechanoreceptors, which again may instigate cyclists to choose a slower and more energetically efficient pedal rate. We tested the hypotheses that in submaximal cycling, the use of a Biopace compared to a circular chain wheel would: (1) lower Tpeak at a preset pedal rate, and: (2) lower pedal rate and oxygen uptake (VO2) at freely chosen pedal rate (FCPR).
Methods
Ten male cyclists (182±4 cm, 77.5±7.0 kg, VO2max: 61.7±4.4 mL O2 min-1 kg-1) performed 10-min cycle ergometer bouts at 180 W using, at random order, a circular or a Biopace II (CR-BP20, Shimano) 52-tooth chain wheel. The cycling was performed at FCPR and separated by a 5-min rest. Means of power output, pedal rate, VO2, and heart rate (HR) were calculated over the last 5 min. Blood lactate concentration (BLC) and rate of perceived exertion (RPE) was measured during the last min. After another 5-min rest, the subjects performed 2 min cycling at 180 W at a target pedal rate of 90 rpm with each of the two chain wheels, for calculation of crank torque profile characteristics represented by minimum crank torque (Tnadir), Tpeak, and crank angle at Tpeak. The crank torque profile represented the sum of the torque applied by both legs. Paired t-tests were used to evaluate differences between the two chain wheels. Significance level was P<0.05.
Data are mean±SD.
Results
Crank torque profile characteristics at the target pedal rate of 90 rpm, were similar for the two chain wheels (Circular/Biopace): Pedal rate (89.9±1.5/88.9±1.7 rpm), Tnadir (4.4±1.3/4.7±0.9 Nm), Tpeak (29.0±2.6/29.3±2.0 Nm), and crank angle at Tpeak (89±8/90±9 deg). At FCPR, power output (178±2/178±3 W), pedal rate (93±4/93±6 rpm), VO2
(2.15±0.08/2.13±0.09 L min-1), HR (119±11/118±11 beats min-1), and RPE
(9.8±1.9/10.3±1.6) was also similar. Only BLC (0.9±0.4/0.7±0.2 mmol L-1) differed significantly, being 23% lower with Biopace.
Discussion

The hypotheses of a reduced Tpeak with Biopace during cycling at preset pedal rate, or lowered pedal rate and VO2 at FCPR were rejected. The lower BLC with the Biopace compared to the circular chain wheel may suggest that the non-circular chain wheel reduced fast twitch muscle fibre activity.

However, further investigations are needed to corroborate this, and to elucidate whether the small absolute difference in BLC response may affect performance when accumulated over hours of cycling or in more intense cycling.

OP2-20 Physical Education and Pedagogics 2/2 - "Turin FG"

THE PRACTICE OF PHYSICAL EDUCATION: LOOKING AT THE PAST, PLANNING FOR THE FUTURE

Hyatt, R.W., Freeman, W.H.

University of North Carolina at Chapel Hill, United States

The field of physical education has changed radically over the last 40 years. This presentation examines three periods of the university professional physical education program in the United States: (1) the traditional field of 40 years ago, (2) the more diverse focal areas of the field today, and (3) how we might plan for the future of a constantly changing field. The traditional field of 40 years ago was focused almost entirely on teacher preparation. Research within the field was primarily applied studies, with a heavy emphasis on health and fitness concerns, along with motor learning studies focused on skill acquisition by children and young people. This was natural in a field that developed from a 19th century health (rather than medical) concern about children. With the move into a more scientific focus within the field since the 1960s, today's university programs include teacher preparation, but in many cases a greater number of students are preparing to become medical professionals of one sort or another, while others are training for careers in sport businesses. Research-focused departments have largely abandoned any support for the teaching and program functions of the traditional field, focusing instead on getting students into medical-related professional schools. Technically speaking, in the new field the human body exists primarily as a locus of parts and functions, a flawed machine to be studied by kinesiologists. In short, the body is viewed mostly as a differentiated structure, not a holistic human, and certainly not something for which the applied is a major concern. So what does this mean in terms of focal areas of the field in the next half century? It means that more large programs will become (as many already are) agglomerates or consortia of a range of interests relating to sport and the human body, both moving and quiescent. This includes the old physical education and coaching interests, along with the growing sport management interests, along with the medical-related interests ranging from athletic training at the lower academic end of services to cardiac services at the upper end, including areas such as physical therapy, physician assistant programs, and medical doctors. It also may mean future curricula with combined degrees, such as Sport Management and an MBA or a law degree. In planning new curricula, we must remember that education for a profession does not end when the student crosses the stage after four years–it should continue throughout a career.

ON WHOSE TERMS? - EXPLORING YOUNG PEOPLE FROM ETHNIC MINORITY GROUPS IN SWEDEN AND THEIR VIEWS ON PE AND SPORT

Suzanne, L.

Swedish School of Sport and Health Sciences, Sweden

On whose terms?

- exploring young people from ethnic minority groups in Sweden and their views on Physical Education and Sport

Suzanne Lundvall, PhD., Swedish School of Sport & Health Sciences, Sweden

In the middle of 1990s Sweden was declared a multicultural society concerning ethnicities, languages and cultures. How do the majority and minority cultures meet in the context of physical education and the field of sport and on whose terms are they executed?

The aim of this study has been to explore, with the help of an interview study executed autumn 2004, how young people from ethnic minority groups and PE teachers in schools in multi cultural areas describe and perceive the subject PE and the field of sport. This is done through exploring the students and teachers formulated discourses in relation to the political assignment of school and to PE and sport as an issue for integration on a social, structural and/or cultural level. In total 32 students (12-18 yr) and 10 PE teachers of these students participated, chosen by a strategic sample.

Results: the school subject PE gives a considerable opportunity for participation in sports and physical activity for the interviewed students. This is specially marked for the girls. When talking about the organization of PE in school, girls place themselves in relation to boys and the male discourse of PE and sports, where they tend to demand less space and view themselves as slower, less active and with less ability. Religion and/or cultural background are not looked upon as a hindrance for exercising and/or participating in sports, although the older girls and the teachers put forward that there may be some difficulties for Muslim girls. The dominant discourses that came forward in the study were mainly based on a sport discourse with quite a narrow view on gender, movement and physical activity. Nature and outdoor activities were by the students put forward as something uninteresting, and partly, frightening.

Conclusions: in the interviews the potential of PE and sport as a tool for social and cultural integration in terms of norms and values of the sport culture of the majority culture are formulated. As long as the cultural identity of the students and their families was constrained by the lack of contact with other parts of society, this was a seen as threat for a more structural integration, not something that sport or the subject PE could contribute to. The nexus of gender in relation to physical activity has its implications and needs to be put on the agenda in terms of identifying which democratic values need to be protected.

THE POSITION OF REGULAR PHYSICAL EXERCISE IN THE LIFESTYLE OF HUNGARIAN PUBESCENT GIRLS

Hamar, P., Munkacsi, I., Soós, I.,

Semmelweis University, University of Sunderland, Hungary

Introduction: The value changes that followed the system change in Hungary resulted in some negative trends. Inactivity has become an integral part of modern life. To name but one example: the fast development of information and computer technology encourages the 'home sedens' lifestyle. A number of past and present studies have addressed this problem, amongst them Mussino (1991), Bíróné (1994), Hamar (1997) and Soós (1998).

The aim of our survey was to establish the position of physical exercise and sport in the lives of teenage girls in Hungary. More precisely, what place does regular physical exercise take in the life of pubescent girls and their families at an age which is so important in terms of future physical activity. Does the attitude towards exercise within the family influence the sport activities pubescent girls take part in? If that is the case, to what extend?

Method: Data was collected from fifteen Hungarian schools during the second half of the 2003/2004 academic year. The questionnaires were distributed with the help of P.E. teachers amongst 1,000 10 to 15 year-old primary and secondary school female students. There were two reasons for selecting one of the sexes only: one theoretical and the other practical. Firstly, female and male puberty takes place at different ages and as a result exercise and sporting habits are noticeably different. Secondly, P.E. lessons at the age period chosen are conducted in most schools in separate all-male or all-female groups and therefore the filling in of the questionnaires was easier to administer in one particular group only.

For our study, we chose the questionnaire methodology. The questionnaire used had been originally compiled by Dishman and Ickes and later revised and applied by Edit Bíróné Nagy and Bohumil Svoboda (1994). The questionnaires were completed anonymously. Subjects were able to comments on the content of the questions by selecting 'yes' or 'no' and in addition to that, where applicable, they were also able to write additional comments. The 20 questions, aimed at finding out about subjects' personal details and preferences for sport activities, were divided into two sets (set I and II).

956 of the returned questionnaires were valid for data analysis. First, percentages were calculated from the data and then the results were analysed by groups of questions and by individual questions.

Results: The results indicate that an increasing number of young girls appreciate the role of sport in keeping healthy. The most dominating factor in forming exercise habits is family background. In addition to this, schools also play an important role in encouraging students to do regular exercise. The results also indicate that the majority of pubescent girls are characterised by a kind of inactive interest in sport which does not result in exercise crucial for their physical development.

HEALTH CONSCIOUS BEHAVIOR IN PHYSICAL EDUCATION: 10-14 YEARS OLD CHILDREN EXPERIENCES

Bognár, J., Fügedi, B., Ulrik, T., Suskovics, C., Kovács, T.L., Katona, Z.

Semmelweis University, Faculty of Physical Education and Sport Sciences (TF), Hungary

Introduction

The Hungarian National Core Curriculum justifies 5 general developmental objectives. Among other factors, it denotes the maintenance of the need for physical activity and recreation for a healthy active life-style. Most physical education programs in our country are generally responsive to the needs of society. One of the most important needs for a sound physical education is to plan and carry out a systematic and progressive program for all children that is worthwhile throughout their lives. If physical education is not promoting to lifelong physical activity and healthy active life-style, then we are not fulfilling the society's and our students' expectations.

Purpose of study

A major purpose of the study was to explore how 5th-8th grade students experience and view the role and function of health in their physical education program.

Methods

Data were gathered by one of the researchers from Hungarian state primary schools from five cities in Hungary. Using purposeful sampling, altogether we collected 3.384 questionnaires from 5-8th students (10-14 years of age). All students were asked to fill out an open-ended questionnaire anonymously. Questions were focused on children PE experiences as related to health conscious behavior. Due to the levels of data, frequencies, descriptive data, and non-parametric statistics were used in the analyses with SPSS 13.0 for Windows.

Results

A large number (67.6%) of students believe that information from physical education class will be useful and beneficial for their future. The usefulness in most cases relates to the types of activities, correct sport techniques and strategies, warming up and cooling down. According to students' beliefs the purpose of physical education is to have an opportunity to be physically active (36.6%), work on strength, stamina, speed, and flexibility as parts of conditioning (33.7%), and to pursue a healthy active lifestyle (20.9%). 63.2% of the sample enjoys physical education a lot but 14.9% does not like it at all. From those who enjoy PE, the reason is they have future plans with sports and games (26.2%), such as become healthier, toned, and physically sound. 17.4% enjoys PE because there is always game time during class, 15.3% likes it due to psychological reasons, another 15.% likes it altogether, and 12.6% generally likes to be active. From those who does not like PE, the reason tends to be they do not like to be active at all (32.0%), they hate running altogether (21.3%), and PE tends to be repetitive and boring (10.7%).

Discussion/conclusions

Students have high expectations towards physical education and quiet often PE teachers cannot meet their students' expectations. From our results it is obvious that we have to further promote PE's contributions to lifelong physical activities and health. Students do not mention health and healthy active life-styles in relation to PE, so our job is to purposefully include the notion in our daily routines.

Plenary session (PLS)

PLS3 Injuries in sport - "Athene"

SPORT INJURIES AND BEYOND - A POPULATION PERSPECTIVE ON THE RISKS AND BENEFITS OF PHYSICAL ACTIVITY

Martin, B.W.

Swiss Federal Institute of Sports Magglingen, Switzerland

The health risks of physical inactivity are well documented, lack of physical activity is recognised as a world wide problem, and physical activity promotion has become an important public health issue on the national and international level. At the same time, the number of sport or exercise related injuries is substantial; in younger patients they are responsible for more than 10% of all emergency department visits and in population surveys they can make up more than 25% of all reported injuries. Both the costs of inactivity as well as the costs of sport injuries can acquire relevant dimensions, as the example of Switzerland shows where it was estimated in 2001 that about 4% of all health costs were caused by the former and about 3% by the latter. Does this mean that the overall health balance of physical activity and sports is not necessarily positive and that the intended health benefits in more physically active populations will be lost at least partly to an increase in sport injuries?

There are a number of studies in athletes and in soldiers showing that greater amounts of training are associated with greater numbers of musculoskeletal injuries. At the same time, there are also indications that the incidence of sports injuries can be reduced drastically by specific preventive measures and by optimised training interventions.

Whether the injury effects of specific sports are observed at the population level depends on the distribution of activity levels for the discipline within the different age and gender groups, and possibly also on the underlying overall activity and fitness levels of the population. Only a limited number of cross-sectional surveys have been carried out so far to study these questions on the population level. They have indicated that the cumulative risk for all injuries is comparable between groups of different activity levels; the risk for sport specific injuries may be elevated in habitually active individuals while it can even be decreased for non-sport specific injuries.

Though methodological issues still have to be solved, there are indications that shifts towards higher levels of physical activity do not have to lead to increases in overall injury risks. Taking into account that health promotion programmes usually focus on low risk activities, and that specific interventions can reduce risks in different sports even further, it should also be possible to keep the number of sport injuries constant or even reduce them.

ADVANCES IN PREVENTING SPORT INJURIES

Myklebust, G.

Norwegian School of Sport Sciences, Norway

Sporting activities have increased among people with all the positive effects for the health. In addition the number of people taken part in competing sports has risen. The high number of athletics in high level sports has increased the number of sport related injuries. With the increase of both the numbers and severity of injuries, a need of prevention studies has become essential to develop, and to try out in different sports.

The most common acute sport injury is ankle contusions. Another injury that has increased the recent years is knee ligament injuries, especially the anterior cruciate ligament (ACL) injury. ACL injuries are serious and give pain and disability for the athletes in the short run, and an increased risk of early osteoarthritis in the long run. Prevention of this injury is not important just for the athlete, but also for the society since these injuries require lots of money and efforts from the health system. There has been an increased focus on injury prevention the last years. The talk will give an overview on the advances in this field, and give examples of preventing studies of ankle, knee and muscle strain injuries. The practical implications of the prevention programs will be highlighted.

Invited symposium (IS)

IS3-01 Consensus statement on overtraining syndrome - "Athene"

CONSENSUS STATEMENT ON OVERTRAINING SYNDROME

Meeusen, R., Duclos, M., Gleeson, M., Rietjens, G., Steinacker, J., Urhausen, A.

Vrije Universiteit Brussel, Belgium

Successful training must involve overload but also must avoid the combination of excessive overload plus inadequate recovery. Athletes can experience short term performance decrement, without severe psychological, or lasting other negative symptoms. This Functional Overreaching (FOR) will eventually lead to an improvement in performance after recovery. When athletes do not sufficiently respect the balance between training and recovery, Non-Functional Overreaching (NFOR) can occur. The distinction between NFOR and the Overtraining Syndrome (OTS) is very difficult and will depend on the clinical outcome and exclusion diagnosis. The athlete will often show the same

clinical, hormonal and other signs and symptoms. A keyword in the recognition of OTS might be 'prolonged maladaptation' not only of the athlete, but also of several biological, neurochemical, and hormonal regulation mechanisms.

It is generally thought that symptoms of OTS, such as fatigue, performance decline, and mood disturbances, are more severe than those of NFOR. However, there is no scientific evidence to either confirm or refute this suggestion. One approach to understanding the aetiology of OTS involves the exclusion of organic diseases or infections and factors such as dietary caloric restriction (negative energy balance) and insufficient carbohydrate and/or protein intake, iron deficiency, magnesium deficiency, allergies, etc. together with identification of initiating events or triggers. In this symposium we provide the recent status of possible markers for the detection of OTS. Currently several markers (hormones, performance tests, psychological tests, biochemical and immune markers) are used, each of them will be outline by one of the presenters. First Dr Gleeson will present the current knowledge on immunological factors anf the link with OTS. Dr Nicolas Lemyre will give an overview of possible psychological features that might be detected with specific psychological tests. Dr Axel Urhausen will present clinical aspect of OTS, especially guideline for the 'exclusion diagnosis' for OTS

During the panel discussion we propose and explain a "check list" that might help the physicians and sport scientists to decide on the diagnosis of OTS and to exclude other possible causes of underperformance.

PSYCHOLOGICAL ASPECTS OF THE OTS

Lemyre P., NO

Without abstract submission.

CLINICAL ASPECTS OF THE OVERTRAINING SYNDROME

Urhausen, A.

Centre Hospitalier de Luxembourg, Luxembourg

As there is no single diagnostic tool to identify an athlete as suffering from an overtraining syndrome (OTS), diagnosis can only be made after exclusion of all other possible influences on changes in performance and mood state. Early and unequivocal recognition of OTS is virtually impossible because the only certain sign is a plateau or decrease in performance during competition or training. The definitive diagnosis of OTS always requires the exclusion of an organic disease, e.g. endocrinological disorders (thyroid or adrenal gland insufficiency, diabetes mellitus), iron deficiency especially with anaemia or infectious diseases (especially infectious mononucleosis, myocarditis).

Despite interesting theoretical assumptions, the validity of the heart rate variability in the diagnosis of OTS is not well established at present and the existing findings in overtrained athletes are confusing. Ergometric tests may reveal a decrement in sport-specific performance if they are maximal tests until exhaustion: Overtrained endurance athletes usually present an impaired anaerobic lactacid performance and a reduced time-to-exhaustion in standardized high-intensity endurance exercise accompanied by a small decrease in the maximum heart rate. Lactate levels are also slightly lowered during submaximal performance resulting in a slightly increased anaerobic threshold. Often the respiratory exchange ratio during exercise is also decreased. A deterioration of the mood state and typical subjective complaints ("heavy legs", sleep disorders) represent sensitive markers in study conditions, however, they may be manipulated, which is especially relevant in team sports. Although measurements of selected blood markers such as urea, uric acid, ammonia, enzymes (creatine kinase activity) or hormones including the ratio between (free) serum testosterone and cortisol, may serve to reveal circumstances which for the long-term impair the exercise performance, they are not useful in the diagnosis of an established OTS. The nocturnal urinary catecholamine excretion and the decrease in the maximum exercise-induced rise in pituitary hormones, especially adrenocorticotropic hormone and growth hormone, and, to a lesser degree, in cortisol and free plasma catecholamines, often provide interesting diagnostic information, but hormone measurements are less suitable in practical application.

From a critical review of the existing overtraining research it must be concluded that there has been little improvement in recent years. The lack of validity of variables in diagnosing an OTS, however, does not mean that these measures are not useful in the monitoring of training and thus, in the long term, in the prevention of an OTS.

Invited symposium (IS)

IS3-02 Children and exercise - "Innsbruck"

A BEHAVIOURAL PERSPECTIVE ON ENERGY-BALANCE RELATED BEHAVIOURS IN CHILDREN

van Mechelen, W., de Bruijn, G., Kremers, S., Brug, H.

VU University Medical Centre, Netherlands

In current society overweight and obesity are a major public health concern, which is increasing exponentially in importance in modern society. We are not only dealing with a problem in the adult population, but also in the paediatric population. The latter is witnessed for instance by the growing cases of type II diabetes mellitus in children. In the aetiology of this problem many factors play an important role. Next to genetic factors, behavioural factors also play an important role. Behavioural factors linked to overweight and obesity are nutrition and physical activity, nowadays referred to as 'energy-balance related behaviours' (EBRB's). In explaining behaviour many models have been applied so far, including models such as the Theory of Reasoned Action and the Theory of Planned Behaviour. Common denominator of such models is that they apply the principle that human behaviour is a function of cognitive behavioral principles in which behavioural intention is the strongest predictor of actual behaviour. However, there is increasing evidence that behaviour is not only directed by cognition, but also by a wide variety of environmental factors, as explained by so-called ecological models. Also, many behaviours are not based on cognition at all, but are 'automated' behaviours (i.e. habits). Bottom line is, that in order to change EBRB's effectively one needs to take into account all these determinants of behaviour. In this presentation examples on these issues will be given based on recent work by our group on behavioural determinants of EBRB's.

A GENETIC PERSPECTIVE

Wilkin T., UK

Without abstract submission.

A GENE-LIFESTYLE INTERACTION PERSPECTIVE

Franks, P.W.

Umea University Hospital, Sweden

Features of the metabolic syndrome are becoming increasingly common in children. Although a decline in children's physical activity levels during the past 40-50 yrs is likely to be an important aetiological factor, the degree of susceptibility to a sedentary lifestyle varies considerably from one child to the next. Indeed, some sedentary children are aerobically fit and have healthy metabolic profiles, whilst others appear highly susceptible to the adverse metabolic consequences of physical inactivity. Thus, other risk factors, such as genetic variation, plausibly modify the effects of physical activity on obesity and metabolism, such that children who carry specific genetic variants may benefit most from maintaining a physically active lifestyle. Identifying the nature of gene-lifestyle interactions may help elucidate the physiological pathways that lead to metabolic disease in childhood. This information may also be used to optimize lifestyle intervention programmes that use genetic information to optimize disease prevention.

Invited symposium (IS)

IS3-03 ACSM symposium: Diabesity - "St. Moritz"

DRUGS OR EXERCISE FOR OBESITY, DIABETES AND THE METABOLIC SYNDROME?

van Baak, M.

Maastricht University, Netherlands

Worldwide the prevalence of obesity, the metabolic syndrome and type 2 diabetes are increasing. It is well recognised that a healthy lifestyle, incorporating a sufficient level of physical activity and a healthy diet, will contribute to the prevention of these disorders. The effectiveness of increasing levels of physical activity in weight management has long been recognised, although it is clear that the weight reducing efficacy of increased physical activity is small in comparison with that of dietary restriction. The recent diabetes prevention trials in the US and Europe clearly show that a lifestyle intervention, including moderate weight loss, a healthy diet and increased physical activity, may postpone the development of type 2 diabetes in subjects with impaired glucose tolerance. A secondary analysis of the European trial demonstrated that within this healthy lifestyle intervention the physical activity component contributed significantly to this outcome. The US trial showed that the lifestyle intervention also reduced the risk of developing the metabolic syndrome in the participants. An exercise training programme alone has also been found to reduce this risk. Based on these and other similar findings, increased levels of physical activity of physical activity are clearly indicated in the prevention of obesity, the metabolic syndrome and type 2 diabetes.

Once obesity, the metabolic syndrome or type 2 diabetes are present, there is still a role for increased physical activity, because it will tackle all associated risk factors. A comparison between the effectiveness of drug treatment and increased levels of physical activity in is obviously difficult to make, but it is clear that the effects of increased activity will have a positive influence on all risk factors (apart from other health effects), whilst drug treatment will usually be targeted at one risk factor only.

In many cases a lifestyle intervention may be not sufficient to fully normalise the risk factors for the development of atherosclerotic cardiovascular disease or type 2 diabetes associated with obesity or the metabolic syndrome. The reason may be low compliance to the healthy lifestyle, or too high levels of these risk factors. In such cases additional drug treatment is needed. Because there are no drugs available that will tackle all risk factors simultaneously, this may lead to treatment with multiple drugs and associated side effects and compliance problems.

INSULIN RESISTANCE, THE METABOLIC SYNDROME AND DIABESITY: THE ROLE OF FITNESS AND FATNESS

Goodpaster, B.

University of Pittsburgh, United States

Insulin resistance is a critical factor in the development of type 2 diabetes. Although generalized obesity and aging have been associated with insulin resistance and type 2 diabetes, the relative roles of physical inactivity and body fat distribution in the etiology and treatment of insulin resistance warrant further attention. Obesity, aging, physical fitness, body fat distribution are all associated with insulin resistance and the metabolic syndrome. Moreover, exercise and diet-induced weight loss independently improve insulin resistance in obese, older adults who are at high risk for the development of type 2 diabetes.

EFFECTS OF STREPTOZOTOCIN-INDUCED DIABETES AND PHYSICAL TRAINING ON GENE EXPRESSION OF TITIN-BASED STRETCH SENSING COMPLEXES IN MOUSE STRIATED MUSCLE

Lehti, M., Silvennoinen, M., Kivelä, R., Kainulainen, H., Komulainen, J.

LIKES Research Center for Sport and Health Sciences, Neuromuscular Research Center, Finland

It is well known that endurance training enhances oxidative metabolism as well as e.g. glucose transport activity and these phenomena are markedly reduced in diabetes. Experimental (streptozotocin-induced) diabetes is accompanied by the reduction in weight gain and skeletal muscle atrophy. In striated muscle a sarcomeric non-contractile protein, titin, forms the backbone of the stress and strain sensing structures. We investigated the effects of diabetes, physical training, and their combination on the gene expression of proteins of titin stretch sensing complexes in skeletal and cardiac muscle.

Mice were divided to control (C), training (T), streptozotocin-induced diabetic (D), and diabetic training (DT) groups. Training groups performed 1, 3, or 5 weeks of endurance training on a motor-driven treadmill (1 h / day / 21 m/min). Muscle samples from T and DT groups together with respective controls were collected 24 hours after the last training session. Total RNA was isolated from the left calf (soleus, gastrocnemius and plantaris) as well as from the cardiac muscle. Gene expression was analysed with Affymetrix GeneChip (MG_U74A V2) and further processed with Microarray Suite and GeneSpring softwares. Proteins of titin-based stretch sensing complexes were trawled and Wilcoxon's Signed Rank test was used to derive biologically meaningful results from the raw probe cell intensities on expression arrays. Microarray results were verified and supplemented with quantitative PCR analyses.

Diabetes induced changes in mRNA expression of the proteins of titin stretch sensing complexes in Z-disc (MLP, myostatin), I-band (CARP, Ankrd2), and M-line (titin kinase signalling, SLIM3). mRNA level of MLP, CARP and Ankrd2 were increased while that of myostatin was decreased in diabetic skeletal muscle. Expression of SLIM3 mRNA was decreased in skeletal as well as cardiac muscle. In addition, mRNA levels of the titin kinase signalling pathway proteins were affected in skeletal muscle. Training alleviated diabetes-induced changes of most mRNA levels in skeletal muscle.

In conclusion, in streptozotocin-induced diabetes mRNA levels of the proteins of titin-based stretch sensing complexes were influenced substantially more in skeletal than in cardiac muscle. In skeletal muscle, we showed diabetes-induced changes in mRNA levels of several fiber type biased proteins (MLP, myostatin, Ankrd2). These results are consistent with the previous observations of diabetes-induced atrophy leading to slower fibertype composition. The ability of exercise to alleviate diabetes-induced changes may indicate slower transition of fiber type.

ENERGY AND EFFICIENCY ANALYSIS OF THE GOLF SWING

Nesbit, S., Elzinga, M.

Lafayette.edu, United States

An energy and efficiency analysis of the golf swing is presented. Full-body computer models were used to estimate the energy production, transfers, and conversions within the body and the golf club. Four amateur subjects were analyzed and compared. The energy approach determined the force and torque components that accelerated the club, illustrated which body segments produced work, determined the timing of internal work generation, measured swing efficiencies, and proved that forces and range of motion were equally important in developing club head velocity.

The generation of work comes primarily from the back and hip joints generating 71.8, 72.2, 70.0, and 68.7 percent of the total body work for the subjects. This core body work is generated by high torques over the entire range of motion of the hip joints, and moderate but consistent torques applied over the considerable twisting range of motion of the spine. The secondary source of the body work comes from the joints of the shoulders and arms accounting for 24.7, 24.2, 26.2, and 28.0 percent of the total body work for the subjects. These joints generate their work primarily through large displacements, especially the right elbow, and in the case of the right wrist and shoulder, two DOF motion. The leg joints generate the remainder of the body work (3.6,3.6, 3.8, and 3.3 percent for the subjects).

The generation of work and its transference to the club appears to be a bottom up and outward event where a type of segmental summation of work occurs from the legs, through the hips, lower back, upper back, shoulders, arms, then wrists. The work generation in each joint generally peaks in the same order from distal to proximal. The work of the individual joints then stops increasing as the work is transferred upward, and the more distal joints change their function from doing work, to providing static support. The generation of joint work is equally dependent upon range of motion of the joint, and the ability to maintain consistent torques over the range of motion. An important measure of the efficiency of the golf swing is how much of the internal work is transferred to the golf club (24.5%, 20.2%, 26.1% and 26.8% for the subjects).

The internal body work is transferred to the club by and through the arms and wrists highlighting their dual work generating and structural functions. The external force, linear work, and linear power are transferred to the club via pulling on the club by and through the arms. The external torque, angular work, and angular power are transferred by and through the wrists. The large range in output torque and force values among subjects are tempered by each subject's ability to maintain these forces and torques over the range of motion of the downswing, thus the differences in club head velocities are not nearly as pronounced as the differences in forces and torques would imply.

MOTOR ADAPTATION DURING GOLF PUTTING

Reinkensmeyer, D., Wolbrecht, E.

University of California at Irvine, Vanuatu

A large number of recent studies have highlighted the key role that anticipatory control plays in motor adaptation during reaching, drawing, and walking. For example, when people are unexpectedly exposed to a novel force field created by a robot, their reaching paths initially become curved, but gradually straighten with practice [1]. When the force field is unexpectedly removed, the reaching paths become distorted in a way that indicates the motor system was anticipating the force field. This anticipation has been attributed to the

construction of an "internal model," a sensory motor mapping between limb state and muscle activation. The process of internal model formation can be mathematically described by a simple difference equation, which can be viewed as arising as a consequence of the use of an error-based, neural learning law. Here we studied whether the motor system uses internal model formation to control the accuracy of golf putting. A healthy adult subject practiced putting on a flat surface toward a hole-like target two meters away. A lightweight robot was attached to the head of the golf putter. Following an initial practice period with the robot passive, the robot unexpectedly applied a velocity dependent force field that slowed the putter head during the forward putting stroke. As a consequence, the subject putted the golf ball too short a distance. With practice over 60 putts, however, the subject gradually adapted to the force field and improved his putting accuracy. Then, when the force field was unexpectedly removed, the subject putted the ball too long a distance. This "after effect" persisted for approximately 40 putts. The presence of an after effect of adaptation indicates that the motor system modified its internal model of the golf putter to account for the altered putter dynamics when the robot resisted the putting stroke. The pattern of gradual adaptation and gradual de-adaptation were consistent with the error evolution observed during adaptation to novel force fields for reaching, drawing, and walking. These results indicate that the motor system updates an internal model of the putter dynamics on a putt-to-putt basis using an error-based learning law. Therefore, recently developed techniques for enhancing motor learning by amplifying errors during reaching [2] and walking [3] may also be applicable to golf putting.

EARLY PUTTING PRACTICE WITHOUT ERRORS RESULTS IN A STROKE UNAFFECTED BY EXTERNAL DISTRACTIONS

Poolton, J., Maxwell, J.P., Masters, R.S.

The University of Hong Kong, Hong Kong

Introduction

Golfers appear at large to be habitual hypothesis testers; even top professionals (famously, Nick Faldo and Tiger Woods) make swing changes in the hope of perfecting their performance. However, explicit control of movement (dependent on working memory) resulting from hypothesis testing behaviour can be disruptive to performance in certain situations (e.g., dual-task conditions or under pressure). Maxwell et al. (2001) proposed that one way to inhibit hypothesis testing, and so, encourage implicit motor acquisition, is to minimise errors in learning. Maxwell et al's 'errorless' learning paradigm for golf putting resulted in superior performance and robust performance under dual-task conditions. Maxwell et al. later showed that the initial period of learning, in which errors were dramatically reduced, seemed to be crucial for implicit learning despite later accumulation of explicit knowledge; we examined this hypothesis.

Method

The task required participants to putt to a hole cut to PGA regulations. Novice participants were randomly allocated to either an Implicit-Explicit (n =17) or an Explicit treatment condition (n =18). Replicating Maxwell et al's putting protocol, participants completed 8 blocks of 50 learning trials beginning 25 cm from the hole. After each block, putting distance increased in increments of 25 cm to a final putting distance of 200cm. Participants either received instructions on putting technique prior to learning (Explicit condition) or prior to the fourth block of trials (Implicit-Explicit). In the Test Phase, participants completed a dual-task transfer test (tone counting), sandwiched between two retention tests. Each test consisted of 50 trials from 200 cm.

Results & Discussion

Analysis of the Test Phase revealed a significant Group x Block interaction ($F(2, 32) = 4.59$, $p < .01$). Relative to both retention tests, dual-task conditions disrupted performance in the Explicit condition; whereas, performance in the Implicit-Explicit condition improved. Notably, the performance breakdown exhibited by explicit learners was correlated with a reduction in the number of visible adjustments made to technique ($p < .05$). It appears that the additional task interfered with movement modification and explicit control; consequently, performance was disrupted. The failure of the Implicit-Explicit condition to breakdown, despite having technical information of the putting stroke, suggests that they were not dependent on the availability of their explicit knowledge for movement control.

Exploiting the benefits of implicit motor learning in golf (e.g. robustness under pressure) is problematic. It appears difficult to limit explicit knowledge accumulation during the extensive bouts of practice that it takes to become an expert. The solution may be to limit the number of errors during initial learning experiences.

IS3-05 Force production and force transmission in skeletal muscles - "Berlin ABC"

BEHAVIOR OF ACHILLES TENDON AND GASTROCNEMIUS APONEUROSIS DURING CONCENTRIC AND ECCENTRIC PLANTAR FLEXIONS

Kawakami, Y., Sugisaki, N., Chino, K., Kanehisa, H., Fukunaga, T.

Waseda University, Japan

There is increasing evidence of substantial muscle-tendon interaction in human skeletal muscles. For instance, during isometric plantar flexion, fascicles can shorten by as much as 30% of their initial length (1). This shortening occurs primarily at the expense of elongations of the series elastic components (tendinous tissues for the most part). In pennate muscles, the tendinous tissues are comprised of external tendons and aponeuroses, the latter of which have been shown to be more compliant than the former (2). A recent study in animals, however, showed different strains for active contraction and passive loading even if the tension is the same (3). Recently we have further shown inconsistent behavior of the aponeurosis and external tendon of the medial gastrocnemius muscle (MG) when the subjects per-

formed maximal and submaximal concentric (CON) and eccentric (ECC) plantar flexion exercises (4). Each exercise was preceded by an isometric action (Pre-iso) on an isokinetic dynamometer. In addition, the subjects performed static ramp actions with the ankle positioned at dorsi- and plantar flexed positions. During the exercises, the length changes of the aponeurosis and external tendon of MG were determined using ultrasound apparatuses. In CON, the length of external tendon significantly shortened from the level of Pre-iso in all test conditions. However, the change of aponeurosis was significant only in the maximal exercises. In ECC, the external tendon was elongated in all test conditions, while the aponeurosis was not elongated even in the maximal effort. In static action, the lengths of both aponeurosis and external tendon increased with increasing force levels. The present results indicate that the behavior of aponeurosis of MG depends on the type of action and that the aponeurosis of MG plays a simple role of muscle force transmission in eccentric actions, while external tendon functions to store elastic energy.

MUSCLE - TENDON INTERACTION IN HUMAN GASTROCNEMIUS DURING WALKING AND RUNNING

Wilson, A.M., Lichtwark, G.A.

The Royal Veterinary College and University College London, United Kingdom

The simplest representation of a muscle tendon unit (MTU) comprises a muscle fascicle (MF) in series with an elastic element (the tendon and aponeurosis, EE). The relative proportion of the contractile and elastic elements of the unit vary between muscles and species, but athletic animals like the horse and wallaby can have very long tendons and short muscle fibres in limb extensor muscles. The most similar muscle in humans is the triceps surae complex which has a long tendon that achieves high strains.

Tendons are elastic and can store energy by stretching when under load. Having a tendon in series with a muscle component means that the length change over time can differ between the MF and the MTU as a whole. For instance

1. The MF can remain isometric (hence doing no mechanical work) whilst the EE stretches and then recoils (seen in human hopping).

2. The MF can shorten gradually storing energy in the EE which is then released with a high shortening velocity. This can enable a MTU to perform work at a velocity higher than the MF can achieve directly.

3. Finally in cyclical movement the MTU can function across a range of external conditions whilst the MF always functions at close to its optimum contraction conditions for power or efficiency.

We have investigated these mechanisms in the medial gastrocnemius (MG) component of the human triceps surae muscle during hopping, walking and running. We have measured Achilles tendon strain during dynamic activities by tracking the position of the muscle tendon junction relative to its insertion on the calcaneous. This is achieved by combining motion analysis with ultrasound imaging. Similarly, we have measured MF length using ultrasound imaging. Our results indicate that the Achilles tendon is a highly compliant structure that can strain as much as 8-10% during high force activities, like one legged hopping, and 4-6% during walking and running. The energy stored in and returned from the tendon during hopping was found to account for approximately 16% of the total mechanical energy required for the hop.

During human gait under different conditions, MFs were found to act isometrically during force production and perform the required work during force decline. This has important implications for energetics of gait, because it allows the muscle to produce force under conditions which minimise energetic consumption and maximise force production (isometric conditions). This can only be achieved with a long, compliant tendon. We demonstrate this with a simple Hill-type muscle model which predicts that GM muscle efficiency during walking and running is maximised with a tendon very similar to the average stiffness we have measured. This is most evident in running, where high MTU shortening velocities are required.

THE ROLE OF TENDON AND APONEUROSIS IN FORCE TRANSMISSION IN UNI-PENNATE MUSCLES

Herzog, W.

University of Calgary, Canada

Tendon and aponeurosis have been associated with storing and releasing energy during cyclic movements. This storage and release of energy has typically been related to a reduced metabolic cost of movement. However, when calculating the energies stored and released, tendon and aponeurosis have been assumed to be arranged in series with each other and in series with the contractile fibres. Although tendons are clearly arranged in series with the muscle belly, the mechanical role of aponeuroses relative to the contractile fibres and tendons is much more complex and needs careful evaluation. Here, we performed in situ and in vivo experiments with the cat medial gastrocnemius, a uni-pennate muscle, and demonstrated that the aponeuroses of this muscle are not arranged in series with either the tendon or the muscle fibres. These results are explained with a theoretical model demonstrating that it is the incompressibility of the muscle that makes the arrangemnt of fibres, aponeuroses and tendon much more complex than a simple in series force transmission. Assuming incorrectly that the aponeuroses are in series with the muscle fibres and tendon would give a vast overestimation of the energy contributions of the aponeuroses to medial gastocnemius function. We conclude from this study that the role of aponeuroses needs careful evaluation and justification for each muscle before assuming an in series arrangement with tendon and fibres, and published results on aponeuroses function need careful interpretation.

INFLUENCE OF PASSIVE FORCE ENHANCEMENT ON ACTIVE FORCE ENHAMCEMENT

Tihanyi, J., Rácz, L., Trzaskoma, L., Costa, A.

Semmelweis University, Faculty of Physical Education and Sport Science, Budapest, Hungary

Introduction. The muscle tension remains elevated having terminated the stretch for a certain period of time called passive force enhancement (PFE). There are several theories explaining this phenomenon. Herzog and Leonard (2002) suggested that the passive force enhancement could be attributed to the increased stiffness of the passive elastic elements. We hypothesized if the muscle stiffness increases due to previous stretch then a second stretch may elicit a greater active force enhancement than the first stretch.

Material and methods. Six physically active male subjects were recruited in this study. The knee extensors of the non-dominant leg were used to test our hypothesis. The subjects were placed in a dynamometer (Muli-Cont II) in sitting position. Isometric torque (Mic) was performed at a joint angle of 30, 40, 50, 70, 80 and 90 degrees. Muscle stretch was carried at a pretension of 0.8Mic by applying 30/s constant velocity flexing the knee between 30 and 50, 40 and 50, 70 and 90, 80 and 90, respectively. Also, eccentric contractions were carried out between 30 and 40 followed by a second stretch between 40 and 50 with 200 ms delay. Similar procedure was done in the descending limb of torque-angle curve initiating the first stretch at 70 followed by the second stretch at 80. EMG activity of vastus lateralis and biceps femoris was also measured.

Results. In the ascending limb of torque-angle curve the eccentric torque was greater with 16% compared with Mic estimated at 40. After the first stretch the torque dropped to the isomeric torque level indicating no PFE. Applying the second stretch after 200 ms the torque increased and the AFE was 7% compared with Mic at 50. In the descending limb of the torque-angle curve at the first stretch the AFE was 32.6 % and torque remained in this level during 200 ms indicating a 33.3% PFE. The torque enhanced during the second stretch and the maximum eccentric torque was 61.3 % higher than the isometric torque at 90. The AFE was 15.2% greater when we applied double stretch compared to the AFE of the single stretch carried out between 80and 90. No significant difference was found in EMG activity of the muscles comparing the different experimental conditions.

Discussion. In agreement with the previous studies we found that active force enhancement is lower at the ascending limb of the torque-angle curve than at the descending limb. We did not experience PFE at the ascending limb which can be explained by the fact that passive elements do not contribute the force enhancement when the muscle works about resting length. On the other hand our results indicate, that the passive force enhancement may play a significant role in increasing eccentric force of the stretched muscle at the descending limb due to the increased stiffness of the passive elastic elements as Herzog and Leonard (2002) suggested.

RESPIRATORY ACIDOSIS BUT NOT METABOLIC ACIDOSIS DELAYS THE DEVELOPMENT OF FATIGUE DURING INTERMITTENT EXERCISE OF HIGH INTENSITY OF A SMALL MUSCLE GROUP IN HUMAN

Hilbert, M., Shushakov, V., Martens, T., Maassen, N.

Medical School Hannover, Germany

Introduction:

Low pH is said to impair several mechanisms, which contribute to muscular performance. Nevertheless, there is increasing data about a preserving effect of acidification on muscle power and excitability (1).

The aim of this study was to compare the influence of respiratory and metabolic acidosis on performance, m-wave and metabolism in intermittent exercise of high intensity.

Methods:

The tests were performed in two separated groups, one with respiratory acidosis (RAC) and a control group (CON,n=9), the other with metabolic acidosis (MAC) and a placebo group (PLA,n=8). The subjects performed handgrip interval exercise with maximum power. Each test consisted of a pre-period (20/90min (RAC/MAC), P1), an intermittent exercise period (10min, P2; 15s work/ 45s rest) and a recovery period (10min, P3). In P1 with PLA and MAC the subjects' were administered 0.12g/kgBW CaCO3 and 0.07g/kgBW NH4Cl, respectively, dissolved in fruit juice (MAC: pHart at the end of P1: 7.34±0.02; CON/PLA: 7.42±0.01). In CON the subjects breathed normal, whereas in RAC the subjetcs' PCO2 was increased by re-breathing before exercise (pHart at the end of P1: 7.36±0.02). This pH-level was maintained in P2 and P3. [K+], [Na+], pH and [lactate], were measured in venous and arterialized blood. Mechanical parameters and heart rate were monitored, m-wave was recorded by surface electrodes. For measurement the motor point of the muscle was stimulated supramaximally with rectangle constant current pulses before and after each exercise bout.

Results:

The pHven during exercise was significantly different ($p<0.001$) between CON/RAC and PLA/MAC, respectively (mean in P2: CON: 7.20±0.03; RAC: 7.16±0.03; PLA: 7.23±0.03; MAC: 7.16±0.03). Performance in RAC was significantly less decreased than in CON ($p<0.01$), no difference between MAC/PLA. M-wave area in P2 was significant lower with acidosis than with CON and PLA, respectively (RAC: $p<0.001$; MAC: $p<0.05$), and lower with RAC than with MAC ($p<0.001$). Duration of m-wave was not different between RAC/CON, but with MAC it was significantly longer than with PLA ($p<0.001$). [Lactate] was decreased with acidosis, but lactate release and muscle-VO2 were not different between RAC/CON or MAC/PLA. The plasma [K+] with MAC was significantly higher than with PLA during the experiment, no difference occurred between RAC/CON. The [K+]-release during exercise was not different.

Discussion:

The reasons for the different effects of acidosis on performance might result from the accumulation of CO2 in the muscle cell and the subsequent decrease in pH. This might have influenced intracellular mechanisms of the excitation-contraction-cycle (2,3). The effects on the [K+] in MAC might be explained by a partly inhibition of the Na+/K+-pump. Nevertheless, we found no correlation between m-wave area and power.

PREECLAMPSIA IS ASSOCIATED WITH EXAGGERATED OXIDATIVE STRESS AND PULMONARY HYPERTENSION AT HIGH ALTITUDE – A NOVEL RISK FACTOR FOR HAPE DURING THE PRACTICE OF SPORTS AT HIGH ALTITUDE?

Schwab, M., Jayet, P.Y., Thalmann, S., Stuber, T., Hutter, D., Salinas, C., Cucchia, C., Spielvogel, H., Villena, M., Allemann, Y., Sartori, C., Scherrer, U.

Botnar Center for Extreme Medicine, University Hospital, Lausanne, Switzerland

High-altitude pulmonary edema is the most frequent life-threatening disease occurring during the practice of sports at high altitude. Exaggerated pulmonary HT and an individual predisposition are hallmarks of HAPE but the mechanism that underpins this individual susceptibility is unknown. There is increasing evidence that not only genetic, but also epigenetic mechanisms play an important role in the pathogenesis of human disease. The "Fetal Programming Theory" postulates that adverse events in predispose to disease in adulthood. In line with this theory, preliminary data from our group indicate that preeclampsia predisposes the offspring to exaggerated hypoxic pulmonary hypertension in later life, but the mechanism is unknown. Exaggerated pulmonary hypertension could be related to a structural (defective pulmonary angiogenesis, vascular remodeling) or functional defect. We, therefore, assessed carbon monoxide diffusion capacity (DLCO), and measured pulmonary-artery pressure (systolic right ventricular to right atrial [RV-RA] pressure gradient, echocardiography) before and during nitric oxide inhalation (40 ppb) in 27 young (age, 12±2 years, X±SE) healthy Bolivian offspring of preeclampsia and 68 sex- and age-matched offspring of normal pregnancies in La Paz (3600 m). The systolic RV-RA gradient was, as expected, roughly 36 percent higher in offspring of preeclampsia than in controls (34±1 vs. 25±1 mmHg, P<0.001). We found no evidence for defective pulmonary angiogenesis, since DLCO was comparable in the two groups. The exaggerated pulmonary hypertension was related, at least in part, to a functional defect, since nitric oxide inhalation caused an almost twice as large (P<0.001) decrease in pulmonary-artery pressure in offspring than in controls. In a second step, we tested for underlying mechanisms of this functional defect. Preeclampsia is associated with augmented oxidative stress in the mother as well as in the offspring, and in experimental animals, oxidative stress facilitates hypoxic pulmonary vasoconstriction. We, therefore, examined the effects of the antioxidant vitamin C on pulmonary-artery pressure in the two groups. Vitamin C significantly decreased pulmonary-artery pressure (by 6.5±1.3 mm Hg, P=0.002) in the offspring, but had no detectable effect in controls. In conclusion, these findings provide the very first evidence that preeclampsia leaves a persistent and potentially fatal epigenetic imprint in the pulmonary circulation of the offspring living at high-altitude, namely augmented oxidative stress, which predisposes to exaggerated hypoxic pulmonary hypertension in later life. We speculate that offspring of preeclampsia may be at risk to develop HAPE when practicing sports at high altitude. If so, prophylactic administration of antioxidants may prevent this life-threatening complication.

CYCLOOXYGENASE INHIBITION REDUCES THE PRESSURE REFLEX TO RHYTHMIC HANDGRIP EXERCISE IN HYPOXIA

Burtscher, M., Riedmann, G., Likar, R.

University of Innsbruck, Austria

Recently we observed attenuated cardiovascular and ventilatory responses to exercise in hypoxia when pre-treated with aspirin (1). Thus, an important role of prostaglandins on ergoreceptor activation may be assumed. This assumption is supported by the findings that hypoxia increases prostaglandin levels and that cyclooxygenase inhibition might attenuate the muscle ergoreceptor response (2). The purpose of the present study was to evaluate the effect of cyclooxygenase inhibition on the hypoxia-related exercise pressure reflex and its main determinants.

Six healthy and fit male subjects (38±12 yrs, 73±8 kg, 179±4 cm) performed rhythmic handgrip exercise for 50 s (1 rep/s) at about 50% of maximal voluntary contraction. Exercise was performed during normoxic and hypoxic (12 % oxygen) conditions with and without forearm occlusion (during exercise and 1 min post-exercise), and with and without cyclooxygenase inhibition by aspirin (10 mg/kg). Hemodynamic responses were monitored with the Physio Flow impedance device (Manatec, France).

Without aspirin pre-treatment the mean arterial pressure response (deltaMAP) to exercise was greater during hypoxia than normoxia without (means ± SEM: 13.0±7.0 vs. 2.0±1.5 mmHg) and with (11.7±4.6 vs. 6.7±4.3) forearm occlusion. With aspirin pre-treatment, however, values between hypoxia and normoxia were similar without (5.3±3.5 vs. 4.3±2.7 mmHg) and with (7.7±4.4 vs. 5.3±6.1 mmHg) forearm occlusion. P<0.05 for treatment-dependent differences between hypoxia and normoxia (without occlusion). In contrast, heart rate responses were enhanced in hypoxia but remained unaffected by aspirin intake. In all conditions, 1 min post-exercise the MAP was not different from baseline.

The hypoxia related increase of the arterial pressure response to handgrip exercise has been prevented by aspirin pre-treatment. The heart rate responses to exercise might mirror a central command which, however, was unaffected by cyclooxygenase inhibition. The deltaMAP was the same with and without forearm occlusion, indicating that group IV fibres may not have contributed considerably to the pressure reflex in hypoxia. Thus, the exercise pressure reflex in hypoxia is thought to be mainly mediated by group III afferents. Because this reflex is attenuated by cyclooxygenase inhibition it is supposed that mechanoreceptors are sensitised by prostaglandins in hypoxia.

HORMONAL INFLUENCES ON THE IMMUNE FUNCTION DURING ACUTE AND CHRONIC HIGH ALTITUDE EXPOSURE

Ermolao, A., Travain, G., Tolomio, S., Zilli, C., Siviero, M., Facco, M., Zaccaria, M.

University of Padova, Italy

We recently observed that acute and chronic high altitude (HA) exposure can modify number and function of immune cells, leading to a disruption in the homeostatic regulation of Th1/Th2 immune responses*. The autonomic nervous system (ANS) and the hypothalamic-pituitary-adrenal (HPA) axis have been demonstrated to play a critical role in mediating many physiological adaptations to HA exposure. Both these systems are also known to modulate the immune function through cortisol (C) and catecholamines secretion.

AIM To evaluate possible relationships between stress hormones activation and immunological parameters during acute and chronic HA exposure.

METHODS 13 moderately active healthy women (age 21.3±3.1yr) reached after 5 days of trekking the Pyramid Laboratory at 5,050 m (Lobuche, Nepal) where they spent 21 days. Before and after HA exposure (SL1 and SL2), and in the first (P1) and 21th day spent at HA (P2), we collected blood samples for peripheral white blood cells, their subsets, IFN-γ, IL-4 and 24-h urine samples for norepinephrine (NE) epinephrine (E) and C.

RESULTS During HA exposure, total lymphocytes, compared to SL1 value significantly decreased at P1, rose at P2 and returned to their basal values at SL2 (SL1 2.0±0.5x103/ml, P1 1.3±0.6, p<.005; P2 2.4±0.6, p<.005, SL2 1.6±0.6, p=n.s).

In particular CD3+ T lymphocytes percentage fell respect to SL1, owing to a significant CD4+ T-cell fall (from 50.4±4.2 to 32.1±8.2, p<.001 at P1, and to 32.0±8.8 p<.01 at P2).

The percent of Natural Killer cells (NK) significantly increased both at P1 and at P2 (CD16+: SL1 14.2±4.5, P1 25.0±2.6 p<.001, P2 21.4±4.6, p<.001 and CD56+: SL1 12.5±5.2, P1 28.2±5.7 p<.001, P2 24.6±3.4, p<.001) while returned to basal values at SL2. From a functional viewpoint, the expression of IFN-γ (a typical Th1/Tc1 cytokine) significantly decreased at P1 and P2 respect to SL1 values (Mean Fluorescence Intensity: 32.0±8.5 at SL1, 19.2±5.5, p<.005 at P1, and 7.0±3.7, p<.005 at P2), whereas IL-4 (a typical Th2/Tc2 cytokine) didn't change.

Among stress hormones, only NE significantly increased at P1 and at P2 respect to SL values (from 178.6±69.2nmol/24h to 498.3±225.2 p<.001 and to 520.8±282.6 p<.005, respectively), E showed only a positive trend (p=.08), while C, respect to SL1 raised significantly at P1 (p<.01) and P2 (p<.05), but showed significantly lower values at SL2 (p<.005). CD3+, CD4+ and NK cells demonstrated a large and significant correlation with NE and C, (R ranged between 0.4 and 0.6), however only NE levels well correlated with IFN-γ expression (R=.537, p<.005).

CONCLUSIONS Our data suggest that the ANS and the HPA axis played a central role on the cellular and functional immunologic adaptations observed at HA. Specifically, the ANS activity, through NE secretion, may be one of the mechanisms responsible for the impairment of the Th1/Th2 immune balance, as demonstrated in other stress conditions.

LIMITATIONS OF HYPERBARIC BAG TREATMENT OF ACUTE MOUNTAIN SICKNESS

Mekjavic, I.B. 1, Gavran, B. 2, Golja, P. 3

1 Jozef Stefan Institute, 2 Univ. of Ljubljana, Faculty of Sport, 3 Nova Gorica Polytechnic, Slovenia

Hyperbaric bags are used at high altitude to alleviate the symptoms of acute mountain sickness (AMS). The patient is placed in a bag, which is then pressurised above the ambient pressure. Consequently, partial pressure of oxygen in the bag increases, which has a beneficial effect on the patient. During a 1-hour therapy, the hyperbaric bag must be adequately ventilated by the rescuer to minimise the CO2 accumulation in the bag. At altitude, the strenuous activity associated with the recommended pumping rate may induce AMS in a previously non-symptomatic rescuer. The aim of the experiment was to assess the physiological strain imposed on the rescuer during a typical AMS therapy, both, at low and high altitude. The CO2 level in the hyperbaric bag was also monitored to assess the potential development of hypercapnia during the AMS therapy.

Eight male subjects participated in 4 separate trials, both as "patients" and "rescuers", in both hypoxia (H) and normoxia (N). The subject's average (SD) age was 26 (2) years, and maximal heart rate (HRmax; bpm) obtained during normoxia was 186 (5) bpm. The "rescuer-patient" pair rested for 10 minutes in a climatic chamber (Ta = 21.2 (0.3)°C). Then, the "patient" lay in the bag (Certec, France) and the "rescuer" commenced a 1-hour AMS treatment. After inflation, the bag was ventilated every 10 seconds. In hypoxic trials, normobaric hypoxia was induced by decreasing the O2 fraction in the chamber to 13.4 (0.1) % (simulated altitude = 3500 m). To assess the physiological strain of the "rescuer" during the AMS therapy, his heart rate (HR; bpm) was measured with a heart rate monitor, and his haemoglobin saturation (SaO2; %) with a pulse oximeter every five minutes. CO2 level in the hyperbaric bag was monitored with a portable CO2 analyser.

Upon completion of the AMS therapy, rescuers' SaO2 attained 98 (0) % and 85 (5) % in the N and H, respectively, whereas the patients' SaO2 was 97 (1) % in the N and 93 (1) % in the H. Rescuers' HR at the end of the therapy was 88 (13) bpm in the N and 95 (9) bpm in the H, which corresponded to 47 (6) % and 51 (4) % of their normoxic HRmax. The difference in subjects' HR between the N and H was not significant ($p < 0.08$). The highest HR of the "rescuers" was observed during the initial inflation of the bag; HR reached 61 (9) % and 65 (9) % of their HRmax, in N and H, respectively. During the AMS treatment, CO2 increased gradually, attaining 2.6 (0.4) % in the N and 2.9 (0.4) % in the H trials.

During a 1-hour AMS therapy in a hyperbaric bag, CO2 concentration in the bag increased to approximately 3 %, despite maintaining the manufacturer's recommended ventilation rate. In normoxic conditions, heart rate of the rescuers during AMS therapy reached up to 60 % of their maximal heart rate, and the physiological strain was further increased with altitude.

OP3-02 Training and Testing 6/7 - "Turin ABC"

CARDIOPULMONARY EXERCISE CAPACITY AND MUSCLE STRENGTH IN CHILDREN AND ADOLESCENTS WITH ACHONDROPLASIA: IS THERE A DISADVANTAGE OF BEING SMALL?

Takken, T., van Bergen, M., Sakkers, R., Helders, P., Engelbert, R.

Wilhelmina Children's Hospital, University Medical Center Utrecht, Netherlands

Aim: The aims of the present study were to determine whether subjects with achondroplasia have a different response to exercise compared to healthy peers, and whether exercise capacity might be related to anthropometric measurements or physical activity levels.

Methods: Seventeen patients (7 boys and 10 girls; mean age 11.8 ± 3.3; range 6.9-19.4) diagnosed with achondroplasia participated in this study. Weight, standing height, sitting height, arm span and head circumference were measured in a standardized manner. Strength of the proximal and distal muscles in lower and upper extremities was measured using a Hand Held Dynameter (Citec dynamometer) in

the following six muscle groups: shoulder abductors, grip strength, dorsal extensors of the wrist, hip flexors, knee extensors and dorsal flexors of the foot. A 3-day Bouchard physical activity record was used to estimate energy expenditure.

The subjects performed a maximal graded treadmill exercise test using a modified Bruce protocol. Heart rate (HR) and gas exchange variables (peak oxygen uptake: VO2peak, VO2peak/kg, respiratory gas exchange ratio: RER, and minute ventilation: VE) during the test were measured using a heart-rate monitor (Polar) and a calibrated mobile gas analysis system (Cortex Metamax B3).

Z-scores were calculated using reference values for healthy children and adolescents. Independent samples T-tests were used to test differences between patients and the reference values.

Results:All anthropometrical measurements differed significantly from reference values. Mean standing height was -5.77 ± 0.98 ($p < 0.0001$) standard deviations lower compared to normal values.

Subjects with achondroplasia showed a reduced muscle strength in dorsal extensors of the wrist, hip flexors, knee extensors and dorsal flexors of the foot. Muscle strength in the shoulder abductors was normal.

Physical activity levels were significantly lower in subjects with achondroplasia compared to reference values, and correlated significantly with VO2peak ($r = 0.594$, $p = 0.05$).

All patients were able to perform the maximal exercise test without complications. HRpeak of the patients was 178.6 ± 14.9 (range 151-201) beats/min and RERpeak was 1.15 ± 0.1 (range 1.0 – 1.41). Z-scores for VO2peak (-3.23 ± 0.66), VO 2peak/kg (-2.59 ± 0.70), and E (-2.20 ± 0.73) were significantly reduced compared to reference values for age and gender ($p < .001$). Peak ventilatory equivalent for VO2 (VEpeak/VO2peak) was higher in subjects with achondroplasia (45.25 ± 5.9) compared with reference values (37.9 ± 2.8 ($p < 0.001$). Peak O2 pulse (HRpeak/VO2peak) was significantly lower in subjects with achondroplasia (5,9 ± 1.9 ml/beat) compared to reference values (9.3 ± 2.3 ml/beat; $p < .0001$).

Conclusion: The cardiopulmonary exercise capacity and muscle strength in subjects with achondroplasia was reduced compared to age and gender matched reference values. Subjects with achondroplasia have a unique response to exercise compared to peers.

APPLIED SCIENCE IN ELITE YOUTH SOCCER: A DIAGNOSIS AND INTERVENTION PROJECT TO OPTIMIZE PREVENTION, REHABILITATION AND RE-INJURY-PROPHYLAXIS OF KNEE AND ANKLE INJURIES

Neumann, G., Stehle, P.

German Federal Institute of Sport Science, Germany

Epidemiological studies show an increased number and impact of serious knee and ankle injuries that occur not only in the field of high level senior soccer but also with dramatically rising figures in youth soccer. Therefore, since 2004 the German Federal Institute of Sport Science (BISp) promotes – in close cooperation with the German Soccer Federation (DFB) – a several years lasting interdisciplinary project to (a) optimize prevention, rehabilitation and re- injury-prophylaxis of knee and ankle injuries in soccer, (b) to create wholesome solutions and (c) campaigns to mediate and integrate these results into the soccer praxis.

Injuries of the lower extremities or the proneness to certain knee and/or ankle injuries are thought to be caused by many factors including situational, training, individual or material aspects. In our study we are interested in measuring and improving physiological and psychological impact factors to optimize prevention, rehabilitation and re-injury-prophylaxis of knee and ankle injuries in soccer. Diagnosis variables include the individual knee and ankle stability, coordinative and psychological abilities. Thus, a manifold of research disciplines (sports medicine, biomechanics, training science, sport psychology, epidemiology) work together. Moreover, the potential influence of the shoe design upon the knee and ankle stability is investigated by another research group.

The study takes place with five elite male youth soccer teams (U 17, U 19) of 1st division clubs. Each team takes part at four diagnosis sessions before and throughout the seasons 2004/05 and 2005/06 to measure the potential individual injury proneness as well as the intervention outcome. Throughout the season, a proprioceptive training program is integrated into the normal warm-up program as well as a weekly handheld assisted monitoring of perceived physical and psychological states.

In order to handle the vast amount of data, a dynamic database has been developed. Thereby (a) multivariate analyses of all variables for all measurements, players and teams become possible as well as (b) a fast and "comprehensible" interpretation and transfer of the measurement results for the coaches and teams - after each measurement, the coaches are given commented graphical and table analyses for the teams, including the individual performance of each player, compared to reference values. Delivering these tools, coaches can react immediately and more sensible to the individual and team needs by i.e. reducing/changing the training for players. The weekly feedbacks of the players' physical and psychological states help to become more aware of temporal stressors that might impair the performance or increase the risk for injuries.

Preliminary analyses indicate a positive influence of the proprioceptive training upon the dynamic knee stability and coordination.

More information about the project can be found under "http://www.bisp-fussball-interdisziplinaer.de".

DIAGNOSIS OF THE FOOTBALL-SPECIFIC VELOCITY IN YOUNG ELITE FOOTBALL PLAYERS

Laudenklos, P., Knop, T., Lottermann, S., Weber, K.

German Sport University Cologne, Germany

INTRODUCTION

In football the performance in competition depends among other parameters on the specific velocity. This ability is characterized by a distance up to 20 meters – with an emphasis of sprints between one and ten meters (Verheijen, 1999) – and shifts in direction (Rehhagel, 2004). Thus the solely use of the linear sprint (Gerisch & Weber, 1992) for the diagnosis of the velocity seems to be insufficient. The aim of this study was to investigate, whether the more specific agility test (Lottermann, Laudenklos & Friedrich, 2003) differentiates more clearly between young top-level and high-level football-players.

METHODS

The players (n = 15568) were members of youth teams from German Bundesliga-Clubs [LZ] (n = 812) or the DFB-Talent-Promotion-Program [SP] (n = 14756) in the age-groups [AG] 1988 to 1995. Every test (20 meter linear sprint [LS] and agility run [AR]) consisted of two heats by which the better one was evaluated. The test-times were measured by light barriers. The means of the two groups were analyzed by t-test for independent samples on a significance-level of 1%.

RESULTS

In LS the means of LZ varied from 3,12 ± 0,11 s [n1987 = 34] to 3,68 ± 0,14 s [n1994 = 102] while the results of SP ranged from 3,13 ± 0,16 s [n1987 = 56] to 3,80 ± 0,23 s [n1994 = 773]. Thereby LZ were significant better in the AG 1990 to 1994 (t varies from 2,94 [AG 1992] to 8,15

[AG 1993]) whereas in the older age-groups no significant differences were detected on the demanded significance-level (t varies from 0,35 [AG 1987] to 2,29 [AG 1988]). In AR the means of LZ varied from 7,58 ± 0,35 s in AG 1988 (n = 65) to 8,29 ± 0,43 s in AG 1994. Thus they are significant better in every single age-group (t varies from 2,82 [AG 1987] to 12,10 [AG 1993]) than SP, whose means are ranged from 7,89 ± 0,46 s in AG 1987 to 8,76 ± 0,50 s in AG 1994.

CONCLUSION

The results confirm the assumption that the AR differentiates more clearly between LZ – as the group of better players – and SP than LS. In the AG 1989 to 1987, there are no differences between LZ and SP in LS, while the differences in AR are still significant. Furthermore, the differences in AR between both groups – related to the standard deviation [SD] of LZ in the respective single-tests – are clearer than in LS and they grow with age. The quotient [(ARSP – ARLZ)/SDAR(LZ)]/[(LSSP – LSLZ)/SDLS(LZ)]] increases from 1,32 in AG 1994 to 6,74 in AG 1987.

EXPLORATORY RELATIONSHIP OF DROP JUMP PERFORMANCE WITH GYMNASTICS VAULTING AND FLOOR EXERCISE SCORES

Sands, W.A., McNeal, J.R., Stone, M.H., Smith, S.L., Dunlavy, J.K., Jemni, M., Haff, G.G., Mizushima, K.

United States Olympic Committe, United States

Purpose: This exploratory study sought to determine the relationship between drop jump performance and personal best scores on floor exercise (FX) and vaulting (VT) among elite male gymnasts. Methods: Nineteen male gymnasts (22.74, SD=2.2 yr; 164.8, SD=6.0 cm; 62.9, SD=7.8 kg) from the Senior National Teams of the U.S.A. (N=15) (Team Silver, Athens, 2004) and the Japan (N=4) (Team Gold, Athens 2004) agreed to participate. Athletes provided personal best FX and VT scores under the rules for the Athens Olympic Games. Athletes performed three trials of a rebound drop jump from 52 cm drop height onto a one-dimensional portable force platform. An arm swing was allowed. Athletes were instructed to rebound as high as possible with a short ground contact time and land on the force platform. Vertical force data were collected by custom computer software at 1000 Hz. Force-time curves were analyzed for maximum vertical force (MVF), rate of force development (RFD), ground contact time (GCT), and flight time. All variables except times were allometrically scaled (variable / body mass^0.66). Reliability analysis showed the first trial was statistically lower than trials two and three; trials two and three did not differ. All intraclass correlations of trials data exceeded 0.85; and relative technical errors of measurement ranged from 3.1% to 7.5% for all variables except RFD (11.1%). The mean of trials two and three was used for further analysis. Pearson correlation coefficients were calculated. Statistical significance was set at P<0.05. Results: variables significantly correlated with FX personal best scores were: RFD: r = 0.47, MVF: r = 0.57. GCT was the only variable significantly correlated with VT personal best scores (r = -0.52). Discussion: The results indicate that the data were reasonably stable. The significant correlations showed that allometrically scaled values of RFD and MVF were modestly predictive of variability of FX scores (r^2 = 0.22 to 0.32). Gymnasts with shorter ground contact times appeared to achieve superior VT scores. VT score variability was also modestly predictable from GCT (r^2 = 0.27). Conclusion: This study demonstrated that approximately 25%-32% of the variability of personal best scores in FX and VT could be predicted from a rebound drop jump test. Drop jump-type training and performance may serve the male gymnast in improving his scoring capability.

MICROARRAY ANALYSIS OF SIMVASTATIN TREATED C2C12 MYOTUBES

Yu, J., Sewright, K., Hubal, M., Schwartz, L., Hoffman, E., Clarkson, P.

Mid Sweden University, Sweden

Statins are lipid-lowering drugs used by over 100 million people worldwide. Myopathy has been reported in 2–7% of cases and some of these cases are more serious involving rhabdomyolysis. So far the underlying mechanisms are unknown. The purpose of this study was to identify global gene expression patterns associated with the introduction of statin to myotubes in culture. For some of the most up- and down-regulated genes, their protein expressions were also analyzed. The satatin treated myotubes were also mechanically strained and protein expression were analyzed and compared with the results from the unstrained myotubes.

C2C12 cells were cultured using standard conditions and 15 μM of Simvastatin was then applied to these cells. A baseline sample and samples taken at 1 and 6 hours post-application were analyzed using Affymetrix MOE430A microarray. This analysis provided data for differing levels of gene expression for all genes in the mouse genome across the three time points. The differential gene expression data were filtered for genes that exhibited a 2-fold up-regulation or a 2-fold down-regulation across both time-points compared to baseline. Five of the most up- and down-regulated genes were selected, and then their protein expressions were analyzed. Proteins were also examined in statin treated myotubes mechanically strain for 1 hour.

61 genes exhibited a ≥ 2-fold up-regulation at both 1 and 6 hour compared to baseline. Of these genes, only 37 have known biological functions and/or localizations. The most common biological functions associated with these genes included transport or signal transduction, cell growth/maintenance, protein metabolism and apoptosis. 24 genes exhibited a ≥ 2-fold down-regulation at both time-points. Biological functions and/or localizations are known for only 9 of these genes. The transcripts of the genes coding for proteins at the membrane and the extracellular space make up a large portion of the data set. Statin treatment also results in significant increases in protein expression in four most up-regulated genes, and decreased protein expression in one down-regulated gene. Immunohistochemistry confirmed the altered expressions of these proteins. Cyclic mechanical strain rectified the changes in only three of the up-regulated proteins. These data indicate that the application of statin to C2C12 myotubes affect signalling and transport-associated gene expression related to cell growth/maintenance, protein metabolism, and apoptosis particularly at the cell membrane and extracellular space. When the cell is exposed to the statin drug, it appears that genes may increase their expression in an effort to adapt to the

changing environment. In rare cases, the cell may be unsuccessful in this attempt and, in vivo, myopathy could result. Mechanical strain may rectify some gene expressions suggesting exercise may in some extent alleviate the muscle pain induced by statin in vivo.

ABSENCE OF DYSTROPHIN IN SARCOLEMMA IS FOLLOWED BY PRESENCE OF INFLAMMATORY CELLS AND INTACT TYPE VI COLLAGEN IN HUMAN DAMAGED SKELETAL MUSCLE FIBERS

Koskinen, S., Paulsen, G., Kjær, M., Crameri, R., Raastad, T.

Institute of Sports Medicine, Denmark

Light microscopical examination of damaged rat skeletal muscle has shown that different collagen types are located similarly in swollen, necrotic and regenerated fibres as in undamaged skeletal muscle fibres (Koskinen et al. 2002). This is compatible with the view that collagen potentially could play an important role in skeletal muscle during the process of fiber damage when cytoskeleton is disrupted, contractile proteins are disorganized and extracellular fibronectin is deposited intracellularly. The aim of the present study is to investigate whether collagen has a similar role in human skeletal muscle. Eleven healthy male subjects (27.5+/-3.5 years, 180+/-8 cm, 82.6+/-6.4 kg) performed 300 (30 sets of 10 repetitions) maximal isokinetic eccentric actions (30 degree per second) with the knee extensors in one leg. Biopsies from the muscle vastus lateralis were taken in both unexercised and exercised legs 30 minutes, 4, 8, 23, 95, and 167 hours after the eccentric exercise. Each subject was biopsied at four time points. Serial transverse sections were immunohistochemically stained for type VI collagen, dystrophin, neutrophil granulocytes (CD16) and macrophages (CD68). Three of the eleven subjects showed dystrophin negative immunohistochemical stained fibers at 95 and 167 hours after the exercise. In these fibers the staining was absent in the part of sarcolemma or the staining was totally absent around the fibers. Type VI collagen immunohistochemical staining was visible in these areas where dystrophin staining was absent. There were typically both CD16 and CD68 positive cells near by the areas or inside the muscle fibers, where dystrophin staining was absent. Furthermore, a biphasic increase in serum creatine kinase activity was observed in these three subjects. The first peak was observed at 23 hours and the second and the highest peak at 95 hours after the exercise. The results from the present study suggest that the delayed peak in blood CK concentrations in three of the subjects is related to dystrophin negative sarcolemma staining and infiltration of inflammatory cells. It is unclear whether the signals that lead to recruitment of inflammatory cells from circulation are originating from skeletal muscle fibers or extracellular matrix. Interestingly, collagen staining in the dystrophin negative areas seems to be intact. This may indicate that collagen has an important role in supporting the part of the skeletal muscle fiber, where sarcolemma is damaged, as well as serve as an attachment site for cells, which are remodeling the damaged site.

EXPRESSION CHARACTERISTICS OF HOUSEKEEPING GENES IN HUMAN LYMPHOCYTES IN RESPONSE TO ACUTE EXERCISE AND CREATINE PYRUVATE SUPPLEMENTATION

Schoenfelder, M., Schulz, T., Meixner, H., Michna, H.

Technical University of Munich, Germany

Introduction: The application of reverse transcription polymerase chain reaction (RT-PCR) method has became a common technique in sports science to detect the modulating influence of exercise onto gene expression and to understand the mechanistic coherence of exercise and health.

The method of choice to quantify the relative abundance of the gene of interest (GOI) is the sensitive technique of real-time RT-PCR. The use of this technique generally requires endogen calibrators to get accurate results and prevent false interpretations. Therefore, the GOIs are set into proportion of endogenous control genes, so called housekeeping genes (HKGs), with the assumption that their expression is unregulated and constant for given experimental conditions.

The aim of the study was to determine if mRNA transcripts of a set of common HKGs are modulated in lymphocytes by acute exercise with or without creatine pyruvate (CrPyr) supplementation.

Materials and methods: Ten healthy male triathlets (age: 35+/-8 years; body weight 78+/-8 kg; BMI 24+/-1; body fat: 14+/-4 %) participated in the present study. All subjects passed through a baseline testing, including bike ergometer time trial at 3 mmol/L lactate and heparin blood sampling at rest as well as in context to the time trial. Subsequent, they had to complete two training periods each of three weeks under placebo or CrPyr (3 g twice a day) supplementation. After each training period all subjects had to absolve an additional time trial. Corresponding to baseline, blood samples were collected pre, post, 3 h post and 24 h post exercise and islolated for lymphocytes by Ficoll centrifugation. Total RNA were extracted by spin columns and analysed for mRNA gene expression (18S rRNA, GAPDH, histon 3, beta actin, ubiquitin, cyclophilin b, creatine kinase M) by two-step real-time RT-PCR. Expression results were analysed by 2^(-delta delta of cycle threshold) method and statistical analysis was performed by two way ANOVA (Holm-Sidak-Test) and Pearson Product Moment Correlation.

Results: Among all raw data of CT values, GAPDH and beta actin showed the lowest variance and the highest positive correlation to each other ($r=0.872$, $p<0.001$). Therefore, these two HKGs served as endogen controls for all other genes tested. Comparing the normalized mean values among the different levels of time and treatment, it was obvious that the influence of CrPyr supplementation would be greater than the influence of exercise or rather time.

Discussion: These data show that it is necessary to evaluate two or more HKGs before they are used as internal controls to validate gene expression data. Additionally, the result indicate that it is obligatory to compare different techniques of RT-PCR data analysis to find the most representative result.

Conclusion: In the given experimental setup beta actin and GAPDH seems to be the most reliable HKGs to normalize mRNA expression in human lymphocytes in response to physical activity and CrPyr supplementation.

EXERCISE GENOMICS IN COLON: GENE REGULATION IN THE COLON MUCOSA BY PHYSICAL ACTIVITY

Schulz, T. 1, Bühlmeyer, K. 1, Schoenfelder, M. 1, Doering, F. 2, Daniel, H. 3, Michna, H. 1

1,3 Technical University Munich, 2 University of Kiel, Germany

Introduction

World-wide dietary choices and physical activity are the most important modifiable determinants of cancer risk besides smoking cigarettes. Since colon cancer is the second most cause of cancer death in europe, and the risk reduction by physical activity could reach 40-50%, research to get insights in the biological mechanisms is expedient. Discussed mechanisms by which physical activity may prevent colon cancer involves both direct and indirect effects: it may helps to maintain a healthful body weight by balancing caloric intake with

energy expenditure, it may improves energy metabolism and thereby reduce circulating concentrations of insulin and related growth factors or it may modulates immune functions. For many issues, the evidence is not definitive either since studies are not yet available or current findings are inconsistent. In addition, there are many unanswered questions about the optimal intensity, duration, and frequency of physical activity. So the purpose of the study was to investigate colonic reactions of gene expression in the rat after physical exercise.
Methods
Male Wistar rats performed a 12 week voluntary physical exercise training program (n=20). 9 male sedentary rats served as a control group (CO). At the end of the study we extracted the mucosa of the proximal colon and isolated total RNA. Real-Time PCR was used to measure gene expression involved in vascularisation (VEGF, HIF-1α, ODC-1), apoptosis (BCL-2, PPARγ) and prostaglandin synthesis (COX-2) respective the insulin and/or insulin-like growth factor axis (IGF-1, IGF-1R and IGFBP3). The four housekeeping genes GAPDH, ß-ACTIN, 18S and ALDA served as references. The BestKeeper program (Pfaffl et al. 2004) was used to analyze the Real-time gene expression data.
Results
We differentiated between 3 running groups: a low running distance (L-EX, <2629m/night), a middle running distance (M-EX, 3003-7458m/night) and a high running distance (H-EX, >8314m/night) group. The HK genes ß-ACTIN, GAPDH and ALDA were found to be stably expressed in contrast to 18S and employed for further calculations. ODC-1 gene expression was 1.8 upregulated. mRNA expression analysis did not provide evidence for any regulation of the marker genes even it revealed some trends for IGF-1.
Discussion/Conclusion
ODC-1 activity is known to be increased after various stimuli including food intake and selected hormones and is discussed as a regulator and modulator of gastrointestinal cell growth. Besides, the enzyme displays an early response to a variety of growth-promoting stimuli. Even if gene expression alterations in the colon induced by physical activty in this study is rather rare, ODC-1 may is a target to show colonic adaptations to physical activity. With respect to the proposed role of ODC-1 as a marker of tissue damage and remodeling our finding may be taken as an indicator for physical activity induced energy turnover or metabolic changes to induce a remodeling in colonic mucosa.

THE GENES POLYMORPHISM AND ELITE ATHLETIC PERFORMANCE

Rogozkin, V., Astratenkova, I., Druzhevskaya, A., Komkova, A., Fedotovskaya, O.

St Petersburg Research Institute of Physical Culture, Russia

Growing evidence suggests an association of genetic variation with the formation, development and manifestation of physical performance of elite athletes. The search for genetic markers of trainability status will likely be more productive than the investigation of molecular markers of the performance phenotype in the untrained state. It has been shown physiologically that for rowing at least 70% of energy requirement comes from aerobic metabolism, the remainder comes from anaerobic sources. Given that the race distance is 2000 meters, which typically takes about 6 to 7 minutes to complete, depending on crew size, muscle mass of rower, gender and elite status, it is more accurate to think of rowing as a power endurance sport. Accumulating evidence suggests that polymorphism of ACE, ACTN3, AMPD1 and NOS3 genes are strongly influence human physical performance [1,2,3]. The purpose of this study was to determine genotype and allele frequencies of ACE I/D, ACTN3 R577X, AMPD1 C34T and NOS3 a/b polymorphisms in rowers and to detect genotype combinations that are prevalent in elite and sub-elite rowers compared to controls.
We examined the DNA of 90 male and female Russian elite (n=58) and sub-elite (n=32) rowers. Genotyping was carried out by PCR. Allele frequencies were determined by gene counting. Genotype distribution and allele frequencies between groups of rowers and controls (n=81) were then compared by Student's t-test.
As expected there was no significant difference in genotype and allele frequencies between groups of rowers and controls, indicating that rowing must be considered as mixed-type sport. When all endurance-associated alleles were combined we determined common endurance alleles frequencies in different groups. The highest value of endurance alleles frequency was observed in elite (68,9%) and sub-elite rowers(81,7 %) compared to controls (70,3%). The prevalent combination of genotypes in all groups was II-RX-CC-b/b. The frequency of this combination was highest in elite rowers (18,9%), sub-elite rowers (18,7 %) the lowest was found in controls (8,6%), indicating that II-RX-CC-b/b combination was optimal for achieving elite level of rowing performance. Besides that there were also detected frequently observed II-RR-CC-b/b; ID-RR-CC-b/b and ID-RX-CC-b/b (each of them 12,0 %) genotype combination in elite rowers.
The results of genotyping for ACE, ACTN3, AMPD1 and NOS3 gene polymorphism suggest that aerobic rather that anaerobic metabolism may be critical for rowing performance. The influence of polymorphic variations in the ACE, ACTN3, AMPD1 and NOS3 genes on the response to physical performance may have important implication in the development of elite athletic performance.

SOLEUS H-REFLEX MODULATION DURING PASSIVE SINUSOIDAL ANKLE MOVEMENT IN YOUNG AND ELDERLY MEN

Kanervo, M., Peltonen, J., Avela, J., Komi, P.V.

University of Jyväskylä, Finland

Ageing is known to impair reflex sensitivity probably due to involvement of presynaptic inhibition. However, the mechanism of this inhibition is not clear. When a muscle is slowly stretched and lengthened during sinusoidal movement H-reflex is first drastically depressed and then recovered in two steps. It has been suggested that the fast recovery (500 ms) takes place due to the relief of presynaptic inhibition and the slow one (over 2 s) due to the recovery from transmitter depletion of the homonymous Ia-afferent terminals (Voigt & Sinkjaer 1998). Therefore, the purpose of the present study was to clarify the possible mechanisms behind the modulation of H-reflex in elderly people.

11 young (26±2 y) and 12 elderly (70±5 y) men participated in the study. Soleus H-reflex was measured during a single sinusoidal dorsi-plantar flexion ankle movement (20°, 20°/s) in a sitting position. Totally 14 time points during the movement and the recovery were tested in randomized order. Before the H-reflex measurement, Mmax was tested and intensity of H-reflex stimulation was adjusted to correspond 25% of Mmax in every condition. Time between the trials was 10 s and three successful trials were recorded for analysis.

H/M-ratio decreased rapidly during the first 900 ms by 75 % and 90 % in Young and Aged, respectively. During the following 600 ms H-reflex recovered to the resting levels of 68% and 63% for the Young and Aged, respectively. This increase coincided with the increase in plantar flexion velocity for both groups. This was again followed by decrease in H/M-ratio over a period of 1500-1800 ms in both groups, but it was more pronounced in Young. During the last 200 ms of the plantar flexion a fast increase was seen (Young 8% and Aged 29%) and this was then followed by a slow return to 90% of resting level over the recovery period (2-4s).

Interestingly, Aged showed stronger depression of H/M-ratio during dorsi flexion than Young. This is in contrast to earlier studies that showed lower depression for aged and spastic subjects (Robertson & Koceja 2003; Voigt & Sinkjaer 1998) as compared to Young. According to these studies this depression was related to decreased presynaptic inhibition and post-activation depression. The results of present study may indicate higher presynaptic inhibition during dorsi flexion in Aged. Thixotropic properties of the muscle may increase the spindle discharge (Woods et al. 1996) during stretch and, thus result in decreased H-reflex sensitivity due to post-activation depression. Both groups showed a fast type of recovery indicating a relief of presynaptic inhibition. However, the slow type of recovery was clearly faster in Aged. This high depression of H-reflex in Aged, which was then followed by a fast recovery, is naturally puzzling and, therefore, further studies are needed.

AGE-RELATED DIFFERENCES IN THE SOLEUS MOTOR UNIT FIRING IN DYNAMIC CONTRACTIONS

Kallio, J., Linnamo, V., Søgaard, K., Komi, P.V.

University of Jyväskylä, Finland

Introduction

Ageing is related to muscle atrophy that leads to decreases in muscle force. The largest decreases are found in fast muscle fibres and fast force production. There is some evidence that in isometric condition with small hand muscles the maximal firing rate is decreased with aging (Kamen et al. 1995). Less is known about the effects of ageing on the firing rate behaviour in dynamic contractions, especially on large leg extensors that have an important role in maintaining balance. Earlier studies with young subjects on dynamic contractions have shown that when the load is constant, the firing rate of motor units is larger in concentric and smaller in eccentric contractions compared to isometric situation (Søgaard et al. 1996, Kossev & Christova 1998). The purpose of the present study was to investigate the effects of ageing on the motor unit firing rates in dynamic contractions of the Soleus muscle.

Methods

In total 8 YOUNG (25.4+3.1 yr.) and 8 OLD (68.8+5.3 yr.) physically active healthy males participated in the study. The present abstract includes the data of 2 YOUNG and 4 OLD subjects. The subjects performed plantar flexions while seated in an ankle dynamometer. The tasks included 1) isometric maximum voluntary contraction (MVC), 2) isometric ramp and 3) isotonic (ISO) contractions, and 4) concentric (CON) and 5) eccentric (ECC) contractions (10 and 20% MVC). In the dynamic trials the subjects lifted (CON) or resisted lowering (ECC) weights at 10 deg/s. Intramuscular EMG was recorded by utilizing 2 bipolar wire-electrodes inserted into the soleus muscle. The measured signal was decomposed to single motor unit action potential trains with Daisy software (Olsen et al. 2001).

Results

Maximal voluntary contraction torque was 33.1% lower in OLD (63.9+17.9Nm) compared to YOUNG (95.6+11.3Nm). The total number of motor units analyzed was 6 in OLD and 7 in YOUNG. On average, the highest motor unit firing rates were observed in CON. In addition, 2 units were found to only fire in CON and 3 units in ISO and CON but not in ECC. The firing rate of the identified motor units was lower in OLD in all measured conditions: At 10% MVC, the firing rates of OLD were 41.0% (ISO), 35.7% (CON) and 43.0% (ECC) lower compared to YOUNG. Similarly, at 20% MVC the differences were 69.4% in ISO, 72.9% in CON and 62.5% in ECC.

Discussion

The identification of motor units in dynamic movement is a challenging task, due to movement of the electrodes and the varying distance of the electrode to the motor unit during the movement. The observed higher firing rate in CON was similar to earlier studies. The preliminary results also suggest that the age-related decrease in the firing rates of distal muscles also applies to dynamic conditions.

NEUROMUSCULAR FUNCTION DURING DYNAMIC MOVEMENTS ASSOCIATED WITH AGING

Hoffrén, M., Ishikawa, M., Komi, P.V.

Neuromuscular Research Center, Finland

Elasticity of the skeletal muscle plays an important role by improving the power output and efficiency in dynamic movements. With aging, the stiffness of tendon structures can decrease when measured in isometric contraction (Morse et al. 2005), suggesting greater utilization of elasticity during dynamic movements. Several studies reported that the greater joint stiffness has been observed in the elderly than in the young (Hortobaqyi & De Vita 2000). However, the metabolic cost is higher in elderly than in young during the human locomotion (Mian et al. 2006). The present study was designed to address the issue whether the elderly can utilize TT elasticity efficiently during dynamic movements.

Twelve young (YA; 25.2 ± 2.5 yr) and thirteen older (OA; 69.0 ± 3.8 yr) adults performed maximal squat jumps (SJ) and drop jumps (DJ) in a sledge apparatus inclined to an angle of 18 deg. DJs were done from three dropping heights (10, 15 and 20 cm). The lowest knee angle (145.6 ± 8.2 deg) was visually evaluated during the measurements and was kept the same in every condition. Kinematics, kinetics and

EMG (SOL, GM, TA) were recorded together with ultrasonography (GM and muscle tendon junction). Average force and EMG were analysed for preactivation (100ms before contact), braking and push-off phases during the jumps.
The ratio ((positive work - SJ work) / negative work) was greater in YA than in OA during DJs. When EMG ratio (push off phase / braking phase) was calculated for GM and SOL muscles, OA showed higher values indicating less efficiency.
Before the contact, due to the preactivation, the GM fascicles shortened in YA but not in OA. During the contact of DJ, the GM fascicles in YA shortened throughout the contact. With increasing the drop height, this fascicle shortening decreased. In OA, however, the fascicles behaved differently and individually although EMG activities during drop jumps were significantly greater in OA than in YA in each phase. Some of them behaved similarly to YA. Other OA showed that fascicles were stretched during the braking phase from the low DJ condition.
The results of the present study confirm that OA could not transfer negative work to positive work more efficiently as compared to YA. The increased fascicle lengthening in OA suggest that OA cannot utilize TT elasticity effectively during the DJs. This may be related to the increased antagonist muscle coactivation, which influences the joint stiffness more than tendon elasticity.

ROLE OF MECHANICAL EXTERNAL WORK AND PENDULAR ENERGY TRANSDUCTION IN GAIT ECONOMY IN HEALTHY 65- AND 80-YR-OLDS

Malatesta, D., Borrani, F., Simar, D., Candau, R., Préfaut, C., Caillaud, C.
Institut des Sciences du Sport et de l'Education Physique (ISSEP), Switzerland

INTRODUCTION
Several studies have reported higher energy cost of level walking (Cw) in elderly subjects at several walking speed (3, 4). The mechanisms involved in this age-related decline in economy of walking remain however unclear. Even though it has been suggested that increased in energy expenditure associated with walking movements and related to mechanical external work (Wext) and to impaired pendular energy transfer may be a contributing factor (3). The purpose of this study was to determine whether higher Cw in healthy elderly subjects is due to greater Wext necessary to translate the centre of body mass during gait.
METHODS
Three groups of subjects participated in the study: G80 (n=10; 81.6±3.3 yr), G65 (n=10; 65.3±2.5) and G25 (n=10; 24.6±2.6). Groups were matched according to gender, height, lower limb length, body mass, lean body mass, percent body fat. The subjects performed five 6 min treadmill walking trials at five different speeds (0.56, 0.78, 1.01, 1.24, 1.46 m/s), separated by 5 min resting periods. During these trials, metabolic and mechanical data were collected. For each subject, VO2 values from the last two minutes were averaged and normalized to body mass. These data were subsequently used to calculate the net energy cost of walking (NCw). Wext changes and the fraction of mechanical energy recovered (Rstep) (2), due to the pendular transduction of potential to kinetic energy and vice-versa, were determined with a kinematic arm (1).
RESULTS
NCw was higher for G80 and G65 than for G25 across the different walking speeds (38% and 23%, respectively; $P < 0.05$). Wext was respectively 42% and 34% higher in G80 and G65 compared with G25 at the three fastest experimental walking speeds (1.01, 1.24, 1.46 m/s; $P<0.05$). Rstep was significantly lower in G80 than in G25 for the same walking speeds (-25%; $P<0.05$) and for the two fastest speeds (1.24 and 1.46 m/s) in G65 compared with G25 (-18%; $P<0.05$). NCw was directly correlated with Wext at the five walking speeds ($r=0.49$; $r=0.40$; $r=0.46$; $r=0.46$; $r=0.68$, respectively; $P < 0.05$). NCw was inversely correlated with Rstep at the four fastest walking speeds ($r=-0.43$; $r=-0.42$; $r=-0.41$; $r=-0.62$, respectively; $P<0.05$).
DISCUSSION/CONCLUSION
These findings demonstrate that greater energy cost in healthy elderly while walking is associated with greater mechanical external work and lower fraction of mechanical energy recovered. Our results suggest that greater mechanical muscular work, due to impaired pendular energy transfer, is involved in energy cost of walking in elderly subjects especially at intermediate and higher speeds. Future research should examine the role of co-activation of lower limb muscles and lower limb stiffness in biomechanics and energetics of walking in elderly.

PERIPHERAL FATIGUE AFTER ALPINE SKIING

Tomazin, K., Dolenec, A., Jereb, B., Ulaga, M., Strojnik, V.
University of Ljubljana, Faculty of Sport, Slovenia

Introduction
It is well known that alteration of neuromuscular functions were not only time (Strojnik and Komi, 1998) but also task dependent (Millet and Lepers, 2004). Fatigue after alpine skiing could originate from sites located proximal (central fatigue) or distal to neuromuscular junction (peripheral fatigue). Measuring knee-extensors torque during electrically-evoked contractions with low- (20 Hz) and high- (100 Hz) stimulation frequencies after different fatiguing exercises has often been used to evaluate the alteration of neuromuscular function distal to neuromuscular junction (Strojnik and Komi, 1998, Millet and Lepers, 2004). Due to this method, we could discriminate between low- and high-frequency peripheral fatigues. In alpine skiing, fatigue is important factor of success and a lot of training efforts are devoted to reduce its effects. However, it is important to know the type of fatigue to employ proper training methods. Slalom is specific in alpine skiing for its emphasis on stretch-shortening cycle. Therefore, the aim of our study was to examine the presence of high- and low-frequency peripheral fatigue after alpine skiing slalom.
Methods

Eight male alpine skiers (19.0±1.3 years., 182.4±3.6 cm, 81.5±4.4 kg) volunteered the study. They performed slalom with 45 gaits, which duration was approximately 45 seconds. Measurements included mechanical twitch characteristics of m. vastus lateralis (VL) and mechanical response of VL to high (100 Hz, 0,8s) and low (20 Hz, 1s) frequency stimulation were measured. From maximal torques during high- and low-frequency electrical stimulation a torque ratio between high- and low-frequency torques was calculated. The measurements of knee torque were performed after standardized warm-up prior the skiing and exactly one and three minutes after the skiing. The significance of differences between measured and calculated parameters prior and after the skiing exercise was tested with paired sample t – test at 5% alpha error.

Results

The maximum twitch torque was reduced one minute after the slalom but potentiated ($P<0.01$), accompanied with half relaxation time prolongation, three minutes after the skiing. Maximal knee torque during the train of electrical impulses decreased significantly only during 100 Hz electrical stimulation after the first minute ($P<0.05$) and was accompanied with significantly reduced torque ratio one minute after the skiing ($P<0.05$).

Discussion/Conclusion

Analysed parameters showed that slalom caused high-frequency peripheral fatigue and were well related to results of former studies showing that high-frequency fatigue is expected after maximally intensive short term stretch-shortening cycle exercises (Strojnik and Komi, 1998). These results imply that training to prevent fatigue in slalom should be specific to high-frequency fatigue.

THE RELATIONSHIP BETWEEN SELF-CONCEPT, ATTRACTION TO PHYSICAL ACTIVITY, AND LEVEL OF PHYSICAL ACTIVITY, IN 6 TO 8 YEAR- OLD GIRLS AND BOYS

Howard, B., Rose, E., Larkin, D., Hands, B., Parker, H.

Edith Cowan University, Australia

Self-concept and attraction to exercise, games and sports are frequently cited as key influences in children's level of physical activity. Whilst there is substantial support for this notion with middle school children, there are few reported findings with children in lower grades. Adopting a stance grounded in Social Cognitive Theory, we examined the relationships between children's self-concepts, aspects of attraction to physical activity, and level of physical activity. Considering the influence of gender socialization, we predicted that girls' and boys' responses would differ. Children (N = 125)(boys = 57; girls = 68) aged 6 to 8 years (M = 6.7, SD = .47) from metropolitan primary schools took part in the study. Each child answered questions administered by a trained interviewer on the Self-Description Questionnaire -1 (physical ability, physical appearance, peer relations, and general self-concept) and the Children's Attraction to Physical Activity Scale (peer acceptance, importance of exercise, liking of games and sport, liking of physical exertion, and liking of vigorous exercise). The children wore pedometers over a 7-day period from which a mean step count was calculated to indicate level of physical activity. Independent t-tests ($p < .05$) revealed significant differences between boys and girls only on the self-concept subscale for peer relations. Pearson's r revealed no relationship between level of physical activity and self-concepts, or attraction to physical activity. However, there were significant relationships between attraction to physical exertion and the self-concept dimensions of (a) physical ability ($r =. 56$, $p < .001$), (b) physical appearance ($r = .41$, $p < .001$), and (c) peer relations ($r =. 53$, $p < .05$). The strongest relationship was between liking of games and sports and general self - concept ($r = .64$, $p < .001$). There was no support for the notion that self-concepts and aspects of attraction to physical activity are related to level of activity. Among other possibilities, this finding may reflect an age related limitation whereby self-descriptions are not realistic or dimensions of attraction to physical activity are not clearly defined. The findings provided partial support for the theoretical stance in this study. General self-concept clearly was related to liking of games and sports. Self-concepts in the physical (ability and appearance) and social (peer relations) domains clearly were related to liking of physical exertion. The results support previous findings that enjoyment derived from being physically active and interacting in games and sports are important to specific aspects of children's self-concept as well as their general self-concept.

THE VALIDITY AND RELIABILITY OF THE CHILDREN'S ATTRACTION TO PHYSICAL ACTIVITY SCALE (CAPA) WITH 6 TO 8 YEAR-OLD AUSTRALIAN CHILDREN

Rose, E., Howard, B., Larkin, D., Hands, B., Parker, H.

Edith Cowan University, Australia

There is increasing concern that physical activity levels of children are declining. One of the limitations in evaluating effectiveness of programmes designed to attract children to physical activity is the availability of measures that are both developmentally and culturally appropriate. The purpose of this study with Australian children was to assess the validity and reliability of a modified version of the Children's Attraction to Physical Activity Scale (CAPA; Brustad, 1993) validated for use with North American children (grades 4 to 7). The CAPA was designed to reflect aspects of attraction to physical activity and comprises of 5 subscales; liking of vigorous activity, liking of games and sports, importance of exercise, enjoyment of physical exertion and exercise, and peer acceptance in games and sports. In this study boys (n = 180) and girls (n = 154) aged 6 to 8 years (M = 6.7 years, SD = 0.47) completed the CAPA by individual interview with trained researchers who recorded responses on a Likert scale ranging from 1 (low) to 4 (high). Internal consistency reliabilities (Cronbach's alpha) were acceptable for three of the subscales; liking of games and sports (.75), importance of exercise (.72) and, liking of physical exertion (.67). With this age group, negatively worded statements reduced the internal consistency of the subscale. When the negative item (6) was removed from the subscale, liking of vigorous exercise, Cronbach's alpha improved from .54 to .75. Similarly, the alpha level for peer acceptance improved from .30 to .55 when the two negatively worded items (7 and 8) were removed. Factor analysis with Varimax rotation provided support for 3 of the subscales: liking of games and sports (all 5 items plus 1 item from liking of vigorous activity), importance of physical activity (all 5 items plus one item from liking of vigorous activity plus 2 from liking of exertion), and liking of exertion (4

items plus 1 from liking of vigorous physical activity). Liking of vigorous physical activity and peer acceptance did not emerge as stable factors and the negatively worded items influenced the factor structure. A second order factor analysis using Promax rotation defined two higher order factors, one representative of attraction to physical activity and the other focused on the negatively worded items. It was clear that negatively worded items were unsuitable for the 5 to 8 years age group. Our findings provide support for a modified version of the CAPA as an overall measure of attraction to physical activity with young Australian children. In order to clarify whether children in this age group are able to clearly differentiate among the five subscales further refinement of some items is recommended.

INVESTIGATING AND UNDERSTANDING PHYSICAL ACTIVITY BEHAVIOR OF CHINESE ADULTS: THE BERLIN EXERCISE STAGE MODEL

Duan, Y., Brehm, W., Wagner, P.

Wuhan Institute of Physical Education, Wuhan, China

The Berlin Exercise Stage Model (BSM) describes eight stages of individual's physical activity: precontemplation (inactive, no idea about physical activity), contemplation (inactive, think about physical activity but no intention to engage in), disposition (inactive, make a decision to engage in physical activity), preaction (inactive, specify goal intentions with detailed plan), implementation (initiation stage of physical activity, less than six months), habituation (regularly active for more than 6 months), fluctuation (irregular active), and resumption (inactive, have intention to restart physical activity after long term drop-out) (1). Through the behavior-change process, multiple attempts and relapse can occur. Furthermore, the BSM also incorporated two social cognitive variables, namely self-efficacy and social support, which are assumed to be essential for stage movement. Consequently, according to the note of Sutton, discontinuity patterns/non-linear trends for social cognitive variables across stages should emerge if BSM is a genuine stage model (2). In order to examine the applicability of the BSM in China and evaluate stage assumption on discontinuity patterns /non-linear trends, Chinese adults (n=856), which consist of three subgroups including 211 bank employees (M=31 years), 346 university staff (M=38 years) and 299 college students (M=19 years), were investigated by using BSM model in physical activity context. The findings revealed the applicability of BSM in China, as stage distribution showed that all Chinese participants could be assigned into one of eight stages proposed by BSM model. By using planned contrast tests, it was found that, among university staff and college students, participants in the habituation stage have superior self-efficacy and feel more social support than those in the fluctuation stage, supporting the discontinuity patterns across the BSM stages partially. By using polynomial trend analyses, significant linear trends were revealed between stages and two social-cognitive variables among three subgroups, with quadratic trends were significant for self-efficacy in bank employees, social support in university staff and social support in college students, indicating selected discontinuity patterns in restricted variables. In conclusion, this study is the first attempt to test the BSM model with Chinese adults, supporting the applicability of the BSM and providing partial evidence on discontinuity patterns/non-linear trends examination. Future research might be targeted on improving the validity of BSM in China and conducting stage-specific interventions to motivate Chinese adults adopting and maintaining physical activity behavior.

IS3-06 Medical ethics and sports medicine - "Athene"

'STEROIDS AREN'T COOL': CRIMINALISING ENHANCEMENT & THE POLITICS OF HEALTHCARE ETHICS

Miah, A.

University of Paisley, United Kingdom

This paper explores the relationship between medical ethics and sports medicine by considering recent conversations in the USA on the doping dilemma. Specifically, the Congressional hearings on Baseball opened with the Chairman Tom Davis calling for a need to help 'kids understand that steroids aren't cool' (Davis, 2005). His words allude to a general transformation of social values and attitudes towards body modification. Indeed, they resonate with wider governmental concern over the prevalence of enhancement interventions (The President's Council on Bioethics, 2003; Elliott, 2003). Yet, these sentiments are confused by Davis' subsequent claim that the 'new [drug] testing program…gets that job done'. His statement fails to recognise that testing is a quite different task compared with changing social values (American Academy of Pediatrics, 2005). In short, young people use steroids for a wider range of reasons other than a competitive edge in sport. The AAP is part of an emerging discourse that treats the doping dilemma as a broader public health issue. This frame raises a number of questions about how the relationship between ethics in sports medicine and medical ethics. Indeed, the last 5 years has shown an increased interest within the medical ethics literature to consider enhancement in sport. I suggest that it is only a matter of time before greater limits are placed on the practice of sports medicine. Indeed, the ensuing controversy surrounding hypoxic chambers is some indication of this. In connection with this emerging public health care discourse, I present a second strand of recent debates on doping, which indicate an increasing sympathy for seeking criminal sanctions for positive doping cases (Donati, 2005). To explain this, I discuss the relationship between the regulation of medical products and their use in sport. I also draw attention to various legal developments that reinforce my claim and warn of a future where doped athletes face criminal prosecution. Finally, I argue for a critical educational framework within anti-doping. Davis' reductionism exposes the absence of a developed science communication and public engagement methodology within sports medicine and science. In conclusion, I urge caution over the criminalizing of performance enhancement in sport and propose a critical healthcare approach to understanding the doping phenomenon in its wider socio-cultural context. Within such a framework, the relationship between sports medicine and medical ethics should be different from convention medical ethics practices, but nevertheless characterised by models of best practice that derive from professional bodies.

WHAT'S WRONG WITH ANTI-DOPING: SOME THOUGHTS CONCERNING THE FEAR OF MODERNITY AND EROSION OF REASON

Moller, V.

University of Southern Denmark, Denmark

This paper is based on the idea that doping is closely related to modernity. It will argue that the current anti-doping campaign reflects an erosion of reason that is caused by a growing fear of scientific progress.

Cycle sports have inspired medical doctors and physiologists to carry out research on the mechanisms of human fatigue. The Monark-cycle, which can be found in laboratories at countless institutes of sports science, symbolises the successful but currently discredited alliance between science and sports. Were it not for the curiosity of science, its wonderful lack of narrow-mindedness and self-restraint, we probably would not have as serious a doping problem as we do today.

The close connection between science and cycle sports is nothing new. What is new is that this connection has been called into question. The heavy-handed way in which the authorities around Europe have begun to take action against doping use in cycling serves as an indication of a growing sense of uncertainty about medicine, even though the scepticism is highly ambivalent. That is, it is neither the production of new medicaments nor the general growth in drug consumption that is the main cause of concern. Instead, it is specifically the connection between medicine and sport to which people take exception. The doping scandal at the Tour de France in 1998 cast a very harsh spotlight on the reality of cycle sport. Although the revelations were shocking, they were not really very surprising. Nothing was found beyond what one might have expected, namely some of the most effective performance-enhancing substances available on the market.

In the process of carrying out their raids and revealing ever more dangerous drugs, what the authorities are doing, all things considered, is eliciting the core problem of modernity. Riders are making use of what modernity is making available to them. This has been the case from the very outset. With this attitude, cycle sport reflects its heritage in modernity. When it is maintained that cycle sport is in crisis, the implication is that modernity is in crisis.

Cycling has come under heavy attack over the past few years. The reason for this, it seems, is that modernity has become old-fashioned, while anti-modern forces has gained in popularity.

WHAT IS WRONG WITH GENE DOPING

McNamee, M.

Swansea University, United Kingdom

The aim of this paper is to offer a critique of recent ethico-political research (Miah, 2004; 2005; Tamburrini, 2000; 2005;2006) that proposes a liberal stance towards doping in general and gene doping in particular. In contrast to these positions, I offer both negative and positive arguments in favour of the status quo as presented by WADA. First, I argue that the argument from inconsistency, which is typically presented, is impotent. Secondly, I present two versions of the slippery slope argument which supports a general anti-doing posture. I conclude with the need to observe a precautionary principle with respect to biotechnology in elite sports.

IS3-07 Spinal cord injury and physical activity - "Innsbruck"

EXERCISE AND WELLBEING IN INDIVIDUALS WITH SPINAL CORD INJURY

Janssen, T., Goedbloed, L., Van der Woude, L.

Rehabilitation Center Amsterdam, Netherlands

An important goal of rehabilitation is to improve the quality of life (QoL) of wheelchair users with a spinal cord injury (SCI). Objective concepts of QoL include mental and physical health (e.g. number of hospitalizations) and functional performance (e.g. Modified Barthel Index (MBI), task performance, Sickness Impact Profile (SIP)). Subjective concepts of QoL contain measures such as the degree of life satisfaction or feeling of well-being. Various factors that affect QoL appear to be related to the degree of physical activity. Inactivity of wheelchair users seems to adversely affect physical and mental health, functional performance and participation level, and independency. After the rehabilitation period, individuals with SCI tend to decrease their activity level, which puts them at risk of ending up in a vicious cycle of deconditioning. In the general population, an active lifestyle and exercise participation have been shown to improve QoL. The purpose of the present overview is to evaluate whether the same holds for wheelchair users with SCI.

Only few studies have evaluated the effect of an active lifestyle and exercise on functional performance. However, based on these, mostly cross-sectional studies, it appears that an active lifestyle and exercise may result in a lower physical strain during daily activities, higher MBI-scores, better SIP-scores, and a better work potential.(1-3) The effects of physical health, as indicated by the number of hospitalizations or medical complications, are less clear and no definitive statements can be made. In contrast, a better mental health appears to result from sports participation. A study by Paulsen et al. (4) showed that wheelchair basketball players had lower depression levels than an inactive control group and Muraki et al. (5) showed that the frequency of sports participation was inversely related to depression scores in a group of 169 men with a SCI. Moreover, various studies have shown that participation in an aerobic and strength training programs can actually decrease depression scores (5-8). These lower depression scores coincided with higher levels of well-being, as indicated by significantly higher scores on the Perceived QoL Scale (6). Whether higher levels of regular daily activity can lead to the same results is not clear yet. In conclusion, it seems that an active lifestyle, exercise and sports participation can contribute to the improvement

of the QoL and feelings of well-being in wheelchair users with a SCI. However, more high-quality longitudinal research is necessary to fully elucidate the suggested relationships.

RESPIRATORY MUSCLE TRAINING IN INDIVIDUALS WITH SPINAL CORD INJURY

Perret, C.

Swiss Paraplegic Research, Switzerland

Among spinal cord injured (SCI) subjects respiratory complications are still one of the most common causes of death (approximately 25%) and occur three to four times more frequently than in the able-bodied population. Thereby, a higher neurological level and completeness of SCI is associated with a higher mortality risk. Due to respiratory complications, duration of hospitalisation during first rehabilitation is prolonged and quality of life in SCI patients is markedly decreased. As a consequence, health care costs increase.

Lesion dependent paralysed respiratory muscles lead to a diminished pulmonary function and respiratory insufficiency. Weakness or failure of the inspiratory muscles may cause alveolar hypoventilation and respiratory failure; the missing expiratory muscles impede a satisfying cough flow. As a consequence pulmonary complications, e.g. pneumonia and atelectasis frequently occur in this population. Thus, interventions to improve respiratory muscle performance and physical fitness of SCI patients are urgently needed.

In this context respiratory muscle training appears to be a promising approach. At present no generally accepted guidelines about respiratory training in SCI exist. Published data is insufficient to make conclusions concerning the effects of respiratory training on respiratory muscle endurance and strength, exercise performance, respiratory complications and quality of life in SCI subjects. Moreover, different types of respiratory muscle training have been used (e.g. respiratory strength vs. endurance training) and it has still to be determined, which form of training (i.e. type, frequency, duration and intensity) will best meet the needs of the clinic and patients. However, our clinical experiences and feedback of patients treated with respiratory muscle training were positive and indicate the potential of such training in SCI subjects. Thus, in the future, well directed studies have to be performed to fill the above mentioned gaps.

OPTIMISATION OF EXERCIES PERFORMANCE IN WHEELCHAIR RACING ATHLETES

Mueller, G.

Swiss Paraplegic Research, 6207 Nottwil, Switzerland

Wheelchair racing is a paralympic discipline where exercise performance is at the highest level in many categories. To win a medal at the paralympic games, athletes have to exercise and prepare for such competitions as able-bodied olympic athletes do.

However, spinal cord injured (SCI) athletes have additional problems to consider due to their impairment. Such problems may cause special or additional exercise training, supplementation, or other arrangements to be used in order to reach the highest possible exercise performance level.

Some of these additional problems are the absence of the sympathetic nervous system regulation in tetraplegic and high lesion paraplegic athletes, the absence of thermoregulation below the lesion level, the lower amount of active muscle mass which also affects respiratory muscles e.g. abdominals and in tetraplegic athletes even most expiratory muscles. This leads to an altered coenaesthesia which needs special attention throughout the whole training process.

THE BRAIN METABOLIC RESPONSE TO EXERCISE: A LINK TO CENTRAL FATIGUE

Dalsgaard, M., DK

Without abstract submission.

BRAIN, NEUROTRANSMISSION AND CENTRAL FATIGUE

Meeusen, R.

Vrije Universiteit Brussel, Belgium

The original central fatigue hypothesis suggested that an exercise-induced increase in extracellular serotonin (5-HT) concentrations in several brain regions contributed to the development of fatigue during prolonged exercise. Serotonin has been linked to fatigue because of its well-known effects on sleep, lethargy and drowsiness and loss of motivation. Several nutritional and pharmacological studies have attempted to manipulate central serotonergic activity during exercise, but this work has yet to provide robust evidence for a significant

role of 5-HT in the fatigue process. However, it is important to note that brain function is not determined by a single neurotransmitter system and the interaction between brain 5-HT and dopamine during prolonged exercise has also been explored as having a regulative role in the development of fatigue. This revised central fatigue hypothesis suggests that an increase in central ratio of 5-HT to DA is associated with feelings of tiredness and lethargy, accelerating the onset of fatigue, whereas a low ratio favors improved performance through the maintenance of motivation and arousal. Convincing evidence for a role of dopamine in the development of fatigue comes from work investigating the physiological responses to amphetamine use, but other strategies to manipulate central catecholamines have yet to influence exercise capacity during exercise in temperate conditions. Recent findings have, however, provided support for a significant role of dopamine and noradrenaline in performance during exercise in the heat. As serotonergic and catecholaminergic projections innervate areas of the hypothalamus, the thermoregulatory centre, a change in the activity of these neurons may be expected to contribute to the control of body temperature whilst at rest and during exercise. Fatigue during prolonged exercise clearly is influenced by a complex interaction between peripheral and central factors.

LIMITS TO PERFORMANCE: INTEGRATION AND ANTICIPATION

St Clair Gibson, A., Dalsgaard, M., Meeusen, R., Jones, D.A., Kayser, B.

University of Cape Town, South Africa

How the information required to moderate pacing strategy during exercise is processed by the brain is still not well understood. Recently work has shown that perhaps the most important factor alowing the establishing of a pacing strategy is knowledge of the endpoint. The brain centre controlling pace strategy and associated power output incorporates knowledge of the endpoint into an algorithm, together with memory of prior events of similar distance or duration, and knowledge of external (environmental) and internal (metabolic) conditions to set a particular optimal strategy for a particular exercise bout in an anticipatory manner at the start of the exercise bout. Once the exercise bout has started, an internal clock, which appears to use scalar rather than absolute time, is used by the brain to generate knowledge of the duration or distance still to be covered, so that power output and metabolic rate can be altered appropriately and continuously by the brain algorithm, using feedback information from both external and internal receptors, with the perception of effort being a scalar representation of these underlying brain algorithmic control processes.

EFFECTS OF CARBOHYDRATE AND FLUID INTAKE ON LEUCOCYTE AND CYTOKINE RESPONSES TO ENDURANCE EXERCISE IN THE HEAT

Suzuki, K. 1-3, Oh, T. 2, Peake, J. 1, Usui, C. 2, Kaneko, K. 2, Ishijima, T. 2, Ogawa, K. 1, Terada, O. 1, Mitsuda, H. 4, Sato, K. 4, Ishii, C. 4, Muraoka, I. 2, Higuchi, M. 2+3

1-3 Waseda University, 4 Asahi Soft Drinks Co., Japan

Purpose: Carbohydrate ingestion is known to promote energy supply and attenuate hormonal and inflammatory responses to endurance exercise. Fluid intake is also important to prevent dehydration, exertional rhabdomyolysis and heat stroke. The present study was designed to investigate the effects of oral carbohydrate and fluid supplementation on body temperature, dehydration state, energy substrate levels, related hormones, cytokines, muscle damage marker and leucocyte responses to endurance exercise in the heat using three different fluids; isotonic and hypotonic carbohydrate drinks and pure water.

Methods: Six well-trained male cyclists completed three separate cycling trials at 60% VO2max for 90 min in hot conditions (28.1±1.5 ºC and 52.6±3.1% relative humidity). Three different fluids were orally ingested ad libitum during 90-min exercise: (1) isotonic drink consisting of 4.0% glucose and 2.0% sucrose, osmolarity 317 mOsm/kg; (2) hypotonic drink consisting of 2.4% sucrose, 1.2% fructose and 0.5% malt dextran, osmolarity 193 mOsm/kg; and (3) deionised water. Each trial was separated by at least one week, and the ingested amount was recorded. Body weight, drink consumption, rectal temperature, and heart rate were monitored, and blood samples were collected before, during (45 min), immediately after, and 30 min after exercise. Blood was analyzed for total and differential leucocyte counts, glucose, free fatty acid (FFA), lactate, catecholamines, cytokines, myoglobin, and osmolarity. All the blood data were adjusted for plasma volume changes by haemoglobin and haematocrit.

Results: Fluid intake was greatest for the hypotonic trial (1403±557 g) and significantly larger than that of the water trial (701±249 g). There were no significant differences between the three different drink trials in exercise-induced increases in core temperature, heart rate, blood lactate, osmolarity and myoglobin levels. However, plasma glucose levels were significantly elevated for the isotonic trial (137±34 mg/dl) than the hypotonic (103±17 mg/dl) and water trials (87±8 mg/dl) at 30 min after exercise. FFA levels, total leucocyte and neutrophil counts increased following exercise, but carbohydrate attenuated these responses at 30 min after exercise in both the isotonic and hypotonic drink trials. The plasma levels of epinephrine and interleukin (IL)-6 were elevated following exercise, but these responses were lower in the hypotonic trial compared to the isotonic and water trials.

Conclusion: Carbohydrate interventions had significant effects to lower FFA and leucocyte responses to endurance exercise in the heat. Interestingly, compared to the isotonic drink and water, the hypotonic drink was more effective for not only fluid supply but also preventing epinephrine and IL-6 responses.

WAVE FORM OF MOTOR UNIT ACTION POTENTIALS DURING CONSTANT FORCE CONTRACTION IN HUMAN MUSCLE

Kamo, M., Morimoto, S.

Japan Women's College of Physical Education, Japan

INTRODUCTION : Amplitude and/or the integrated value of the surface electromyogram (sEMG) increased with time during submaximal sustained contraction. The increase of interference sEMG contains both a central mechanism, motor unit (MU) discharge pattern and a peripheral mechanism, changes in the motor unit action potential (MUAP) wave form. The contribution ratio of the each factor to sEMG remains unclear. In the present study, we focused on wave form changes of surface detected MUAPs during voluntary constant force contraction at low levels.

METHODS: Subjects were requested to sit on a high stool. To record the force developed at the ankle, the lower leg, articulatio pedis, was fastened with a strap connected to a strain gauge. The angle of the knee joint was set at 90 degrees. The subjects isometrically produced a constant force for 3min. The target force was set below the force level at which MUAPs became undistinguishable during the contraction (≤20%MVC). MUAPs were detected bipolarly using surface disc or array electrodes (Ag/AgCl with a diameter of 5-mm) placed on the vastus medialis or vastus latelaris muscles. We analyzed amplitude (peak-to-peak voltage) and duration (time between first and last base- line intersections) of MUAP and measured spike intervals during the contraction. Furthermore, conduction velocity (CV) of MUAP was calculated from the relationship between the time delay in the negative peak of MUAP detected from each surface electrode and the distances between the electrodes.

RESULTS: Spike interval of MU gradually became elongated during the constant force contraction for 3min. CV initially started to steeply decrease for 1min, then, the decrease became gentle. During the initial 1min of the contraction, the amplitude and duration of MUAP gradually increased, then became sustained during the last 2min. The magnitude of the change was about 10-20%.

CONCLUSION: Even though the low level contraction only weakly activated slow MUs, the magnitude of MUAP increased significantly. These findings suggest that peripheral mechanisms, such as these changes in MUAP, influence sEMG during low-level contraction.

ADIPOSE TISSUE AS AN ENDOCRINE ORGAN: EFFECTS OF EXERCISE AND DIETARY THERAPY

Kimura, M., Yoda, E., Shinozaki, T., Kadoriku, H., Shibasaki, Y., Tateishi, N., Yamauchi, H., Suzuki, M., Hosoyamada, M., Shibasaki, T.

Kyoritsu University of Pharmacy, Japan

Obesity is becoming a worldwide medical problem. Risks of the onset of metabolic syndrome are exacerbated by overweight conditions. Nevertheless, the mechanism of the harmful influence of obesity has remained obscured until quite recently. In addition to its classical function as an energy reservoir, adipose tissue is now known to be very active as the largest endocrine organ. It produces several hormones that are referred to as adipocytokines.

Adiponectin (Ad) is an extremely important adipocytokine: Ad putatively acts as an anti-diabetic and anti-atherogenic factor. Numerous studies have reported an inverse relationship between body weight and/or fat volume and blood Ad concentration.

On the other hand, food restriction (FR) and exercise (EX) are commonly recommended for prevention and amelioration of obesity and life style-related diseases. In obese and diabetic patients, weight reduction induced by FR increases the Ad level in blood. However, only sparse and conflicting evidence has been reported in relation to the effects of EX on blood Ad concentrations. For that reason, we examine whether blood Ad concentrations are similarly regulated by EX as with weight-matched FR in spontaneously hyperphagic and obese rats.

A 12-week wheel running EX brought no change in plasma Ad concentration even though it engendered similar reductions in weight and fat volume to those of FR. Against our expectations, these similar changes in weight induced by different interventions imply contradictory changes in plasma Ad concentration.

Gender differences are reported in blood Ad concentrations. Therefore, sex hormones might affect the expression and/or secretion of Ad from adipocytes. Previous studies have reported that castrated mice have high plasma Ad concentrations, and that testosterone administration decreased plasma Ad levels in those mice. Another study reported the presence of higher Ad concentration in hypogonadal men than in eugonadal subjects. Those levels decreased following testosterone replacement therapy.

On the other hand, some types of EX are known to increase blood testosterone levels. In the present study, chronic EX significantly increased plasma testosterone concentrations over those of control and FR rats. For all animals, a significant inverse relationship existed between the levels of plasma testosterone and Ad concentration.

These results suggest that the hypoadiponectinemic effect of testosterone might offset the hyperadiponectinemic effect of reduced fat volume observed in EX rats. We speculate that different results garnered from previous studies designed to examine the effects of EX on Ad might be attributable to variable effects of EX on blood testosterone levels (training status, sampling timing, aging, and species, etc.), and that the type of EX training that raises testosterone levels might suppress the expression and/or secretion of Ad from adipocytes.

ACUTE EXERCISE ALTERS EXPRESSION OF STEROIDOGENESIS-RELATED ENZYMES IN THE SKELETAL MUSCLE OF RATS

Aizawa, K., Maeda, S., Lemitsu, M., Otsuki, T., Jesmin, S., Miyauchi, T., Mesaki, N.

University of Tsukuba, Japan

Sex steroid hormones, such as testosterone and estradiol, are mainly synthesized in ovary, testis, and adorenal cortex and have various physiological actions. Aromatase cytochrome P450 (P450arom), 3beta-hydroxysteroid dehydrogenase (HSD), and 17beta-HSD are essential component enzymes in the steroidogenesis metabolic pathway. Recently, several studies have been reported the presence of the steroidogenesis-related enzymes in the brain, liver, and kidney as well as ovary and testis tissues. In the skeletal muscle, testosterone and estradiol play an important role of buildup in the muscle form and strength. However, the presence of the steroidogenesis-related enzymes in the skeletal muscle and effect of these enzymes by a single bout of exercise are unclear.

PURPOSE: We investigated whether the gene and protein expressions of steroidogenesis-related enzymes, namely, P450arom, 3beta-HSD, and 17beta-HSD, are present in the skeletal muscle and the expression of these enzymes is altered by acute exercise in male rats.

METHOD: Sixteen male SD rats (10-week old) were randomly divided into two groups. Exercise rats (n=8) performed treadmill-running exercise (30m/min) for 30min. Immediately after this exercise, the gastrocnemius muscle was quickly removed. Control rats (n=8) remained at rest during the same 30-min period.

RESULTS: The present study evaluated the presence of mRNA and protein expression of P450arom, 3beta-HSD, and 17beta-HSD in the gastrocnemius muscle by using quantitative RT-PCR, Western bolt, and in situ hybridization analyses. The mRNA expression of P450arom, 3beta-HSD, and 17beta-HSD detected in the gastrocnemius muscle. The protein expression of P450arom and 17beta-HSD detected in the gastrocnemius muscle. The mRNA expression of 17beta-HSD and P450arom in the gastrocnemius muscles was significantly higher in the exercised than in the control rats, but that of 3beta-HSD did not change. Additionally, the protein expression of 17beta-HSD and P450arom in the gastrocnemius muscles were significantly higher in the exercised than in the control rats.
CONCLUDION: The present results suggest that steroidogenesis-related enzymes locally express in the skeletal muscle and the expression of 17beta-HSD and P450arom are increased by a single bout of exercise. Thus, the acute exercise-induced increase in expression of steroidgenesis-related enzyme may be enhance the locally steroidogenesis in the skeletal muscle.
Supported by grants from the Ministry of Education, Science, Sports and Culture of Japan (17300204).

IS3-10 High-Tech in skiing - "Berlin ABC"

THE ALPINE SKI BINDING: WHAT DO WE KNOW, WHERE SHOULD WE GO?

Senner, V., Lehner, St.

Technische Universität München, Germany

Alpine ski bindings seem to have lost the importance they used to have until the beginning of the nineties. There are several reasons for this discouraging development. First today's manufacturers are selling ski and binding as a system and this does not allow the customer to choose between different brands. Competition between the producers is therefore built on the ski and its success in ski race. Secondly manufacturers marketing efforts in the last few years have reduced functionality of ski bindings to just "fix-the-boot-to-the-ski". Safety however has become a very unpopular marketing argument. Third – and for this science should be blamed – no convincing solution has brought up to overcome the No.1 problem in skiing, the high incidence of knee injuries. Finally the entire ski industry and also many researchers have been focusing on the topic "carving" under various aspects such as its impact on skiing performance, its implications regarding new skiing technique, its impact on muscular and joint loads or regarding metabolic consumption. The ski binding however was overlooked for these years.
This presentation will try to structure the current knowledge on ski bindings and identify the open questions, giving biomechanists, engineers and sport scientists the motivation to continue with research in this field. It will explain that since the late 70ties all knowledge has been available to build ski bindings being perfectly able to protect the tibia. A look at today's bindings however will demonstrate that this knowledge still has not been completely transferred into current designs.
Understanding that protection of the knee was not a consideration when the actual bindings have been developed, it is obvious that the scientific community had to struggle towards a better understanding of knee injury mechanisms in skiing. A brief summary of some of the major studies conducted by three US research groups D. Mote (Maryland), M. Hull (California) and B. Johnson, J. Shealy, C. Ettlinger (Vermont) will be given. Their results and those of other scientists clearly define the problems; their observations however were interpreted differently regarding setting values of release bindings. Whereas the Vermont scientists conclude that current recommended torques and moments are optimum, French researchers see the need to reduce the settings especially for female skiers. To prove the efficiency of this idea (and to demonstrate that this is not a trade-off regarding inadvertent release) the French are currently conducting a monitored case-control prospective epidemiological study with reduced binding settings. American efforts go towards improvements in the standardization of i.e. boot to binding interfaces, improved shop practise for retail and rental and ACL awareness programs. The ongoing German efforts towards ski binding and improved safety technology will close the presentation.

METHODS FOR TESTING SLIDING PERFORMANCE ON SNOW

Rhyner, H., Lüthi, A., Fauve, M.

Swiss Federal Institut for Snow and Avalanche Research (SLF) Davos, Switzerland

Sliding of skis on snow is influenced by many variables. The following ones are important for us: Concerning the skier: its his weight and aerodynamics. For the ski: its hardness and dynamical behaviour. For the ski base: its hardness, surface roughness, heat conductivity and wetting behaviour are the main factors regarding sliding on snow. Snow is the other side of the sliding system where following variables are important: surface temperature, roughness and hardness. At snow temperatures around zero degree Celsius the liquid water of snow is another important variable. The influence of all these variables can be analysed in field tests, under the condition that all variables are measured on the same scale and remain constant during the tests. We have conducted over 2500 test runs during which we have analysed the influence of some of the aforementioned variables. Such field tests are very time-consuming and expensive. Therefore we have developed a device which allows sliding tests under laboratory conditions. The friction coefficient of small ski samples on ice or snow is measured on a 180 cm diameter turn-table under constant conditions. These laboratory measurements allow comparisons between different sliding materials and systems on a small scale before whole skis can be built . Measurements with this device is used as well for the development of a new friction model..

HIGH TECH IN ELITE ALPINE SKI RACING

Müller, E., Müller, J., Schiefermüller, C., Kröll, J., Schwameder, H.

University of Salzburg, Austria

Sport biomechanics plays an important role in optimising the training quality in ski racing. The areas of applying biomechanics in the training process of elite skiers are very diverse. In the first area those parameters which essentially influence performance have to be analysed. These investigations have to be done during field studies using highly developed kinematic, kinetic and electromyographical measurement systems. The scientific challenges lie in the precision of the parameters determined (accuracy of the measurement system) and in the fact that the athlete should not be interfered severely by the measurement system during performance. The results of such

investigations lead to a better understanding of movements used and provide coaches and athletes valuable support in directing training goals.

The efficiency of the training process also depends on the quality of performance tests available. Standardised tests should be built into the trainings process for all performance-relevant features. These tests must satisfy the criteria of objectivity, reliability and validity. In recent years a ski specific test battery using various high tech measurement devices has successfully been developed at our department.

Especially in seasonal sports like alpine ski racing the quality of training relies to a great extent on the availability of specific training exercises. Specific exercises must be in harmony with those parameters of movement which characterise the structure of competition technique. Most of these exercises can only performed on specially developed training devices. Both, training exercises as well as training devices have to be evaluated using kinematic, kinetic and electromyographical methods.

Numerous investigations in the area of motor learning and technical training have indicated that suitable feedback systems can significantly contribute to shortening acquisition time. These systems, on the one hand, should measure as exactly as possible the characteristics which are to be improved in training and, on the other, make the measurement results available to the athlete in an easily understandable form and within the most effective 'PR-KR Interval'.

And, last but not least, biomechanical investigations should also assist the athlete's efforts of optimising the equipment. Alpine skis and the corresponding equipment as bindings and risers are not optimised yet for individuals in ski racing regarding length, shape, stiffness etc. The bases for this optimisation are measurements of the mechanical characteristics of the material in typical and natural skiing conditions. This knowledge is used to optimise the skiing equipment to finally enhance the performance.

DECREASE IN THE NUMBERS OF MECHANORECEPTORS IN RABBIT ACL: THE EFFECTS OF AGEING

Aydog, S.T., Korkusuz, P., Doral, M.N., Tetik, O., Demirel, H.A.

Department of Sports Medicine, Faculty of Medicine, Hacettepe University, Turkey

It is proposed that there is a positive correlation between the numbers of mechanoreceptors and proprioceptive function. On the other hand, normal aging process is associated with deficits in proprioception.

This study is designed to test the hypothesis that aging resulted in decreased numbers of mechanoreceptors. Anterior cruciate ligaments of 14 male rabbits (2 months, n=5; 12 months, n=4 and 60 months, n=5) were extracted and the total numbers of Ruffini, Pacini and Golgi tendon-like receptors were accounted.

As a result, the numbers of mechanoreceptors, especially Ruffini receptors, decreased with aging ($p<0.05$). Increased age was associated with changes in the morphology of mechanoreceptors.

In conclusion, aging results in both diminished numbers and changed morphology of mechanoreceptors.

TRAINING INDUCED ADAPTATIONS IN MUSCLE EXTRACELLULAR MATRIX AND TENDON IN RATS: HOW DOES CONTRACTION TYPE INFLUENCE COLLAGEN- AND GROWTH FACTOR EXPRESSION?

Heinemeier, K., Olesen, J., Schjerling, P., Haddad, F., Langberg, H., Baldwin, K., Kjær, M.

Bispebjerg hospital, Denmark

Introduction: Tendon and muscle extracellular matrix (ECM) are essential for force transmission in skeletal muscle. Though acute exercise is known to increase collagen synthesis in both muscle and tendon, differential effects of specific training types on collagen expression in muscle ECM and tendon are unknown. Furthermore, mechanisms involved in the adaptation of these tissues are not fully understood. We investigated the effect of concentric-, eccentric- and isometric training on expression of collagens, and of growth factors, known to induce collagen synthesis, in rat muscle and -tendon.

Methods: Three groups (n = 8) of young adult female Sprague-Dawley rats were subjected to concentric-(CT), eccentric-(ET)- or isometric (IT) training. The m. gastrocnemius was activated by electrically stimulating the sciatic nerve at a frequency (~ 50 Hz) and voltage adjusted to produce maximal isometric tension. Sets, divided by 5 min rest, consisted of 10 x 2 s stimulations with 18 s rest between contractions. Rats were trained for 4 days with 2 sets on day 1, 3 sets on day 2, and 4 sets on day 3 and -4. Rats had their right foot placed in a footplate with an angle of ~ 44° relative to the tibia. For the IT group the angle was fixed during muscle stimulation. During contraction the footplate was moved from 44 ° to 64 ° for the CT group and from 44° to 24 ° for the ET group. RNA was extracted from medial gastrocnemius- and Achilles tendon tissue 24 h after the last training bout, and mRNA levels for collagen I and -III, transforming growth factor-b-1 (TGFb1), insulin like growth factor-IEa (IGF-IEa) and mechano growht factor (MGF) were measured by real-time RT-PCR. Real-time RT-PCR results were normalised to the weight of the individual tissue samples.

Results: Training increased type I collagen mRNA in muscle tissue ($p<0.001$) and in tendon a specific increase was seen in response to CT and IT ($p<0.05$). In both tendon and muscle tissue, type III collagen mRNA increased markedly (up to 20-fold in tendon) in response to all types of training ($p<0.001$). Muscle subjected to ET had a greater increase in mRNA for TGFb1, IGF-IEa and MGF than muscle subjected to CT ($p<0.05$). Additionally the effect of IT on IGF-IEa and MGF was larger than the effect of CT ($p<0.05$). In tendon tissue we also found an increase in TGFb1, IGF-IEa and MGF mRNA but no difference was seen between the different types of training ($p>0.05$).

Discussion: The increased collagen expression supports a training-induced adaptive response in muscle ECM and tendon. Furthermore ET appears to have a larger potential than CT for increasing the expression of collagen-inducing growth factors in muscle. This may be connected to a greater force production during eccentric contraction, or perhaps to a greater local shear stress in the muscle tissue. The changes seen in tendon were not dependent on training type, which indicates that this tissue is unable to distinguish between the 3 contraction modes.

CAUSES OF MUSCLE CELL DAMAGE: MECHANICAL STRAIN OR CALCIUM OVERLOAD?

Fredsted, A., Gissel, H., Clausen, T.

University of Aarhus, Denmark

Background: Prolonged or unaccustomed exercise leads to muscle cell damage, detectable as a release of the intracellular enzyme lactic acid dehydrogenase (LDH). This is correlated to excitation-induced influx of Ca2+ (1). If the cytosolic concentration of Ca2+ is elevated locally or globally to critical levels for longer time periods degradative mechanisms may be initiated leading to membrane damage. It cannot be excluded, however, that the mechanical strain on the muscle occurring during contraction contributes to the damage. We here explore this question using a chemical tool, N-benzyl-p-toluene sulphonamide (BTS), which specifically blocks muscle contraction in fast-twitch muscles (2).

Methods: Isolated extensor digitorum longus (EDL) muscles (20-25 mg) were prepared from 4 wk old Wistar rats and mounted on holders for isometric contractions. Muscles were incubated in normal Krebs-Ringer bicarbonate buffer and continuously gassed with a mixture of 95 % O2 and 5 % CO2. Muscles were stimulated intermittently (10 sec on, 30 sec off) at 40 Hz (1 ms pulses of 10 V) for 15, 30 or 60 min or exposed to the Ca2+ ionophore A23187.

Results: Electrical stimulation increased 45Ca influx 3-5 fold. This was followed by a progressive release of LDH. In the presence of BTS at a concentration (50 μM) causing 90% inhibition of contractile force, excitation induced the same increase in 45Ca influx, but the increased release of LDH was completely suppressed. Both in the absence and in the presence of BTS (50 μM), A23187 markedly increased LDH-release. Muscles exposed to passive mechanical stretching of up to 0.39 N, which is comparable to the tension developed during electrical stimulation, showed no release of LDH in the 180 min exposure period. In control muscles, electrical stimulation induced a drop of 49% and 54% in the contents of ATP and creatine phosphate, respectively. These drops were significantly reduced in BTS treated muscles to 32% for ATP ($p=0.001$) and to 42% for creatine phosphate ($p<0.05$).

Conclusion: During isometric contractions muscle excitation is associated with a large influx of Ca2+ and a progressive release of LDH. We suggest, that BTS treated muscles have a better capacity (more ATP) to clear the cytosol for the incoming Ca2+, thereby reducing the membrane damage caused by Ca2+ activated degradative mechanisms. Even though A23187 treated muscles do not contract, a large increase in Ca2+ influx and LDH release occurred. Thus, we conclude that the degree of cell damage during isometric contractions depends mainly on the size of Ca2+ influx and on the energy status of the cell, but not on mechanical stretch.

CHANGES IN MUSCLE FIBRE CSA AND MUSCLE FIBRE PENNATION ANGLE WITH DISUSE AND TRAINING IN ELDERLY POSTOPERATIVE PATIENTS

Suetta, C., Magnusson, S.P., Dalgas, U., Berget, J., Andersen, J.L., Koskinen, S., Aagaard, P., Kjær, M.

Institute of Sports Medicine, Bispebjerg Hospital, Denmark

Introduction

Sarcopenia has long been recognized as a major cause of muscle strength loss in old age, however, the contribution of changes in muscle architecture has seldom been considered. Furthermore, it is well known that a substantial amount of muscle mass and strength is lost during joint-surgery related immobilization (Häggmark 1981). However, despite the increasing prevalence of musculoskeletal diseases that requires surgery in the elderly, regimes for optimal rehabilitation remains unknown and in general, only limited research is available on the role of training in preventing or reversing age and disuse-related changes in muscle morphology. The purpose of the present study was therefore to compare the change in muscle size and muscle architecture induced by unilateral Strength Training (ST) or Electrical Stimulation (ES) of the quadriceps muscle compared to a Standard Rehabilitation (SR) program after hip-replacement surgery.

Methods

Thirty patients (60-86 yrs) scheduled for unilateral hip replacement due to osteoarthritis (OA) were randomised to either 1) ST (3/wk×12 wks), 2) ES (1 h/day×12 wks) or 3) SR (1 h/day×12 wks). Muscle biopsies were obtained from vastus lateralis (VL) of both legs at baseline, 5 and 12 wks post-surgery to analyze for changes in muscle fibre CSA. Muscle architecture was evaluated by measurement of muscle fibre pennation angle in the VL muscle by use of ultrasonography. Non-parametric tests were used for statistical analyses (significance level, $p<0.05$).

Results

At the onset of the study significantly reduced muscle fibre pennation angle (- 15%) and single fibre CSA of type I (-14%) and type II (-26%) muscle fibre area was observed in the OA-leg compared to the healthy leg. After 12 wks of strength training a 20% increase was observed in muscle fibre pennation angle (7.2±0.50 to 8.6±0.60, $p<0.05$) whereas no increase was observed with ES and SR. Furthermore, a significant increase was observed in type I muscle fibre CSA (+17%, $p<0.05$) and type II muscle fibre CSA (+37%, $p<0.05$) with strength training but not with ES and SR.

Discussion

The present study is the first to demonstrate that postoperative strength training is highly effective in increasing muscle fibre area of both type I (+17%) and type II (+37%) fibres, similarly to the effects shown in healthy elderly individuals (Frontera 1988, Häkkinen 1998). In addition to the muscular changes pertaining to single muscle fibers, strength training also induced marked alterations in muscle architecture by increasing muscle fibre pennation angle of the VL muscle compared to electrical stimulation and a standard rehabilitation regime.

EFFECT OF ECCENTRIC CONTRACTION VELOCITY ON MUSCLE DAMAGE

Chapman, D., McGuigan, M., Nosaka, K.

Edith Cowan University, Australia

Controversy exists concerning the effect of contraction velocity on exercise-induced muscle damage. Some studies report greater muscle damage induced by fast velocity than slow velocity eccentric actions, but the opposite is shown by others. Our previous study (Chapman, et al. Int J Sports Med in press 2006) showed that 210°/s compared to 30°/s eccentric exercise induced greater muscle damage. However, to equate muscle tension time the number of repetitions was vastly different between velocities (30 vs 210). The present study compared a slow (30°/s) and fast (210°/s) velocity eccentric exercise for changes in markers of muscle damage by equating the number of repetitions. Eight male volunteers (26.4+/-6.2 yrs) performed 210 (35 sets of 6) eccentric actions of the elbow flexors on an isokinetic dynamometer. Dominant and non-dominant arms were randomly assigned to perform slow (SV:30°/s) or fast (FV:210°/s) velocity maximal eccentric exercise separated by 10 days. Each maximal eccentric action (60-180° full elbow extension) was followed by a passive movement to the flexed position with a 90s rest between sets. Dependent variables included maximal voluntary torque for isometric and concentric (3 velocities) contractions, range of motion (ROM), upper arm circumference (CIR), muscle thickness (MT) and B-mode ultrasound echo intensity (ULT), muscle soreness (SOR), serum creatine kinase (CK) and lactate dehydrogenase (LDH) activities. Measures were taken before, immediately post, 1 hr and 24-120 hrs after each eccentric exercise protocol and comparisons between FV and SV were made by a repeated measure ANOVA. Work performed during exercise was significantly ($p<0.01$) greater for FV (13364 J) than SV (9298 J). Both exercises resulted in significant decrements in isometric and dynamic torque ($p<0.05$), but FV resulted in a significantly ($p<0.05$) slower recovery of isometric strength at 130° and 150° elbow flexion compared with SV. Significantly ($p<0.05$) larger decrease in ROM was evident after FV than SV. MT and ULT changed significantly ($p<0.05$) larger following FV than SV. FV resulted in significantly ($p<0.05$) larger increases in CIR and SOR compared to SV. Peak serum CK activity was significantly greater ($p<0.05$) following FV (6282 IU/L) than SV (1808 IU/L), and LDH activity recorded a greater peak following FV (468 U/L) than SV (389 U/L). These results indicate that FV induces greater muscle damage than SV, and recovery of muscle function after FV was slower than SV, although the magnitude of decrease in muscle function immediately after exercise was similar. This work confirms the finding of our previous study. It would appear that the slower recovery of muscle function after FV, and the greater changes in other measures were due to fewer muscle fibres sharing the workload, resulting in greater strain on the connective elements of fewer fibres.

RELATIONSHIP BETWEEN HEART RATE AND OXYGEN UPTAKE IN ELITE CYCLISTS

Lounana, J., Campion, F., Medelli, J.

CHU Amiens, France

Purpose. To study the possible changes in power output (W), heart rate (HR), oxygen uptake (VO2), and HR-VO2 relationship in elite cyclists at maximal incremental exercise test during two different periods of sport season.

Methods. 20 elite male cyclists (29.5±4 years; 181±7 cm; 74.1±4.3 kg; VO2max: 72.7±5.3 ml•kg-1•min-1), including 14 professional cyclists and 6 elite amateur cyclists, performed two incremental tests (50W/3-min stages) until exhaustion on an electromagnetic bike ergometer. Gas exchange was continuously monitored (mixing chamber, sampling every 30 s.). Test 1 took place at December during the pre-training phase (OFF period), and test 2 at June in the middle of the active period of training and competition (ON period). Mean values were studied at the first and second ventilatory thresholds (VT1, VT2) and at maximum workload (MAX). The values of the last minute of each completed step were averaged and used for the HR-VO2 regression analysis with calculation of slopes and intercepts and prediction of HR or VO2 values throughout the range of exercise intensities.

Results. A duration of 5.6 ± 0.5 months on average separated test 1 and 2. In comparison to period OFF, W and VO2 were higher at VT1 (211±28 vs. 191±28 watts; 41.7±5.5 vs. 38.4±4.1 ml•kg-1•min-1; $P < 0.05$), at VT2 (308±29 vs. 288±36 watts; 53.7±5.1 vs. 48.6±5.5 ml•kg-1•min-1; $P < 0.01$) and at MAX (446±31 vs. 404±30 watts; 72.7±5.3 vs. 65.8±5.1 ml•kg-1•min-1; $P < 0.001$) during period ON. Similarly, VO2 or %VO2max values corresponding to indicated HR values set between 135 and 175 bpm were higher ($P < 0.001$). Inversely, other parameters were significantly lower during ON compared to OFF, such as the HR at VT2 and at MAX ($P < 0.05$), the target HR corresponding to any given intensity above 65% of VO2max ($P < 0.01$) as well as the slope of the HR-VO2 regression (2.19±0.3 vs. 1.76±0.2; $P < 0.001$).

Discussion and conclusion. Bland and Altman procedure have shown a level of agreement higher than 95% for every comparison paired according to the two test periods. This study shows that the power output, heart rate and oxygen uptake values can significantly change over a sport. Notably, the HR-VO2 relationship doesn't remain steady between the pre-training and the racing period, suggesting that a single athletic evaluation for the whole season is neither sufficient nor suitable for effectively monitoring and guiding the training of elite cyclists. We therefore propose that elite cyclists should perform at least two evaluations per season, one in period OFF and the other in period ON.

VERY HIGH-INTENSITY TRAINING WITH SHORT REST PERIODS DECEASES MUSCLE BUFFER CAPACITY

Edge, J., Goodman, C., Bishop, D.

Massey University, New Zealand

Previous results in our laboratory indicate that training intensity affects changes in muscle buffer capacity (Bm) and supports the hypothesis that the accumulation of H+ within skeletal muscle and blood may be an important stimulus to improve Bm. If H+ accumulation

during training is important to changes in Bm, then altering the length of the rest period between intervals (and therefore H+ accumulation) should influence adaptations to Bm. The purpose of this study was to compare the effects of a 1-min or 3-min rest interval between very high-intensity cycling intervals during training on changes to Bm and muscle metabolism during high-intensity exercise.

Twelve, moderately-trained females (mean ± SD: age 20 ± 3 y, mass 62.3 ± 10.0 kg), performed a graded exercise test to determine VO2peak and the lactate threshold (LT), followed 48 h later by a constant-intensity cycle test (CIT: 45 s at 200% pre-training VO2peak). Muscle biopsies (vastus lateralis) were taken before and after the CIT to determine Bm (in vitro) and muscle metabolites. Subjects were randomly assigned to either high-intensity interval training with 1-min (HIT-1) or 3-min (HIT-3) rest periods between intervals. Each subject had a matched partner (matched on the LT) in the opposing group, with whom they were required to complete an equal amount of work during each training interval and session (6-12 x 2 min at 150% LT, 3 d.wk-1 x 5 weeks).

There were increases in VO2peak (9-11%; $p<0.05$) and the LT (8-15%; $p<0.05$) for both groups, with no differences between groups. There was a decrease in Bm for the HIT-1 group (13%; $p<0.05$) and an increase in Bm for the HIT-3 group (6%; $p<0.05$) following the training period. Following training there were no changes to pre or post-exercise [ATP] or [PCr]. However, there was a reduction in [La-] (32-34%) and [H+] (48-50%) during the CIT for both groups ($p<0.05$), with no differences between groups.

We have shown that very high-intensity training with short rest periods (HIT-1) does not result in greater improvements in Bm, but actually decreases Bm in moderately-trained females (13%). As we have previously shown an acute decrease in Bm following very high-intensity exercise, it may be that a chronic decrease in Bm results when very intense exercise bouts are repeated over time. These findings contrast with previous results within our laboratory using a similar training protocol (2 min intervals, 1 min rest periods). The present results may be due to the higher training-intensity employed than previously (150% LT v 130% LT). In contrast, training at the same workload (150% LT), but with longer rest periods (HIT-3), resulted in a small increase in muscle buffer capacity. Therefore, during very high-intensity training, the rest period per se, does affect training adaptations to Bm. Despite the difference in changes to muscle buffer capacity between groups, there were no differences in muscle metabolism or H+ regulation during supra-maximal exercise.

RELIABILITY AND SENSITIVITY OF A CYCLING TIME TRIAL IN A GLYCOGEN DEPLETED STATE

Currell, K., Jentjens, R., Jeukendrup, A.E.

University of Birmingham, United Kingdom

It is very difficult to conduct laboratory studies into the effects on various manipulations on very prolonged endurance exercise performance (>3h). When measuring performance the protocol used must be reliable, valid and sensitive enough to detect small changes that are relevant to athletes. Little data is available on the reliability of performance trials of that duration. The aim of this study was to investigate the reliability of a protocol designed to simulate endurance events of long duration (~ 6h) by lowering endogenous carbohydrate stores the day before.

Seven male subjects were recruited (Age 27 ± 7 yrs, VO2max 66 ± 5 ml.kg-1.min-1, Wmax 367 ± 42 W). The subjects underwent four trials to determine the reliability and sensitivity of the protocol. Three of these trials were placebo trials with the final two trials being randomised and counterbalanced with a carbohydrate beverage (6.67% Maltodextrin solution). For each trial subjects entered the laboratory in the evening to undergo a glycogen depleting exercise trial lasting approximately 2.5 h. The subjects subsequently returned the following morning in a fasted state to undertake a 1h steady state ride at 50% Wmax followed by a time trial of approximately 40 min duration. During the steady state ride measures of expired gas, blood, heart rate and RPE were collected every 15min. A 600ml bolus of a placebo drink was given 5min prior to the start of the steady state period followed by a 150ml bolus every 15min throughout the steady state period and a third and two thirds of the way trough the time trial. The placebo trials were analysed for reliability of time to completion of the time trial using a coefficient of variation (CV), with 95% confidence intervals. The presence of any systematic error between placebo trials was analysed using a repeated measures ANOVA. The relationship between measurement error and time to completion was analysed using Pearsons r. A paired t-test was used to analyse any differences in time to completion between the placebo and carbohydrate trials.

The mean time to complete of the three placebo trials was 2546s, 2585s and 2568s for trials 1,2 and 3 respectively. There was no significant difference between these trials ($P > 0.05$). There was no significant correlation ($P > 0.05$) between the measurement error and the time to completion. The CV between trials 1 and 2 was 4.5% (95% CI 2.9 – 10.4%) and between trials 2 and 3, 3.8% (95% CI 2.4 – 9.9). There was no significant difference between the placebo and carbohydrate trials ($P > 0.05$). However there was a 7.7% (95% CI -6.67 – 22.06%) improvement in time to completion with the ingestion of carbohydrate.

Very few studies have investigated reliability during very prolonged exercise. The variation of the current protocol is similar to previous studies in the literature for time trial protocols with shorter duration. This is the first study to report reliability of a test designed to simulate ultraendurance performance.

MAXIMAL ECCENTRIC TRAINING HAS AN OSTEOGENIC IMPACT ON AREAL BMD IN BONES HABITUALLY UNEXPOSED TO LARGE ECCENTRIC MUSCLE CONTRACTIONS

Wulff Helge, E., Kanstrup, I.-L.

Institute of Exercise and Sport Sciences, University of Copenhagen, Denmark

From animal studies it is well known that strain rate and magnitude resulting from muscle contractions are important stimuli in mechanotransduction leading to bone formation. It is also known that force development is higher in maximal eccentric than in maximal concentric contractions. PURPOSE: Thus, we wanted to investigate the impact of eccentric training on areal bone mineral density (aBMD). The main hypothesis was that four months of maximal eccentric training three times a week would increase aBMD. Secondly, we hypothesized to find an association between increase in maximal eccentric muscle torque (MEMT) and increase in aBMD. METHODS: Subjects were 15 female recreational runners (running > 2 hrs/wk), age 23-40 years, all normal menstruating. Eight participated in the strength training and seven were controls. Training consisted of maximal eccentric knee extension and flexion, forearm supination and pronation, and hip flexion. Regional and whole body aBMD (g/cm2) were measured by DXA, and MEMT was measured as isokinetic peak torque (Nm). RESULTS: At baseline aBMD values in the non-dominant forearm were lower than in the dominant forearm ($P<0.05$) in both control and training group, but in the latter this difference disappeared after training. At four months aBMD in the trained group was significantly increased from baseline in the trained non-dominant forearm (distal ulna (+12%) and total ulna (+5%), $P<0.05$). At four months MEMT in the trained non-dominant extremities were increased in forearm pronation (+45%, $P<0.05$), knee extension (+16%, $P<0.005$), and knee flexion (+13%, $P<0.05$), but there was no site-specific association to the augmentation in forearm aBMD. CONCLUSIONS: Eccentric training is a potent stimulus in bone formation in non-weight bearing bones that habitually are unexposed to large eccentric muscle contractions.

The finding of no site-specific association between the increases in aBMD and MEMT indicate that eccentric muscle contractions leading to bone strain not necessarily lead to parallel increases in maximal isokinetic muscle torque.

COMPARISON OF SIX WEEKS OF COMPLEX TRAINING AND PERIODISED RESISTANCE TRAINING ON THE DEVELOPMENT OF LOWER-BODY STRENGTH

Schneiker, K.T., Billaut, F., Bishop, D.

The University of Western Australia, Australia

The development of strength is a crucial component in the preparation of team-sport athletes for an upcoming competitive season. Determination of the optimal combination of maximal strength and power training to develop various qualities of strength is therefore an important consideration. It has been suggested that complex training may be a superior means of developing muscular power in comparison to more conventional methods. The purpose of this study was to compare the effectiveness of a periodised (P) training protocol and a complex (C) training protocol on the development of lower-body strength during pre-season training. Sixteen state-level Australian Rules Football players (age: 19.2 ± 2.5 y, height: 182.7 ± 7.7 cm, body mass: 78.5 ± 8.8 kg) were matched on maximal strength and high-load power and separated into two training groups. The P-group performed six weeks of periodised resistance training involving three weeks of maximal strength training followed by three weeks of power training. Training for the C-group involved alternating sets of maximal strength and power exercises for the entire six-week period. Importantly, the C-group performed the same total volume of training using the same exercises at the same intensity as the P-group. All subjects were pre and post-tested using lab and field tests to determine various qualities of strength. Maximal strength was determined using the half-squat (1RM). High-load power was determined by measuring peak power output during the loaded squat jump at 30% of 1RM (LSQJ). Low-load power was determined by measuring vertical jump height (VJ), 5-m sprint time (5S), 20-m sprint time (20S) and peak-power output during a 4-s maximal cycle sprint (PP4). For both groups (P and C, respectively), there were significant improvements ($P < 0.01$) in 1RM (170.0 ± 25.1 kg to 202.2 ± 29.3 kg and 168.8 ± 13.6 kg to 202.8 ± 15.7 kg), LSQJ (3368.6 ± 520.3 W to 3661.9 ± 456.8 W and 3221.4 ± 463.8 W to 3582.5 ± 399.4 W), VJ (61.1 ± 6.7 cm to 63.4 ± 6.1 cm and 54.2 ± 4.9 cm to 57.7 ± 6.1 cm), 5S (1.25 ± 0.09 s to 1.07 ± 0.11 s and 1.24 ± 0.09 s to 1.06 ± 0.04 s), 20S (3.18 ± 0.08 s to 3.03 ± 0.10 s and 3.24 ± 0.14 s to 3.05 ± 0.09 s) and PP4 (1332.9 ± 199.5 W to 1425.4 ± 173.7 W and 1265.0 ± 158.1 W to 1347.1 ± 136.4 W). There was no significant difference between groups in changes for any of the tests ($P > 0.05$). In conclusion, this study has found that complex training is not superior to a more traditional periodised training program when matched for exercises, total volume and intensity. In agreement with prior complex training studies (Burger et al., 2000) the present results suggest that maximal strength and power can be developed concurrently and that complex training is not at a disadvantage to periodised training.

EVALUATION OF THE TURNOVER RATE OF FIBROBLASTS IN LIGAMENT TISSUE BY ANALYSIS OF DNA-TELOMERE LENGTH. A COMPARISON WITH SKELETAL MUSCLE FIBRES

Kadi, F., Ponsot, E., Krogsgaard, M., Mackey, A., Kjær, M., Langberg, H.

Department of Health Sciences, Sweden

Introduction

It is well accepted that ligaments heal at a slower rate than many other tissues. It is hypothesised that the low regenerative potential of ligaments is due to their hypocellular composition and not to a poor ability of ligament cell types to regenerate. In this respect, the analysis of DNA-telomere length can serve as a biomarker of a cell's regenerative potential and ability for further cell division. The aim of this project was to compare DNA telomere length of ligament tissue to that of skeletal muscle fibres.

Methods

Skeletal muscle samples were obtained from 7 healthy young individuals and were compared to samples from the proximal anterior cruciate ligament taken during surgery from 7 young individuals. Total DNA extraction was achieved by incubation in proteinase K digestion buffer. The genomic DNA was then digested with a restriction enzyme to generate a smear of DNA fragments containing telomeres with different lengths of the TTAGGG repeat sequence. Telomeres were detected using Southern blot analysis. The telomeres were detected by hybridization to a 32P-labelled (TTAGGG)4 probe, followed by exposure to x-ray film. The signals were analysed using Scion software. The signal obtained provides a distribution profile of telomeric lengths of all myonuclei present in the tissue. Average telomere length indicates the most frequent DNA telomeric lengths of the tissue whereas the minimal telomere length indicates the shortest DNA telomeric lengths found in the tissue.

Results and conclusions

Average telomere length in ligaments was 11.4 ± 0.9 Kbp and the minimal length was 4.9 ± 0.4 Kbp. In skeletal muscle corresponding values were 11.1 ± 0.9 Kbp (average) and 5.3 ± 0.4 Kbp (minimal). We found no significant differences between the skeletal muscle and ligament tissues both with respect to the average and minimal telomere length. These results indicate that the cells present in ligaments have a similar regenerative potential than skeletal muscle fibres and suggests that the low healing capacity of the ligament tissue is not due to ligament cell types ability to proliferate and generate new cells, but rather to a low cell density.

PHYSICAL EXERCISE CONDITIONED SERUM MOBILIZES MESENCHYMAL STEM CELLS (MSCS)

Bloch, W., Bierwirth, S., Weber, S., Platen, P., Schmidt, A.

Institute for Circulation Research and Sportmedicine, Germany

Physical exercise conditioned serum mobilizes mesenchymal stem cells (MSCs)

Wilhelm Bloch, Steffen Bierwirth, Sebastian Weber, Petra Platen, Annette Schmidt.

German Sport University of Cologne, Dept. of Molecular and Cellular Sport Medicine

INTRODUCTION: Adult mesenchymal stem cells (MSCs) are commonly settled down in the bone marrow and have the distinction that they are able to differentiate in muscle, cartilage, bone and adipose tissue. Therefore MSCs are necessary for tissue regeneration but also to build up tissue. Prerequisite for such a regenerative effect is that MSCs reach their target tissue. For this stem cells have to be mobilized. At the moment it is not clear if MSCs are directly influenced by exercise. Therefore during the following study it was be analysed if the conditioned serum of exhausted athletes influence the migratory activity of MSCs.
MATERIAL AND METHODS: 6 athletes performed a warm up phase of 12 minutes and were trained until subjective exhaustion within a short time (VO2 max within 6-8 minutes). Serum was taken from the athletes before the warm up phase (pre exercise), directly after the exercise and 1 hour after the exercise. In a modified boyden chamber assay the migratory activity of the mesenchymal stem cells was analysed under influence of the serum pre exercise and post exercise.
RESULTS: Compared to the pre exercise condition a significant increase of MSC migration was observable post exercise (140±16% (p=0,004). One hour post exercise this increase was reduced little but was also significant (128±9%(p=0,03)). Whereas no influence was seen on proliferation and apoptosis of the MSCs post exercise.
DISCUSSION: In the present study we were able to show that training has a direct influence on he mobility of mesenchymal stem cells. Surprisingly was the point that this increase of motility was obvious directly after training. It seems to be probably that this mobilisation of MSCs is a kind of fast reaction on extreme physical exercise.

CORRELATION BETWEEN BMI, PHYSICAL PERFORMANCE, INSULIN SENSITIVITY, AND ADIPOCYTOKINES IN CHILDREN – BASELINE AND FINAL DATA OF THE CHILT III PROJECT

Graf, C., Koch, B., Brixius, K., Pruys, M.-L., Hofrichter, A., Manderfeld, A., Müller, A., Predel, H.-G., Bloch, W.

German Sport University, Germany

Obesity in childhood necessitates the development of effective counter strategies by changing lifestyle and reducing possible co morbidities. The aim of the present study was to examine the effect of an outpatient interdisciplinary programme for obese children and adolescents (CHILT III project – Children's health InterventionaL Trial) on BMI, physical performance, adipocytokines, and insulin-sensitivity.
Methods: The pre- and post-examination the anthropometric data of 68 children (33 boys, 35 girls) were assessed. Blood was obtained after 12 hours of fasting to analyse the adipocytokines adiponectin, ghrelin, resistin and leptin as well as insulin, proinsulin as parameters for insulin sensitivity. Homeostasis model assessment of insulin resistance was calculated classified with age- and gender-specic percentiles. Watt performance and VO2max were registered via spiroergometry.
Results: 61 children finished the program. BMI was reduced in 64.4%. Decrease in BMI was associated with a decrease in insulin (r=0.314; p=0.043), HOMA-IR (r=0.317; p=0.041), leptin (r=0.637; p<0.001) and an increase in adiponectin (r=-0.394, p=0.010). No correlation was found with changes in VO2max, ghrelin, resistin and proinsulin. Changes in HOMA-index were positively correlated with proinsulin (r=0.616; p<0.001), leptin (r= 0.592; p<0.001) and negatively with ghrelin (r= -0.339; p=0.028). Proinsulin and resistin were negatively correlated with watt per kg (r= -0.367, p=0.022; resp. r=-0.403, p=0.041), not with VO2max. At baseline 27 child (52.9%) was classified with normal glucose tolerance (HOMA < 95.p) and 24 children (47.1%) had a severely disturbed glucose tolerance (HOMA ³ 95.p). After the intervention 6 children improved their HOMA-IR, 8 impaired and 28 did not change their index. The children, which improved their HOMA-IR, decreased the proinsulin level about –5.3 ± 8.4 pmol/l; children with an impairment increased their proinsulin level about 4.3 ± 5.3 pmol/l and children with no change had a slight decrease about -0.9 ± 8.2 pmol/l (p=0.079).
Conclusions: These results suggest that an outpatient family-based program leads to BMI-reduction, associated with a decrease in leptin and increase in adiponectin as marker for a lower fat mass. An increase in watt per kg, representing a combined strength and endurance performance is associated with a decrease in proinsulin and resistin as an indication for a potential lower atherosclerotic and metabolic risk. Whether this effect may modify the risk of atherosclerosis or diabetes awaits further and long-term studies.

EXERCISE EFFECTS ON THE IMMUNE RESPONSE IN A MODEL OF EXPERIMENTAL ARTHRITIS

Vaisberg, M.W., Bacurau, F., Pontes, F., Costa Rosa, L., Navarro, F.

Federal University of São Paulo, Brazil

INTRODUCTION – Rheumatoid Arthritis, a chronic inflammatory disease of autoimmune nature, affects the immune response. Even though the kind of alteration is still a controversial topic, resources are used to act in the immune system in almost all therapies, particularly in the modern ones. The immunomodulatory function of exercise has been demonstrated in several models that showed immune response unbalance. Such reports motivate us to study a model of arthritis comparing animals submitted to exercise to sedentary ones. OBJECTIVES - We aimed at studying a model of collagen-induced arthritis comparing the immune response of animals submitted or not to physical exercise.
MATERIAL AND METHODS - Female Wistar rats, weighing between 150-200 g were kept in ideal laboratory conditions and divided into three experimental groups: control (C), arthritis (A) and swimming/arthritis (SA). Experimental arthritis was induced by the inoculation of type II collagen in complete Freund adjuvant into the right hindlimb. The training consisted of 5 weekly sessions of swimming for six weeks. Each session lasted one hour, during which a load, equivalent to 5% of the rat body weight, was attached to the tail. After the training protocol, the animals were decapitated. Their spleens were then removed and weighed, macerated and placed in culture so that it was possible to evaluate the proliferation of splenocytes. We also dosed the cytokines interleukin-1 (IL-1) and interleukin-2 (IL-2) in the culture supernatant by ELISA. RESULT - The weight of the spleen in the sedentary animals with induced arthritis had increased, while the ones of trained animals returned to a weight similar to the control (C- 0,59 g, A 1,15 g, SA 0,55g). Regarding the lymphocyte proliferation, we observed a reduction in the values obtained in the arthritis group, however, we could observe that this immunological parameter was normalized in animals that underwent training (C- 1272 +_ 120 cpm, A 697+_49 cpm, SA 1116+_213 cpm). The dosage of IL-1 (pg/ml) showed a decrease in the arthritis group; however, in the trained group there was a statistically significant correction of the values obtained (C- 23,3+-2,2, A 14,0+_0,7, SA 15,5+_1,3). The dosage of IL-2 (pg/ml) showed a marked increase in the trained group (C - 66,8+_14,8, A- 55,0+_7,9, SA- 144,7+_33,9). DISCUSSION - In accordance with medical literature, our results suggest an alteration in the immune response in the arthritis group, demonstrated by splenomegaly, decrease of the splenocyte proliferative response and changes in cytokines production. These alterations are corrected by means of a moderate physical training protocol, which suggests possible immunomodulatory mechanisms related to the improvement of arthritis in the trained group.

HYPERTHERMIA DURING COMPETITION IN ELITE ATHLETES

HYPERTHERMIA DURING COMPETITION IN ELITE ATHLETES

Julio Calleja González 1, Xabier Leibar Mendarte 2, Julen Erauzkin Barrenetxea 2, Iñaki Arratibel Imaz 3, Ricardo Mora Rodríguez 4, Nicolás Terrados Cepeda 5.

1 Universidad P. Vasco. 2 Centro de perfeccionamiento Técnico. Fadura-Getxo. Dirección de Deportes. Gobierno Vasco. 3 Tolosa Kirol Medikuntza. 4 Facultad de Ciencias del Deporte UCLM, Toledo. 5 Unidad Regional de Medicina del Deporte. Principado de Asturias Fundación Deportiva Municipal de Avilés.

Introduction. Hyperthermia (increases in core temperature above 38°C) induced by intense exercise causes central fatigue ([1]) and reduces time to exhaustion in cyclists that exercise in the heat ([2]). The cited studies have been performed in a lab setting using trained subjects. However, it remains unclear if elite athletes experience hyperthermia during their regular training and competition and furthermore if that could negatively affect performance. The purpose of this study was to measure core temperature response to regular training or competition of elite athletes.

Subjects. 29 athletes (8 professional cyclists, 12 rowers, 3 endurance runners of international level and 6 triathletes of international caliper) were studied during competition.

Methods: At least 1 hour prior to the exercise subjects ingested a pill containing a telemetric temperature sensor (CorTempTM Ingestible Thermometer, HQInc. USA) which signals were collected and recorded (CorTempTM 2000 Recorder;HQInc. USA) at rest and frequently during exercise. The manufacture's reported sensitivity ranges from de 0º a 50ºC with an accuracy of ± 0.1 ºC. Dry bulb temperature and relative humidity were also recorded (Kestrel 4000 NK; Nielsen–Kelleman, USA). In addition heart rate was recorded using a telemetric unit (Accurex, Polar, Kempele, Finland).

Results. For most test temperatures averaged 25 ºC and relative humidity never exceed 60%. In one test dry temperature rose to 32.5ºC and humidity to 72 %. The highest core temperatures recorded during competition ranged from 38.1 to 42.3ºC with (average of 39.5 ºC). 5 out of the 29 athletes (17%) reached core temperatures above 40ºC. The highest heart rates during competition ranged from 185 to 203 bt/min (average 186 bt/min).

Conclusions: In endurance sports during long lasting competitions events core temperature reaches high levels in elite athletes (39.5 ºC). This high core temperature is achieved despite normothermal environmental conditions (25º C). Thus it is possible that endurance performance during competition is affected by hyperthermia.

AWARENESS AND USE OF CAFFEINE BY ATHLETES COMPETING AT THE 2005 IRONMAN TRIATHLON WORLD CHAMPIONSHIPS

Desbrow, B., Leveritt, M., Hiller, D.

Griffith University, Gold Coast, Australia

Despite its legality, caffeine remains on WADA's monitoring program, which results in the drug be placed under heightened scrutiny for further tracking of trends in use for future prohibition list consideration1. This study assessed the knowledge and prevalence of caffeine use by athletes completing at the 2005 Ironman Triathlon World Championships. Caffeine-related questionnaires were administered to 140 (105M and 35F, 40.3±10.7 years) athletes (8% of all participants) from 16 countries throughout race registration. 50 athletes further consented to immediate post-race blood samples for analysis of plasma caffeine and paraxanthine using HPLC. 100 (71%) athletes correctly identified caffeine as being unrestricted in triathlon. Only 15 (11%) athletes were not planning on using a caffeinated substance immediatley prior to or throughout the race. Cola (78%), Caffeinated Gels (42%), Coffee (37%), Energy Drinks (13%), and No Doz Tablets (9%) were the most popular caffeinated choices. More than half the athletes (52%) stated that they did not know an optimal caffeine dose for their sport. The most common sources for information on caffeine were reported as self researched/experimentation (44%), fellow athletes (42%), magazines (38%) and journal articles (33%). Mean±SD (and range) plasma caffeine and paraxanthine levels were 22.3±20 umol/l (1.7-98.4) and 9.4±6 umol/l (1.8-28.9) respectively. Seven athletes (14%) finished with plasma caffeine levels > 40 umol/l. Plasma values from elite athletes did not differ from age group competitiors. Surprisingly, despite the prevalence of its consumption and the training experience of this athletic group many participants remained either confused or misinformed of its legality. Levels of plasma caffeine taken immediately post race indicate that athletes completing in ironman races often finish with quantities of caffeine that have been shown to improve endurance performance (i.e. approx 20umol/l or a dose of approx 3 mg/kg bw)2,3. Average paraxanthine levels would indicate that the initiation of caffeine ingestion was typically ≥3-4 hrs prior to race completion.4 This widespread use of caffeine by ironman athletes appears largley the result of self research and peer experimentation rather than by consultation with qualified professionals.

RELATIONSHIP BETWEEN BODY COMPOSITION, BONE MINERAL DENSITY AND DIETARY INTAKE IN ADOLESCENT ELITE FEMALE ARTISTIC GYMNASTS

García, A., Torres, A., Palacios, N., Garrido, G.

Faculty of Physical Activity and Sport Sciences (U.P.M.), Spain

Introduction

Artistic gymnastics is a speciality sport that must be started at an early age to achieve elite status. It is an impact sport that requires both physical (strength, speed and balance) and non-physical qualities (harmony, grace and risk). Traditionally body image and weight control are areas of concern in this sport.

We evaluated body composition, bone composition and food intake of these adolescens elite artistic female gymnasts. We looked for the relationships between certain micronutrients and bone composition.

Methods

Subjects were 16 Spanish adolescent gymnasts of National Team calibre age=15.5(1.6)yr; ht=151.6(4.2)cm; wt=43.7(4.9)kg; BMI=19.0(14.7)kg/m2; age of onset of training 6.5 (1.5)yr; time spent elite training=5.0(2.7)yr.

Diet composition was estimated by food weighing (Mettler-Toledo scale with 1g accuracy) for a 5 day period. During the same 5 day period, they completed a 24h activity questionnaire. Bone mineral density (BMD), bone mineral content (BMC), and body composition were measured by Dual-Energy X-ray Absorptiometry (DEXA) with a Norland XR-46 densitometer. Bone age was determined by X ray analysis of the non dominant hand.

Results

Energy intake (kcal/d) was 1768(261) and percentage of energy from macronutrients=20%P, 54%CH, 26%L. Percentage of energy at differents meals= 28%Breakfast, 30%Lunch, 30%Dinner, 12%Snacks. We found marginal intake with respect to the recommendations for: calcium (mg)=1137.1(245.3); magnesium (mg)=259.5(50.4) (both related to bone composition); vitamin E (mg)=8.4(2.2) and fiber (g)=15.7(4.1). Regarding the different meals calcium intakes come from (40%B; 14%L; 34%D; 12%S) and magnesium (28%B; 30%L; 33%D; 19%S); main food group for calcium and magnesium intake were dairy (75%) and cereal groups (28%) respectively. Gymnasts showed a retardation in bone aged of 1.2(1.2)yr; menarche aged=15.5(2.1)yr. Body composition was lean body mass LBM(g) =36096(3344); fat mass FM (g)=5933(1728); percentage of fat %F=13%; and total Body mineral content BMC(g)=1993.3(515.1). Different anatomical areas (L2-L4, femoral neck, proximal forearm) showed BMD (g/cm2) 0.9792(0.1294), 1.0367(0.1274), 0.6840(0.0639) and BMC (g) 35.792(6.100), 2.698(0.424), 1.825(0.215) respectively. No significant correlation was found between micronutrient intakes (calcium and magnesium) and bone composition. A positive relationship ($p<0.05$) was found between energy intake and FM but not to LBM.

Discussion/Conclusion

Energy intake (kcal/d), calcium and magnesium were lower than recommended but similar to the values reported by others for similar populations (1). BMD and BMC were higher than sedentary peers, specifically in high impact areas. To increase calcium and magnesium content in the diet we propose a serving more per day of dairy calcium fortified and whole cereal products.

THE GLYCEMIC INDEX AND PHYSICAL ACTIVITY

Mettler, S., Lamprecht-Rusca, F., Stoffel-Kurt, N., Wenk, C., Colombani, P.C.

ETH Zurich, Switzerland

Background: A food's GI is a percentage representing the area under the blood glucose response curve (over two hours and measured at defined intervals) relative to the blood glucose response curve of a reference food (glucose or white bread). One of the GI's characteristics is that it describes a specific food and does not seem to be related to subject specific factors such as age, gender, body mass index, ethnicity or absolute glycemic response. However, we recently have detected a substantial 25 GI unit difference in a commercially available breakfast cereal's GI when comparing endurance trained to sedentary subjects (Mettler et al, in press).

Objective: We therefore intended to validate the results and to further investigate the possible impact of the subjects' training status on the glycemic index.

Subjects and design: Young, adult males of normal body mass index and normal glucose tolerance were tested twice with a 50 g reference glucose solution and twice with a breakfast cereal containing 50 g of available carbohydrates in a randomized order. Ten subjects were sedentary (SE), 12 were moderately trained (MT) and 12 were endurance trained (ET). Blood glucose and insulin were measured.

Results: The GI (80±22, 63±18, 57±15 for SE, MT and ET respectively, mean±SD) differed significantly between SE and ET subjects ($p=0.02$, mean difference: 23 GI units, 95 % CI = 3 42 GI units). The GI of the MT subjects was intermediary, but did not differ significantly from the SE or ET subjects. The insulin index did not differ significantly between the groups ($p=0.65$).

Conclusion: In accordance with our previous results (Mettler et al, in press), we observed a GI dependence of the commercially available breakfast cereal on the training state of the healthy males. The training state is the first reported factor influencing the GI that is subject specific and not food specific.

POST-CIRCUIT RESISTANCE EXERCISE GLUCOSE FEEDING ON GHRELIN RESPONSES IN MALE COLLAGE STUDENTS

Ghanbari-Niaki, A., Fathi, R.

Tarbiat Modares Universit (TMU), Iran

Ghrelin has been reported to increase food intake and acts on energy balance in human and animals. Plasma ghrelin is changing in several circumstance such as fasting, weigh reduction, obesity, nutrition disorders, macronutrient intake, glucose and insulin injection and after a concentric exercise. A changes in plasma ghrelin in several circumstance such as fasting, weigh reduction, , macronutrient intake, glucose injection and after a concentric exercise. The purpose of this study was to investigate the effect of glucose (0.5g/kg of weight) feeding immediately after a single bout of circuit resistance exercise %60 1RM, 10exercise, 20s for each 3 circuits) . Fourteen college students (18-23 year in age, 160-184 cm in height, 62-99kg in weight and 21.4-29.3 in BMI) volunteered in this study. Blood samples were taken immediately , 30min, and 60min of either glucose (0.5g/kg of weight) or equal volume of water ingestion in overnight fast state . The results indicate that during first 30min of recovery ghrelin significantly increased in both groups(from 97 ± 16,and 79 ±

11.3pg/ml to 131± 19 and 135 ± 16.6 pg/ml in glucose and water group respectively). However, during the 60min of recovery plasma ghrelin was decreased in glucose group (from131± 19 pg/ml to 112.3± 28 pg/ml) but it increased in water group(from 135 ± 16.6 pg/ml to 255 ± 63 pg/ml). This is the first finding indicate that glucose feeding immediately after a single circuit resistance exercise reduces plasma ghrelin.

EFFECT OF SMALL DOSES OF ALCOHOL ON THE ENDURANCE PERFORMANCE OF TRAINED CYCLISTS

Lecoultre, V., Schutz, Y.

University of Lausanne, Switzerland

Introduction: Alcohol (OH) is considered among athletes as deleterious to endurance performance. However, athletes' OH consumption in most western countries is similar to their non-athletes counterparts, and sometimes it occurs before training session/competition. The effect of OH may be detrimental to performance, as onset of early hypoglycemia, alteration of cardiac work, increase of diuresis or alteration of neuro-muscular excitability. Nevertheless, some effects of OH could be beneficial to performance, i.e. by an increase of self confidence and a decrease in pain perception and anxiety.

The aim of this study was to investigate the acute effect of a small alcohol dose (approximately one standard dose) on endurance performance and metabolic response of trained amateur cyclists.

Methods: 13 male well-trained cyclists took part to this study. After measurement of maximal aerobic power and VO2max, they familiarized with a 60 minutes time-trial (TT). Subjects then came twice to the lab in standardized nutritional conditions and completed the TT in a randomized single blind condition. The TT was performed in a calorimetric chamber 30 minutes after drinking a cold fruit juice solution containing 0.5 ml OH per kg fat free mass (25 g OH) and 50 g of carbohydrates (CHO) or a control (C) solution of the same volume and containing the same amounts of CHO. Power, heart rate, pedaling cadence, VO2, VCO2, energy expenditure (EE) were continuously recorded. Blood alcohol level, glycemia, blood lactate and ratings of perceived exertion (RPE) were measured at regular intervals.

Results: At the start of the TT, blood alcohol levels reached 0.18 ± 0.6 ‰.

OH induced a significant ($p< 0.01$) decrease of global performance vs. C, as assessed by average power (OH: 233 ± 23 W vs. C: 243 ± 24 W). Time course of mechanical power was influenced by OH, the latter inducing an early decrease of power during the TT compared to control ($p<0.01$). In OH condition, VO2, VCO2, EE and glucose oxidation were significantly lower ($p< 0.05$) compared to C. However, this is related to the lower power output observed during the OH trial. In contrast, OH did not influence gross efficiency, global heart rate, RPE, glycemia and blood lactate concentration.

Discussion: These results show that consecutive to acute low dose of OH ingestion, a decrease of high intensity endurance performance occured. This decrease was not related to modifications of metabolic or physiologic parameters such heart rate, glycemia or blood lactate concentration. These results suggest a central effect of OH affecting either integrated peripheral feedback or central drive. A cephalic response after the ingestion of OH and/or a metabolic effect after intestinal absorbtion may affect performance.

Conclusion : Performance of well trained amateurs cyclists during a 1 hour TT was significantly decreased by low acute dosage of OH producing alcoolemia much below 0.5 ‰. The absence of OH induced metabolic alterations suggest that the decreased performance may be due to a modulation of central drive or peripheral feedback.

Oral presentation (OP)

OP3-10 Psychology 5/5 - "Turin FG"

THE COACH-ATHLETE RELATIONSHIP: WHEN INTENSIVE TRAINING BECOMES EMOTIONAL ABUSE

Kerr, G.K., Stirling, A.

University of Toronto, Canada

The coach-athlete relationship can be one of the most important and influential relationships experienced by a young athlete within a competitive sport environment. In elite sport, it is not uncommon for athletes to identify their coach as a primary mentor and for athletes to spend more time with their coach than with their family. With coaches today pushing athletes to physiological and psychological extremes in pursuit of sporting excellence it is important to continuously question the means by which the end goal of optimal performance is reached. What stands as appropriate and inappropriate coaching behavior is currently an issue of controversy within sporting communities. Elite sport has traditionally been predominated by an authoritarian approach to coaching athletes in which yelling, directing or disparaging comments are often viewed as a required part of the coaching process to 'toughen up' high-performance athletes. It is curious that these commonly used coaching practices would not be tolerated from teachers or other instructors of young people. Interestingly, very little research has attempted to explore the topic of emotional abuse in sport. This presentation will report on the findings of a study designed to investigate elite athletes' experiences of the coach-athlete relationship. Semi-structured interviews were conducted with 5 retired elite female gymnasts and 5 retired elite female swimmers. Results revealed that the coaches exerted substantial power over the athletes, and that this power extended beyond athletic endeavours to other areas of the athletes' lives. The significant influence a coach has over his or her athlete ultimately creates a position of vulnerability to the abuse of the athletes. The major forms of emotional abuse reported by the retired elite athletes included shouting, belittling, humiliation, and avoidance, all of which had a negative impact on the athlete's sense of self. Findings of the current study also revealed that the athletes interpreted coaching practices as 'normal' during their athletic careers but relabeled specific coaching behaviors as emotionally abusive once retired from sport. These findings are interpreted to suggest that potentially emotionally abusive methods are often used in the coach-athlete relationship in order to produce successful performances in elite sport. This presentation will address the types of emotional abuse experienced by the athletes, the process by which this abuse occurs, and criteria for establishing appropriate coaching behavior in sport. Furthermore, this presentation will propose an innovative approach to coaching, the education and mentoring of coaches, and the development of elite athletes.

LEADER BEHAVIORS IN OUTDOOR ADVANTURE PROGRAMS IN TURKEY (A CASE STUDY)

Dinç, S.C., Bulgu, N.

Hacettepe University, Turkey

Over a period of 25 years, recreational outdoor adventure popularity has increased in Turkey, especially around mountain environment. Because of its excitement and fun, more and more people are participate in a series climbing party. According to Graydon (1992), the safety, success and fun of a climb depends for the most part on leadership and organization. Thus, the purpose of the study was to determine leader behaviour which are exhibited by the climbing party leaders, and perceived and preferred leader behaviour that are desired by participants which match the situational requirements throughout the outdoor activity. The present results serve as a pilot study to refine an outdoor leadership scale in Turkey.

The method applied in this study was qualitative in which data were collected through observation, focus group and interviews. A total of 63 activity participants (22 female, 41 male) whose age ranging from 24 to 46 years, attended to 8 focus group sessions which were recorded with video camera and individual in-depth interviews were made with their 11 male climbing leaders (28-37 years) after observations on the climbing party.

The responses and observation field notes were transcribed word for word and distributed to four faculty members in sport recreation program. The evaluators categorized each response of leaders and activity participants into 8 meaningful category in leadership behaviour which contains aware of risks and manage it, decision making in activity, social interaction and teamwork, personal interaction with participant, mutual trust, excitement associated with activity, wilderness and environmental ethics and role modelling.

As a conclusion the findings of this study indicated that both leaders and activity participants agree with each other in opinion that the outdoor leader experience is essential to reach objectives in outdoor pursuit safety. It also indicated that leader behaviour determine participant activity satisfaction, motivation, knowledge, low impact practices during the activity. It is remarkable another findings that were discrepancy between participant preference and leader favour about risk perceptions in the same situation during the activity. These different perceptions might cause discrepancy in terms of leadership style.

Graydon, D. (1992). MOUNTAINEERING The Freedom of the Hills. 5th Edition, Seattle: Mountaineers.

TEAM VALUE AND PERFORMANCE IN SPORT TEAMS

Sjovold, E., Hoigaard, R.

Norwegian University of Science and technology, Norway

Team culture and team values are assumed to have significant impact on team performance. Team culture can be defined as the extent of values shared by team members and moreover Bales (1999) defined values as, "a mental process in the mind of an individual that relates perceptions, images, fantasies, and concepts to each other" (p. 86). Given the importance of team value there is somewhat surprising when Kao and Cheng (2005) states that no empirical attempt has been made to assess team culture, and furthermore that there is a lack of measurements to make such assessing. We argue that the culture and values of high performance teams fit their specific task and context. No general approach will benefit team development and therefore the need for carefully measurement and feedback is mandatory for success.

At least in Norway most practitioners base their interventions on a "one-size-fit-all approach" stemmed either from fixed phase models like Tuckman's (Tuckman 1965, Tuckman and Jensen 1977), role preference model like Belbin (1981) or both in combination. Having worked with high performance teams and studied groups for more than 25 years, we still have not found any group that have developed according to a fixed phase model, or identified an "ideal" role structure in any high performing team. Quite contrary is our experience that most groups very quickly adapt to the level of development (maturity) and arrange their role structure to fit their task and the context in which they operate. It is very rare to find two teams showing the same role-structure or level of maturity. This is especially true even when looking at high performance teams. However, there is no reason to doubt the findings of neither Tuckman nor Belbin. Tuckman's therapy groups surely followed a sequence "forming", "storming", "norming" and "performing". But they were therapy groups, not managerial, project or sport teams. Belbin's groups of managers conducting their highly structured business-game surely performed best with what he suggested as the ideal role structure. But that was in the context of that particular business game, not as managers operating in a complex business environment or players in a world class sports team. There exists no documentation that supports the assumption that all groups follow the same sequences of development. Neither so the assumption that one type of role-structure is best to meet all situations. McGrath (1991) states that such assumptions rise from the fact that most researches have studied ad hoc students groups, and not "real-life" groups in real settings.

Based on the lack in value research in sport the purpose of this study is two fold. First, give an overview of The Systematizing Person-Group Relations (SPGR) (Sjøvold, 1995) as one appropriate theory and method for assessing team culture and values. Secondly, illustrate the use of SPGR in measuring the future effective team value in a world class handball team.

WHEN LESS IS MORE - DECISION MAKING IN TEAM SPORTS

Raab, M., Lempertz, C., Gärtner, K., Zastrow, H., Arnold, A., Tielemann, N.

University of Flensburg, Germany

In team sports decision making receives growing interest in research. Whereas there are many empirical findings and paradigms present a unified theory explaining the majority of phenomena is still absent. We apply a dynamic theory because it is better capable in principle to describe team sport relevant phenomena such as time-pressure decisions, predictions of decision times, or preference reversals.

One development in particular will be demonstrated in this abstract, namely the integration of paradigms such as eye-tracking and option-generation tests evaluating theoretical assumptions. Previous work has shown that generating few options in an attack situation such as in handball and choosing the first option results in better decisions than generating more options and choosing options later in the generation process (Johnson & Raab, 2003). However how these effective strategies are learned and dependent on gaze behavior is unknown and will be tested in this study.

It is assumed that visual strategies with more fixations in different segments of the presented attack situation will result in more options generated and poorer choices compared to visual strategies implementing a lower amount of fixations by a selected spatial distribution. These spatial strategies should be more present in experienced players compared to more novice players.

Four age groups in handball (n = 59) with different expertise are tested in regard of their individual decision making competences using eye-tracking method and an option generation test. In a handball video test participants decided by verbal recording intuitive choices in an attack situation, generated alternative choices and finally decided for the best option. During this test the number of fixations, fixation duration and fixation sequence was recorded.

The results demonstrate that (a) an expertise effect for decision time, $F(3, 57) = 2.95$; $p < .05$; (b) more fixations of less experienced players, $F(3, 57) = 2.75$; $p < 05$, (c) a less-is-more effect support that less options generated result in better choices, $F(3, 57) = 73.01$; $p = .001$ that is more prominent in experienced players. In addition gaze strategies that concentrate particular on the predicted segments of the display result in better choices than distributed fixation strategies. Again evidence for a less-is-more effect on the physiological level, indicating potentially a causal relation between these two measures was found.

These results demonstrate that lab simulated decision making can be described by a less-is-more effect coming from a dynamic theoretical perspective of sampling important information. Conclusions from the project in regard on visual training and decision making training are provided.

PREVALENCE OF COACH BURNOUT IN ELITE SOCCER

Hjälm, S., Hassmén, P., Kenttä, G., Gustafsson, H.

Örebro University, Sweden

Introduction

Burnout is a multidimensional syndrome that affects not only those working in traditional helping professions but also athletic coaches are afflicted (Raedeke, 2004). Little is, however, known in regard to the prevalence of burnout among coaches, especially among those coaching at the elite level (Goodger, Gorely, & Harwood, 2004). The purpose of this study was therefore to examine the prevalence of burnout in a population of elite soccer coaches, active either in the First or Second league for men or the First league for women.

Methods

In a population of 53 elite soccer coaches in Sweden, 13 coaching in the First league for men, 14 in the First league for women, and 20 in the Second league for men volunteered to participate (89%). Burnout levels were measured using the Maslach Burnout Inventory Educators Survey (Maslach, Jackson, & Leiter, 1996), slightly modified by substituting the word "student" with "athlete".

Results

Significantly ($F2,44=4.88$, $p<.02$) more coaches in the First league for women (71%) experienced a high level of Emotional Exhaustion as compared to those coaching in the First league for men (23%) or in the Second league for men (45%). More coaches in the First league for women also experienced problems associated with Depersonalization and Personal Accomplishment than coaches in the other two groups, although these differences were not statistically significant ($ps>.09$). All coaches in the First league for men reported being on fulltime coaching contracts, in contrast to only 10% in the First league for women and 50% in the Second league for men. Support staff was also more frequent in the First league for men (5-6) than in the league for women (3-4) or Second league for men (4-5).

Discussion

More coaches active in the Premier league for women suffer from signs of burnout than either of the groups coaching men. Higher financial strain, limited support, and possibly conflicting demands from female and male soccer players can explain these differences in burnout prevalence. Because coach turnover is a serious problem in most sports (cf. Raedeke, 2004), further research to detect precursors of burnout and whether teams with men or women places different demands on their coaches is warranted. We suggest that both coaches and athletes are included in future studies to also cover the interplay between coach and athlete and the complex communication process inherent in most sports.

INCREASES OF STRENGTH AND RESISTENCE TO FATIGUE IN RESPONSE TO STRENGTH TRAINING PROGRAMS WITH DIFFERENT EXTERNAL LOADS

Bravy, Y., Netreba, A., Vinogradova, O.

State Research Center of The Russian Federarion Institute for Biomedical Problems RSA, Russia

The aim of investigation is to reveal the effects of three strength training programs upon contractile properties of knee extensors.

30 young physically active males gave their informed consent to participate in the experiment. Their hip and knee extensors were trained using training device "leg press" with pneumatic drive. They were divided into three equal groups trained with different intensities: low – 20-30% of maximal voluntary contraction (MVC, LI-group), medium – 60%MVC (MI-group), and high – 90% MVC (HI-group). The characteristic property of MI-training regime was that the movement was stopped before reaching the end point and the countermovement began immediately. The subjects were trained for 9 weeks, three times a week. On the first day the heavy session (high volume of load)

was performed and on the third and fifth days the "maintaining" sessions (low volumes of load). Before, during (every other week) and after 9 week training the legs strength was tested using 1 RM approach. The resistance to fatigue during 45 maximal isokinetic knee extensions at the angular velocity of 120 degrees per s was recorded before and after training period.

After 9 weeks strength training increases of maximal voluntary contraction in training regime (1 RM) were recorded in all training groups. The highest increment was recorded for HI-group. The increment in MI-group was 31% and did not differ significantly from that in HI-group. LI-group demonstrated the lowest increment of 18%. The strength in HI- and LI-groups increased rapidly during the first period of training and at the third week it was comparable with the post-training value. The MI-group demonstrated an even dynamics during the whole training period. The differences in the strength dynamics between groups might be related to the differences of training effects upon central and peripheral parts of the neuro-muscular system. The HI- and LI-groups were motivated to move leg as quickly as possible that is to improve central control mechanisms, whereas MI-group performed the extension with very low speed, and the movement was associated with a considerable accumulation of metabolites in working muscle groups which is believed to trigger the muscle hypertrophy.

Resistance to fatigue of knee extensors significantly increased after 9 weeks training in MI-group. The observation might be related to the fact that the subjects were motivated for overcoming the pain sensation in working muscles arising as a result of metabolic changes, accumulation of hydrogen ions in particular. Thus the increase of muscle strength caused by moderate training without relaxation is comparable to the increase achieved with higher training loads, moreover this training mode allows to improve resistance to fatigue.

RELATION BETWEEN THE RECOVERY AND PERFORMANCE VARIBLES IN SPANISH ELITE CYCLISTS

Benito, P.J., Meléndez, A., Calderón, F.J., Martín, C., Díaz, V., Peinado, A.B., Morencos, E.

Politecnical University of Madrid, Spain

INTRODUCTION Besides being useful as an alternative indicator of the assimilation of training loads, the variables controled during the recovery (REC) provide information about the state of preparation for aerobic endurance trials(Hautala y col., 2006, Martinmaki y col., 2006). The Excess Postexercise Oxygen Consumption (EPOC) is also considered to be a great indicator of the load magnitude. The principal aim of this study was to analyse the evolution of the ventilation (VE), Heart rate (HR) and the EPOC, during the following 20 min. to a maximal ergospirometric trial. SUBJECTS AND METHODS Twenty cyclists and 12 triathletes participated in this study. They were chosen from the group of cyclist and triathletes of the Comunidad de Madrid (Spain), to achieve an incremental trial in a cicloergometer. Their age was 23,8(4,54) years old and the VO2 max, 76,54(10,20) ml kg min-1 of VO2 max. The protocol consisted of 15 min to establish the base line and a trial that started with 30w of load, the increments were o 5w s-1 in a cicloergometer, followed by a REC period of 20 min. The REC during the first two min. was done actively at 50 w and 70 rpm. RESULTS The EPOC, HR, as well as the Lactate (LH) concentration kept increased after the 20 min. of REC. The CO2 production and the VE rates have come back to rest levels. In the 5th minute the athletes have recovered the 85,1(4,56)% of the ventilatory reserve, calculated as the difference between the maximum VE obtained and the basal rates (6). The HR recovered was the 73,3(6,4)% of the reserve calculated with the previous procedure. It takes place dissociation between the VE and the LH REC, which remains increased once ended the 20 min of REC. There were not found any significant relation between the VO2 max (l m-1) or relative to weight (ml kg m-1),the maximun load obtained during the trial expressed in absolute values or relative to weight and the REC variables analysed. DISCUSSION The REC of the HR resulted to be faster in the firsts min. (first 2 min) and then it became slower. This agrees with previous papers(Thornton y Potteiger, 2002), but they differ in the moment in which the slow REC starts, what can provide information about the specificity of sport and level o training(Cruz y col., 2001).Bush et al. have demonstrated that the higher the exercise intensity the longer the REC and the higher the concentrations of LH in capillary blood (Bush y col., 1999). In this way it seems that the most effective way to accelerate the REC is through a combine method between active REC and massage (Monedero y Donne, 2000), but to achieve an active REC at the 50% of VO2 max. has resulted to be positive and is well-advised in most of the papers (Hautala y col., 2006, Martinmaki y col., 2006). CONCLUSIONS The REC process during the 20 first min. of a maximum trial is different for the breathing patterns with regard to the cardiac ones. At the end of the mentioned REC the VE has come back to rest levels, while the cardiac factors still remain increased.

FUNCTIONAL MODEL OF ITALIAN ICE HOCKEY

Galvani, C., Colombo, I., Cavalazzi, E., Marini, C., Sanbiase, C., Casolo, F., Faina, M.

Catholic University of Milan, Italy

It is actually accepted that, because of the shifts' high intensity, hockey players require to develop muscle strength, anaerobic power and anaerobic endurance; the duration of the game and the need to quickly recover also demands a good aerobic system. The functional model of ice hockey has been particularly studied in United States and Canada; on the contrary physiological qualities of European ice hockey players are not well known. Therefore the purpose of this study is to verify the actual energy expenditure of Italian ice hockey and the actual physiological qualities of ice hockey players.

18 ice hockey players, belonging to a middle rank club of Italian championship, volunteered to participate in the study and underwent both laboratory tests (incremental test to exhaustion on treadmill), and field test (modified repeated sprint skate test –RSS) in order to identify, respectively, V'O2max, peak blood lactate concentration (LApeak), anaerobic threshold (AT) and anaerobic power and capacity. Moreover 3 players played a simulated on-ice hockey match during which oxygen consumption and heart rate were continuously monitored, while blood lactate was detected at baseline and every 2 min (V'O2, HR, LA).

Physiological parameters of the studied hockey team are statistically lower for V'O2max (14%), anaerobic power (40%) and capacity (30%) if compared with USA ice hockey players (53.2vs60.4 ml/kg/min, $p<0.05$; 7.5vs11.5 W/kg, $p<0.005$; 6.1vs9.3 W/kg, $p<0.005$, respectively). The players performed for 6.03±0.49min of a 20-min game. Each shift lasts 54.07±5.27sec with an average of 7 shifts per game. V'O2 during the shifts reached 72.84±12.32% of V'O2max with average on-ice values of about 56.56±5.01% of V'O2max. Blood lactate remained elevated above resting values (average LA 4.98±0.74mM) with peak values of about 6.87±1.45mM.

These preliminary results on Italian ice hockey players demonstrate that they possess lower physiological qualities if compared with elite American or Canadian ice hockey players. Such a difference can be partly explained by the fact that the studied players don't practice any specific off-ice training session to enhance aerobic or anaerobic components. Besides this energy demand of the game doesn't seem high enough to stimulate to the maximum extent and in the optimal required amount both aerobic and anaerobic energy systems. Not taking into consideration the technical and tactical abilities, it could be concluded that low physiological qualities are the main limiting factors of Italian ice hockey players. Therefore attention should be given to the physical preparation both on-ice and off-ice.

ANALYSIS OF BODY-BALANCE FUNCTIONS OF BALLET-DANCERS

Petfi, Á. 1, Ángyán, L. 2

1 University of Pécs, Medical Faculty, 2 University of Pécs, Faculty of Adult Education and Human Resou, Hungary

Background Dance as a conscious effort to move the body through a series of poses and pattern tracings, requires improving body-balancing functions parallel with other motor abilities (flexibility, endurance, speed, strength and power). Objective The aim of this study was to compare the effects of body size and physical endurance to body-balancing functions of ballet-dancers with a group of athletes. Methods The subjects were ten female ballet-dancers aging 18.9±1.4 years, and ten female athletes (5 basketball players and 5 football players) aging 18.3±1.2 years. Body weight, height, and fat (%) was measured, and body mass index (BMI) as well as waist-to-hip ratio was computed. Heart rate and arterial blood pressure was measured. The body-balancing functions were tested on one leg standing on a beam 50 cm long, 4 cm high and 3 cm wide. The subject should keep balanced in this position for one minute. Each time the subject lost her equilibrium, a new attempt started again. The number of attempts needed to keep in balance was computed. Dynamic balance was tested by walking on a sport beam 6 m long, 5 cm wide and 8 cm high. The postural sways were recorded during standing on two legs on a computerized stabilometer for 30 seconds. All measurements were done before and after a 20 meter shuttle run test. Results The BMI for ballet-dancers was 19.2, and 21 for the control group, respectively. This difference was statistically significant (p<0.04). The resting heart rate and arterial blood pressure values were in the normal range for both groups, no significant differences were found between them. The ballet-dancers performed better the different body-balance tests than the control group (Table I.)
Table I. Differences between ballet-dancers and controls performing body-balance tests
Body-balance test Difference p
One leg standing 3.8 attempts/min 0.02
Walking on the sport beam 1.1 attempts 0.05
Body sways 1.7◦ 0.002
The ballet-dancers showed no significant changes in the body-balancing functions after endurance test (shuttle run). Conclusions The present results show that both static and dynamic body-balancing functions of ballet-dancers are significantly better than that of the control group. Furthermore, the physical exercise (shuttle run) does not disturb the body-balancing functions.

LONGITUDINAL PROFILING OF URINARY STEROIDS BY GAS CHROMATOGRAPHY/COMBUSTION/ISOTOPE RATIO MASS SPECTROMETRY: DIET CHANGE MAY RESULT IN CARBON ISOTOPIC VARIATIONS

Saudan, C., Kamber, M., Barbati, G., Robinson, N., Desmarchelier, A., Mangin, P., Saugy, P.

Institut Universitaire de Médecine Légale, Switzerland

Longitudinal profiling of urinary steroids was investigated by using a gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) method. The carbon isotope ratio of three urinary testosterone (T) metabolites: androsterone, etiocholanolone, 5b-androstane-3a,17b-diol (5b-androstanediol) together with 16(5a)-androsten-3a-ol (androstenol) and 5b-pregnane-3a,20a-diol (5b-pregnanediol) was measured in urine samples collected from three top-level athletes over two years. Throughout the study, the subjects were living in Switzerland and were residing every year for a month or two in an African country. 13C-enrichment larger than 2.5 ‰ was observed for one subject after a two-month stay in Africa. Our findings reveal that 13C-enrichment caused by a diet change might be reduced if the stay in Africa was shorter or if the urine sample was not collected within the days after return to Switzerland. The steroids of interest in each sample did not show significant isotopic fractionation that could lead to false positive results in anti-doping testing. In contrast to the results obtained with the carbon isotopic ratio, profiling of urinary testosterone/epitestosterone (T/E) ratios was found to be unaffected by a diet change.

USE OF ISOTOPE RATIO MASS SPECTROMETRY TO DETECT DOPING WITH ORAL TESTOSTERONE UNDECANOATE: INTER-INDIVIDUAL VARIABILITY OF 13C/12C RATIO

Saudan, C., Baume, N., Desmarchelier, A., Strahm, E., Sottas, P.-E., Bagutti, C., Cauderay, M., Schumacher, Y.O., Mangin, P., Saugy, M.

Institut Universitaire de Médecine Légale, Switzerland

The metabolic effect of multiple oral testosterone undecanoate (TU) doses over 4 weeks was assessed in 7 voluntary men. The protocol was designed to detect accumulation of the substance by choosing the appropriate spot urines collections time and to study the urinary clearance of the substance after weeks of treatment. Urines were analysed by a new GC/C/IRMS method to establish the d13C-values of testosterone metabolites (androsterone and etiocholanolone) together with an endogenous reference compound (16(5a)-androsten-3a-ol). The significant differences in inter-individual metabolism following TU intake was illustrated by large variations in d13C-values of both T metabolites (max D d13C-values = 5.5 ‰), as well as by very stable longitudinal T/E profiles and carbon isotopic ratios in the first hours following administration. According to T/E ratios and d13C-values, the washout period after 80 mg TU intake was less than 48 hours for all subjects and no accumulation phenomenon was observed upon chronic oral administration.

HYSTERESIS OF FORCE AND SURFACE MECHANOMYOGRAM DURING MUSCLE STIMULATION

Orizio, C., Diemont, B., Gobbo, M.

University of Brescia, Italy

Aim of the work was to analyse the hysteresis of the force and of the surface mechanomyogram (MMG) signals in human tibialis anterior (TA) during a triangular, increasing-decreasing, linear variation of the stimulation rate. The MMG describes the muscle transverse thickening during contraction.
The TA of 8 healthy sedentary subjects (age 25-35 years) was supra-maximally stimulated at the most proximal motor point. The stimulation train lasted 12 s: during this period the frequency varied linearly, following a triangular fashion (2 Hz  fusion frequency (FF)  2Hz). FF provided force ripple ≤ 5% of the single twitch amplitude. The triangular stimulation train trailed a potentiation

phase. Force was detected by a load cell connected to a wooden plate strapped to the subject's foot. Muscle surface displacement was detected by a laser distance sensor pointed at the muscle belly. During the stimulation triangle the first and the last 5 mechanical responses, which presented isolated single twitches, were averaged to find the following parameters: peak of force (peak twitch, Pt), maximal contraction/relaxation rate (MCR, MRR) from the force signal; peak of displacement (Pd), maximal shortening/elongation rate (MSR, MER) from the MMG signal. Paired t-test was performed to verify significant changes in the twitch parameters at the beginning and at the end of the stimulation frequency triangle (significance $p< 0.05$). During the triangular stimulation the average force and MMG were calculated per each stimulation frequency. After this the area beneath the force-frequency relationship was calculated for both the on-going (OG) and the down-going (DG) phases of the stimulation triangle. The ratio between DG/OG areas was an estimation of the hysteretical process.

Results. OG phase: Pt= 4.73 ± 1.80 N, MCR= 22.37 ± 2.88 %Pt/s, MRR= 10.97 ± 1.81 %Pt/s, Pd= 1.05 ± 0.32 mm, MSR= 21.07 ± 3.90 %Pd/s, MER= 10.39 ± 1.63 %Pd/s; DG phase: Pt= 3.77 ± 1.52 N, MCR= 23.07 ± 4.60 %Pt/s, MRR= 10.01 ± 1.88 %Pt/s, Pd= 0.93 ± 0.33 mm, MSR= 21.88 ± 4.41 %Pd/s, MER= 11.69 ± 2.79 %Pd/s. Differences in the OG and DG twitch parameters were statistically significant for Pt and Pd. In all subjects a counterclock-wise hysteresis was present for force and MMG. This led to area ratios of 142.75 ± 21.39 (force) and 124.53 ± 14.13 (MMG).

Comments. The force hysteresis could have been explained by muscle activity potentiation or lengthening of the relaxation processes. Our results about force and MMG parameters during OG and DG single twitches do not support this hypothesis. More likely it seems that hysteresis may be due to the faster rise of tension than decay (because calcium release rate is larger than re-uptake and cross-bridges binding is faster than detaching). This conclusion is confirmed by the parallel MMG hysteresis showing that muscle contractile elements are shorter, at each stimulation frequency, and, as a consequence, more tension is generated.

MUSCLE STIMULATION TECHNIQUES UNDERESTIMATE CENTRAL CONTRIBUTIONS TO FATIGUE DURING MAXIMAL VOLUNTARY CONTRACTIONS

Swart, J., Tucker, R., Harley, Y., Albertus, Y., Noakes, T.D., St Clair Gibson, A.

Sports Science Institute of South Africa, South Africa

Percutaneous stimulation of muscle has been used to evaluate muscle fatigue and to estimate changes in the central nervous system which reduce force output, otherwise known as central activation failure (CAF) (1;2;5). Recently this technique has been promoted as an accurate measure of quantifying central and peripheral components of fatigue (3;4). We re-examine this interpretation and test the hypothesis that changes in central activation might contribute more to the force reduction measured during a 2 minute MVC than is currently believed. Twelve healthy male subjects performed a series of maximal voluntary contractions (MVC) of their right biceps brachii muscle. An initial 5 second MVC was followed by muscle stimulation of the biceps brachii. A two minute MVC was then performed, following which a second 5 second MVC and muscle stimulation were performed. Torque produced by muscle stimulation before and after the 2 min MVC declined from 13.1 ± 4 NM to 5.4 ± 2 NM (59%). Torque during the 2 minute MVC declined from 56.34 ± 11 NM to 18.7 ± 7 NM (67%). Central activation failure during the 2 minute MVC as calculated by muscle stimulation techniques was 12%. However, torque recorded during a 5 second MVC (36.1 ± 8 NM) which followed immediately after the 2 minute MVC was approximately double the average torque recorded at the end of the 2 minute MVC (18.7 ± 7 NM). There were no associated changes in stimulated muscle force before and after the 5 second MVC, indicating that recovery of peripheral fatigue did not contribute to the increase in force during the 5 second MVC. The increase in voluntary force production following the 2 min MVC was more than twice that expected if the calculated degree of central activation failure had been completely reversed. The results indicate that muscle stimulation techniques may significantly underestimate the reduction in force output resulting from central activation failure at the end of a 2 minute maximal voluntary isometric contraction.

THE INFLUENCE OF CARBOHYDRATE CONSUMPTION ON ALTERATIONS IN LEUKOCYTES AND CYTOKINES FOLLOWING EXERCISE IN TEMPERATE AND HOT CONDITIONS

Peake, J., Abbiss, C., Peiffer, J., Nosaka, K., Laursen, P., Suzuki, K.

University of Queensland, Australia

Purpose: Consumption of carbohydrate during endurance exercise attenuates alterations in leukocyte counts and systemic cytokine concentrations. However, exercise in the heat may modify these effects, via lower oxidation of exogenous carbohydrate and greater muscle glycogenolysis. Therefore, we compared the influence of carbohydrate consumption on immune changes following exercise in temperate versus hot conditions. Methods: Subjects were 10 well-trained male cyclists (mean +/- SD VO2max 4.7 + 0.2 L/min). Each cyclist completed a placebo and a carbohydrate exercise trial in both temperate (18.1 +/- 0.4 deg C, 58 +/- 8% relative humidity [RH]) and hot conditions (32.2 +/- 0.7 deg C, 55 +/- 2% RH). The protocol for each trial involved steady-state cycling at 60% VO2max for 90 min, and then a 16-km time trial at each cyclist's fastest self-selected pace. The placebo and carbohydrate treatments consisted of a jelly solution (25% w/v) of low calorie content or sucrose, respectively. The cyclists consumed 0.48 g of placebo/carbohydrate jelly per kg body weight 15 min before exercise, and then 0.24 g jelly per kg body weight every 15 min up to and including 75 min during exercise. The cyclists consumed water ad libitum during exercise. Blood was sampled 30 min before exercise, as well as immediately after 90 min of steady-state exercise and the time trial. Results: Plasma glucose concentration increased significantly ($P<0.01$) following all four exercise trials, and was higher ($P=0.0002$) in the carbohydrate than the placebo trial following exercise in the heat. Total leukocyte, neutrophil, lymphocyte and monocyte cell counts increased following all exercise trials ($P<0.0001$). Carbohydrate attenuated total leukocyte and neutrophil counts ($P<0.05$) following exercise in both temperate and hot conditions, but this effect appeared to be greater in the heat. The

serum concentrations of the cytokines interleukin (IL)-6, IL-8, IL-10 and tumor necrosis factor (TNF)-alpha were elevated following all exercise trials (P<0.01). IL-8, IL-10 and TNF-alpha were all higher (P<0.05) following exercise in the heat; serum IL-1 receptor antagonist (IL-1ra) concentration increased only after the hot trials. Carbohydrate did not influence changes in any cytokines following exercise. Plasma norepinephrine concentration increased (P<0.0001) following all exercise trials, and was higher following exercise in the heat than the cold. Carbohydrate attenuated norepinephrine (P=0.02) following exercise in the heat. Conclusion: Carbohydrate appeared to attenuate the mobilisation of leukocytes during exercise in the heat, possibly by reducing blood flow, resulting in less demargination of leukocytes from endothelial surfaces into the circulation. The lack of any effect of carbohydrate on cytokine responses to exercise contrasts with previous findings. This disparity could possibly be attributed to differences in exercise intensity and/or the absorption of carbohydrate jelly versus drink.

A COMPARISON OF MUSCLE DAMAGE AND SYSTEMIC INFLAMMATORY RESPONSES TO SUBMAXIMAL VERSUS MAXIMAL ECCENTRIC EXERCISE

Peake, J., Nosaka, K., Muthalib, M., Suzuki, K.

University of Queensland, Australia

Purpose: Maximal eccentric exercise causes greater muscle damage than submaximal exercise. However, it is unknown whether there is also a greater systemic inflammatory response. Therefore, we compared alterations in markers of inflammation and muscle damage after submaximal versus maximal eccentric exercise. Methods: Using a cross-over design, 10 healthy young men not involved in regular resistance training firstly performed submaximal and then maximal eccentric exercise, separated by 2 weeks. The submaximal exercise protocol involved 10 sets of 60 eccentric actions of the elbow flexors of one arm at 10% of maximal isometric strength on an isokinetic dynamometer. Each set was separated by 1 min of rest. The maximal exercise protocol involved 10 sets of three maximal (100% strength) eccentric actions of the elbow flexors of the other arm on the dynamometer. Each set was separated by 3 min of rest. The range of motion and velocity of muscle action was 60–0 deg and 30 deg/s, respectively, and each muscle action was followed by 2 s of passive recovery. Thus, the total working time was 20 min for the submaximal trial and 60 s for the maximal trial. Blood was sampled, and maximal isometric strength and range of motion (ROM) were assessed before, immediately after, 0.5 h, 1 h, 3 h, 1 d, 2 d, 3 d and 4 d after exercise. Blood was analyzed for differential leukocyte counts, cytokines, C-reactive protein, myoglobin and creatine kinase. Results: Maximal isometric strength and ROM decreased significantly (P<0.0001) after both exercise trials. The decrease in strength and ROM were significantly greater (P < 0.01) following the maximal trial than the submaximal trial. Plasma myoglobin concentration and creatine kinase activity increased significantly (P=0.001) after both trials, however no significant differences existed between the trials. Total leukocyte and neutrophil counts were significantly elevated (P<0.01) 3 h after both trials, with no significant differences between the trials. Serum interleukin (IL)-6 concentration increased significantly (P<0.05) up to 3 h after the submaximal trial, but not after the maximal trial. In contrast, the serum concentration of the soluble receptor 1 for tumor necrosis factor (TNF)-alpha increased significantly (P<0.01) up to 1 d after the maximal trial, but not after the submaximal trial. The serum concentrations of IL-1 receptor antagonist (IL-1ra), IL-10, TNF-alpha, granulocyte-colony stimulating factor and C-reactive protein did not change significantly after either exercise trial. Conclusion: The larger decline in maximal isometric strength and ROM suggests that muscle damage was greater after maximal than submaximal eccentric exercise. However, the greater muscle damage was not associated with a stronger inflammatory response, at least at the systemic level. Inflammation may be restricted to local areas of damaged muscle tissue where leukocyte infiltration and pro-inflammatory cytokine production occur.

THE EFFECT OF REST ON RUNNING ECONOMY FOLLOWING ECCENTRICALLY INDUCED MUSCLE DAMAGE

Paschalis, V., Koutedakis, Y., Baltzopoulos, V., Mougios, V., Jamurtas, A.Z..

University of Thessaly, Greece

Introduction

Runners, in order to maintain their strength, use resistance training regularly in their training program. However, resistance training, especially when involving eccentric contractions, can result in muscle damage, which leads to muscle performance decline (3). Running economy has been shown to be negatively affected by downhill running 48 hours post-exercise (1) but this finding has not been confirmed by a study from our laboratory (4). It has been suggested that, compared to immobilization, engagement in activities with sore muscles after strenuous exercise leads to faster force recovery and provides some relief of delayed onset muscle soreness (DOMS) (5). On the other hand, light immobilization has been found to have no effect on enhancing recovery of muscle function and DOMS after eccentric exercise-induced muscle damage (6). Given the dearth and contradictory nature of the existing data, the purpose of this study was to examine whether rest, following an exercise session designed to cause muscle damage, can affect running economy.

Methods

Ten healthy male volunteers performed 120 maximal voluntary repetitions at an angular velocity of 1.05 rad∙s-1 applied in both legs. Following this session, subjects rested completely for 48 hours. Muscle damage indicators [Creatine kinase, DOMS], muscle performance indicators [eccentric, concentric and isometric peak torque at 60o and 110o knee flexion] and running economy indicators [oxygen consumption, pulmonary ventilation, respiratory exchange ratio, respiratory rate and heart rate during treadmill running at 2.2 and 3.3 m.s-1) were assessed pre- and 48 hours post-exercise.

Results

All studied muscle damage and performance indicators (table) revealed significant changes compared to pre-exercise data (p<0.05). However, except for a significant decline of heart rate (p<0.05), none of the other running economy parameters disclosed any significant changes (p>0.05).

Discussion

It is concluded that rest following intense eccentric exercise does not affect the development of muscle damage, muscle performance or running economy. Short-term immobilization after injury is believed to allow newly formed granulation tissue to achieve a more rapid increase in tensile strength, allowing it to better withstand the forces created by contracting muscle (2). The role of exercise in relation to rest following muscle damage-induced eccentric exercise should be further investigated.

GROWTH HORMONE RESPONSE TO 30 AND 50HZ WHOLE-BODY VIBRATION IN HEALTH YOUNG MEN AND WOMEN

Howard, K., Miller, O., Dowling, I., Hunter, A., Jakeman, P.

University of Limerick, Ireland

Little is known of the hormonal response to whole-body vibration (WBV) in humans. The neurogenic effect of vibration stimulates muscle afferents, reflex activation of alpha motoneurons and muscle contraction, i.e. a tonic vibration reflex (Cardinale and Bosco, 2003). Neurotransmitter pathways, including collaterals of the central motor command stimulated by WBV, could augment growth hormone (GH) secretion by acting directly on the anterior pituitary gland and/or by modulating the hypothalamic secretion of GH-releasing hormone (GHRH) or GH release-inhibiting hormone, somatostatin. Proprioceptor feedback from peripheral skeletal muscle subjected to vibration may also modulate pituitary GH release (McCall et al, 2000).

The aim of this study was (i) to investigate whether the growth hormone response to short-term whole-body vibration was dependent on the vibration load applied and (ii) whether the growth hormone response to whole-body vibration differed between the sexes. As the measured GH response has been shown to be assay dependent comparison with a second assay of 'biologically active' growth hormone (Strasburger et al, 1996) was performed.

Healthy young male (n=22) and female (n=19) subjects were exposed to vibration loads of 2mm displacement at a frequency of 30Hz and 50Hz that exerted a measured r.m.s. acceleration of 14 and 40 ms-2, respectively. Serum growth hormone was measured prior to and immediately following ten, 60s bouts of WBV in a standing position and the results compared to a resting control.

The GH response to WBV was found to be highly variable. All data are reported as the mean (SD) and analysed by paired Student's t-test. A positive increase in GH was observed in response to 30Hz WBV in 9 of the female (DGH 4.0(2.8) ng.ml-1; $P<0.05$) and 3 of the male (DGH 6.1(1.4) ng.ml-1; $P<0.05$) subjects. Subjects who responded to 30 Hz WBV also responded to 50Hz WBV but no significant difference in GH response to 50Hz was observed for either female (DGH 3.7(2.3) ng.ml-1) or male (DGH 4.5(1.5) ng.ml-1) subjects.

These data indicate WBV is more likely to induce a GH response in female than male subjects. It is not know whether the growth hormone response to vibration is frequency and/or acceleration dependent but exposure to a 3-fold increase in accelerative load of a 50Hz vibration stimulus was no more effective in inducing a GH response than a 30Hz stimulus in these subjects. Whether the benefit to muscle function purported to occur following long-term exposure to whole-body vibration is attributable to the enhanced secretion of this anabolic hormone remains to be determined.

ANTHROPOMETRIC MEASURES, AGE AND GENDER AS PREDICTORS OF PERFORMANCE IN SIMPLE MOTOR SKILLS DURING CHILDHOOD AND ADOLESCENCE

Gortsila, E., Maridaki, M., Kellis, S., Kotzamanidis, C.

Univeristy of Athens, Greece

The present study investigated whether in childhood and adolescence performance in simple motor skills can be predicted from the age and gender of the subjects, as well as from the simple anthropometric measures of height, weight and their derivative BMI.

The study sample included 3911 school boys and girls aged from 7 to 13 years from the whole of Greece, randomly chosen through a stratified proportional sampling procedure. The motor skills measured were the height of a vertical jump with one hand from a standing position, the length of a horizontal overhead throw from a sitting position of a 1Kg ball and the average length covered during 1 second during a 20 meter sprint. For each of these dependent variables stepwise regression models were applied with age, gender, height, weight and BMI as the independent variables. BMI was categorized into lean, overweight and obese. The same procedures were repeated with the performance of the three motor skills adjusted for the subjects' height.

The results showed that performance in horizontal overhead ball-throwing can be fairly well forecasted from the predictors. The coefficient of determination (r-squared) was 58.0% with height, weight, gender, BMI group and age entering in this order the regression equation. The coefficient of BMI group was negative in all regression equations. With standing vertical jumping r-squared was 52.7%, with height, age, gender and BMI group entering the regression equation. The relation was weaker in the case of the speed of a 20 meter sprint (r-squared =28.6%, with height, gender, BMI group and age entering the regression equation). When the kinetic variables were adjusted for the subjects' height the regression model remained strong only for the horizontal overhead ball-throwing (r-squared =52.3%). For the vertical jump r-squared dropped to 9.0% and for the speed of a 20m sprint r-squared was 9.6%.

Height was the most important predictor in all cases. Boys performed better than girls in all three motor skills, while obesity had a negative effect on performance. Age was an important predictor but not a decisive one, which may be an indication that performance in the particular motor skills is not expected to exhibit a spectacular improvement during the age span under consideration.

The findings show that in childhood and adolescence performance in simple motor skills like horizontal overhead ball-throwing, where neuromuscular coordination does not play a significant role, can be fairly well predicted by the simplest anthropometric variables of height, weight and obesity as well as by the children's sex and age. A slightly more complex task like vertical jumping from a standing position does not fare as well in its prediction, while the performance in more compound tasks like running requires much more than the simple information given by anthropometric measures to be adequately explained.

THE IMPORTANCE OF IL-6 IN THE RESPONSE TO SHORT-TERM INTERMITTENT IMMOBILISATION STRESS IN RATS, BOTH IN CIRCULATION AND DOWNSTREAM: ILLUMINATED USING AN IL-6 ANTIBODY

Smith, C., Wilson, N.W., Louw, A., Myburgh, K.H.

Stellenbosch University, South Africa

The importance of interleukin (IL)-6 in a) the stress-induced activation of the HPA-axis, c) the immune cell inflammatory response, and c) the downstream tissue responsiveness to glucocorticoids (GC) was investigated, using an antibody to IL-6 (Ab, 1ug/rat/day i.p.) in a model of intermittent immobilisation stress in male Wistar rats. Four experimental groups (each n=10) were used: non-stressed placebo-treated (saline i.p.) rats (CP), non-stressed Ab-treated rats (CA), placebo-treated rats subjected to 2hr/day of immobilisation (IP) and Ab-treated immobilised rats (IA). Rats were sacrificed by decapitation after 4 days, 24 hours after the last intervention procedure. Data show that immobilisation stress significantly increased serum corticosterone (CORT) levels. Ab treatment delayed body mass loss and attenuated the stress-induced increase in [CORT] ([Mean±SD]: CP 21.2±17.7; CA 26.0±21.8; IP 50.3±14.9; IA 35.7±24.4 ng/ml). Serum IL-1 was significantly lower in IA compared to all other groups. Neither immune cell counts, nor non-stimulated reactivity of PBMCs in vitro differed between groups. However, Ab resulted in increased LPS-induced IL-6 secretion by PBMCs in vitro, independent of immobilisation. Peripherally, Ab augmented the stress-induced downregulation of GC receptor levels, and upregulated tyrosine aminotransferase (TAT) and glutamine synthetase (GS) activity in both skeletal muscle and liver (e.g. TATliver (U/mg protein/min): CP, 226.5±57.7; CA, 287.8±90.4; IP, 599.5±186.8; IA, 756.9±201.2), indicating that IL-6 antagonizes peripheral GC action during the stress response. Results show that a) stress-induced activation of the HPA-axis is dependent on IL-6, b) IL-6 plays a major role in maintenance of IL-1 levels during stress, c) IL-1 plays a role in PBMC function that is usually obscured by IL-6, and d) IL-6 antagonizes GC action in skeletal muscle and liver, suggesting that IL-6 may function as a molecular brake to prevent an overshoot of GC action.

CARDIORESPIRATORY RESPONSE TO 20 KM OF ROAD RUNNING ESTIMATED BY THE COSMED K4B2

Kinoshita, N. 1, Tadokoro, K. 2, Ando, J. 3, Onishi, S. 1, Yamazaki, H. 1, Oguma, Y. 1, Katsukawa, F. 1

1 Keio University, 2 Kanagawa Prefectural Board of Education, 3 Ogusu Highschool, Japan

It is a scientific challenge to measure the energetics of 20 km of road running and there is no evidence by direct measurement for such long distance in a real condition. We estimated cardiorespiratory and metabolic responses to running a 20 km road race and assessed it by laboratory data.

The subject was a 37 year-old male runner (181 cm, 75 kg) who used to competitively participate in decathlon in his university and afterwards had been running 5 km on average everyday. He had participated in full marathon races and the best record was 3 hours and 29 min. VO2max was estimated by graded exercise test on treadmill in laboratory and on a separate day, submaximal and steady state VO2 were measured by multiple stages of 5-min running tests (between 10 and 12.6 km/hr) with 10-min recoveries between the stages on a 400-m outdoor track to yield a formula calculating O2 demand at given running velocity (Medbo, et al). The 20 km road race for the measurement was held on a calm day with 40% of relative humidity and 750 mmHg of barometric pressure. VO2, VCO2, minute ventilation (VE) and heart rate (HR) were measured by the Cosmed K4b2 and averaged by 30 sec. The running velocity was obtained by GPS and verified by lap times recorded using the wristwatch, both of which were worn by the subject. Aerobic energy expenditure was calculated according to Jeukendrup, et al., for every 30 sec and integrated for the entire race. O2 cost of running (Cr) was calculated by (VO2-VO2rest)/[running velocity].

VO2max and HRmax were 61.7 ml/kg/min and 202 bpm, respectively by laboratory test. The formula for the O2 demand was VO2 = 0.181*[running speed (m/min)] + 4.951 (r square = 1.0). The race time was 1 hour and 29 minutes. Running velocity, VO2, Cr and respiratory quotient were 216+/-21 m/min, 45.8+/-4.5 ml/kg/min, 189+/-23 ml/kg/km and 0.99+/-0.05, respectively and were relatively constant throughout the race. Despite of the constancy of VO2 (74.3+/-7.3% of VO2max), HR increased towards the end of the race; average %HR reserves of each 5 km were 79, 87, 91, and 95% in a row. VE, VE/VO2 and VE/VCO2 were 106+/-12 l/min, 31+/-2, and 31+/-2, respectively and gradually increased towards the end of the race. Measured VO2 were larger (5% on average) than predicted O2 demand besides the initial acceleration phase. Total aerobic energy expenditure was 1532 kcal (363 g of carbohydrate and 518 g of fat).

The Cosmed K4b2 was applicable for measurement in long distance road running. The results indicated that a good runner maintained a speed and O2 cost with larger VO2 expected from the track study during 20 km of road race. The ventilatory and O2 uptake efficiency slightly deteriorated towards the end of the race. The large difference between %VO2max and %HR reserve indicated that metabolic responses can not be accurately estimated by HR for such long distant road race.

CONSISTENCY OF THE COSMED K4B2 WITH QUARK B2 IN MAXIMAL EXERCISE TEST FOR ENDURANCE ATHLETES

Kinoshita, N., Oguma, Y., Katsukawa, F., Onishi, S., Yamazaki, H.

Keio University, Japan

The purpose of the study was to compare the Cosmed K4b2 with the Quark b2 and to evaluate the change of consistency of K4b2 measurement.

The first trial was performed 2 months after the O2 sensor of the K4b2 was replaced. Maximal exercise tests were performed to 6 triathletes (20+/-1.8 yrs, 170+/-6 cm, 59.6+/-7.5 kg, VO2max; 4007+/-634 ml/min or 67.1+/-6.0 ml/kg/min) on treadmill. We used 3 K4b2s, each of which was randomly assigned to 2 subjects. Breath-by-breath analysis was performed by using a Cosmed kit for testing the K4b2 and Quark b2 simultaneously using the same turbine flowmeter which allowed independent gas analyses by each instrument using the same value of ventilatory parameters for each breath. The same tests were repeated to 2 triathletes 3 months after the first with the same 2 K4b2s and the Quark b2 as in the first. All calibration results were within the acceptable range in both trials but response time (T90) of O2 sensor in the K4b2 were 50 msec in the first and 200 msec in the second. Measured values averaged by 10sec were compared between the 2 instruments by Bland-Altman plots for each test where systemic and random biases were quantified by a log/log transformation.

In the first trial, the random biases of VO2, VCO2, and respiratory quotient were proportional to the size of measured values but not for the systemic biases which were within acceptable range; 2.4+/-1.1%, 2.5+/-1.7%, and 3.3+/-2.2%, respectively. No significant differences were observed in systemic biases for VO2 or VCO2 among 3 K4b2s. When these small systemic biases were neglected, random biases

were 3.6+/-0.8 %, 3.5+/-0.7%, and 2.5+/-0.3%, respectively. In the second trial, large systemic bias was evident in VO2 (9.2%) but not in VCO2 (2.7%) and the K4b2 underestimated VO2 proportionally to the size of measured values.

Systemic bias was evident only for VO2 in 5 months after the replacement of O2 sensor in the K4b2. Since the chemical property of the O2 sensor of the K4b2 (galvanic fuel cell) was time-dependent while that of the Quark b2 (zirconia) was highly stable, the large bias for VO2 in the second trial could be attributed to the change of the O2 sensor property and indeed, we observed prolongation of T90 despite of being within the acceptable range. Respiratory frequencies of the subjects were very high at the peak level (65+/-5/min) where the influence of T90 prolongation would be significant even if it was still within acceptable limits. This phenomenon might explain inconsistent results of the former studies about the accuracy of the K4b2.

We concluded when a newly installed O2 sensor was used or T90 of the O2 sensor was optimally adjusted, the K4b2 would provide closely comparable data with reliable values measured by the Quark b2 for the maximal tests of highly capable athletes. This concern might not be necessary for sedentary subjects or submaximal tests.

MAXIMAL LACTATE STEADY STATE IN ALLOXAN DIABETIC RATS

Oliveira Camila, A.M., Ribeiro, C., Mota, C.S., Araújo, M.B., Zanirato, N.S., Luciano, E., Mello, M.A.

Unesp, Brazil

Several studies with animal models have demonstrated that physical activity counteracts the complications caused by diabetes, preventing cardiac dysfunctions, as well as improving glucose tolerance and homeostasis. However, the study of the metabolic effects of exercise in rats is frequently questioned due the lack of information about the intensity of effort performed by the animal during exercise. The ´maximal lactate steady state´ (MLSS), the higher concentration during exercise at which lactate entry in blood equals its removal, is considered the gold standard to determine the endurance exercise capacity and exercise intensity. Therefore, the aim of the present study was to determine the MLSS in diabetic rats during swimming exercise. Diabetes induction was made by intravenous alloxan administration (30 mg/Kg b.w.) in adult male Wistar rats after a 15-hour fasting (D, n = 10). Vehicle (citrate buffer) injected rats were used as control (C, n = 11). After diabetes induction rats were adapted to water for two weeks. At the end of this period blood samples were collected after a 15-hour fasting to confirm diabetes. After 48 hours, the MLSS tests started. The MLSS test, adapted to rat conditions by Gobatto et al. (2001), consisted of swimming sessions of 20 min in 100x80x80 cm swimming pools, supporting a load attached to chest of 4% b.w. in the D group and 5% b.w. in the C group in the first session. Then, depending on the result of the previous test the load was reduced, if the blood lactate rose continuously without stabilizing, or increased, if it did stabilize, in 0.5% b.w.. There was an interval of at least 48 hours between each evaluation and three to four tests were necessary to find the MLSS. Blood lactate was determined at rest and at each 5 min until the 20th min to find the MLSS. Blood lactate stabilization was defined as a lactate variation between the tenth and twentieth minute smaller than 1 mmol/l; and the MLSS, as the highest workload at which the blood lactate stabilized. Results were analyzed statistically by test t-student, with a level of significance of 5%. Confirming diabetes induction, the fasting blood glucose was higher in D than in C rats (C = 93.79 + 8.76; D = 328.57 + 63.69* mg/dl). The load corresponding to the MLSS was lower in the D group than in the C group (C = 5.80 + 0.80; D = 4.60 + 1.13* % b.w.). On the other hand, blood lactate stabilized in higher concentration in the D animals compared with the C animals (C = 5.13 + 1.50; D = 6.40 + 0.97* mmol/l). In short, we conclude that diabetes reduced the endurance capacity of the animals, what must be taken into account when submitting such animals to experimental protocols that use exercise.

BOVINE COLOSTRUM AND GOAT MILK POWDERS REDUCE HEAT-INDUCED "LEAKY GUT" IN RATS

Cummins, R.A. 1, Prosser, C. 2+3, Stelwagen, K. 2, Gill, N. 1, Milne, C. 4

1 Waikato Institute of Technology, 2 AgResearch Ruakura, 3 Dairy Goat Co-op(NZ) Ltd, 4 Anglesea Sp Med, New Zealand

'Leaky gut' is a condition in which hyperpermeability of the intestine compromises the gut's barrier function. Both heat and exercise can cause leaky gut. Leaky gut can be accompanied by nausea, cramps and diarrhoea and has been postulated to be a trigger for heat stroke under extreme conditions (Mosely and Gisolfi, 1993, Lambert 2004). Athletes who exercise for prolonged periods at high intensity in the heat may therefore be at risk of developing exertional heat stroke due to leaky gut. We report on two linked studies which assess the efficacy of supplementation with bovine colostrum and goat milk powder in reducing leaky gut.

In the first study we determined that bovine colostrum and goat milk powder each enabled a monolayer of cells grown in culture to maintain its integrity when challenged with EGTA. In the absence of colostrum or goat milk the trans-epithelial resistance of the cells fell to 60% of baseline when so challenged. In the second study, male rats were assigned to one of three dietary groups: standard diet (control group, n=8); standard diet plus bovine colostrum powder (1.7 g/kg; colostrum group, n=8) or standard diet plus goat milk powder (1.7 g/kg; goat milk group, n=8). Elevation of core body temperature of the control group to 41.5 degrees C increased transfer of Cr-EDTA from gut into blood 34-fold relative to ambient temperature conditions ($P<0.05$) indicative of increased gastrointestinal permeability. Significantly less ($P<0.01$) Cr-EDTA was transferred into blood in rats in either the colostrum group (27% of control value) or goat milk group (10% of control value) after similar heating. The changes in the colostrum group were not significantly different than those of the goat milk group ($p>0.05$). In view of the results of the cell culture study we suggest that the mechanism of the protective effect of bovine colostrum and goat milk powders involves direct modulation of tight junction permeability in the intestinal epithelium.

In summary, both bovine colostrum powder and dairy goat milk powder can attenuate heat-induced gastrointestinal hyperpermeability in rats. The next crucial step is to determine whether these supplements can prevent leaky gut in human athletes who are at risk of developing exertional heat stroke.

MASKED INCREASE IN THE CONCENTRATION OF SERUM DEHYDROEPIANDROSTERONE SULPHATE AND TESTOSTERONE AFTER A PROLONGED EXHAUSTIVE EXERCISE IN SEDENTARY WOMEN

Enea, C., Boisseau, N., Millet, C., Bounaud, J.Y., Díaz, V., Dugue, B.

Faculty of sport sciences, Poitiers teaching hospital, France

The purpose of this study was to examine whether the concentrations of anabolic steroids in blood such as serum dehydroepiandrosterone sulphate (DHEAs) and total testosterone are affected after a prolonged exercise leading to exhaustion in young sedentary women.

Eight sedentary women (21.9 +/- 1.6 years), under similar oral contraception (monophasic, ethinyl-estradiol < 0,05 mg) performed a control session (C) and a limited-time exercise (LT) in a randomised order. The two sessions were separated by one week. All the sessions started at 9.00 am after the volunteer got a standardized breakfast. The LT session consisted of a cycling exercise at 75% of maximal oxygen consumption until exhaustion (mean cycling time 22.3 +/- 2.6 min). During the control session, subjects rested at the laboratory. Blood specimens were drawn in standardized condition, before (T0), 30 min (T30) and 90 min (T90) after the end of the exercise. Specimens were taken during the control and the exercise sessions at the same time of the day. Serum DHEAs and total testosterone were assayed using RIA kits (Immunotech, France and Orion Diagnostica, Finland; respectively). Plasma volume shifts were estimated using haematocrit values for T30 and T90. The data were analyzed using the Wilcoxon signed-rank test for paired data.

When expressed using raw or corrected values for hemoconcentration/hemodilution, neither DHEAs nor testosterone concentration variation appeared at 30 or 90 minutes of recovery. However, total testosterone concentration tended to decrease during the course of the control session, with a significant reduction at T90 ($p< 0,05$). When considering the changes due to biological variations and plasma volume shifts, a significant increase in the total testosterone and DHEAs was found 30 minutes after the end of the exercise ($p< 0,05$).

Altogether, our results indicate that a prolonged exercise leading to exhaustion can increase the serum concentration of anabolic hormones in sedentary women. Even if it is worth to know the real concentration of anabolic hormones potentially active on target tissues after exercise, our study stresses the importance of taking into account the changes due to plasma volume shifts and biological variations. Such strategy is unfortunately not common in studies dealing with exercise endocrinology.

HIGHER OXYGEN CONSUMPTION DURING ACTIVE RECOVERY FROM INTENSE EXERCISE IN SOCCER PLAYERS

Omori, K., Okumoto, T., Ebsshi, H.

University of East Asia, Japan

Introduction: It is well known that low-intensity active recovery immediately after intense exercise enhances blood lactate removal and increases oxygen consumption (VO2) during recovery. Most ball games (e.g. soccer) can be characterized as "intermittent" exercise, thus, repeated high and low intensity exercise occurs in ball games. It is assumed that intermittent exercise must relate to the athletes' potential for physiologically recovery from intense exercise, suggesting that this is required for success in soccer. It was also hypothesized that the VO2 during active recovery in soccer players is higher than in athletes who habitually perform continuous exercise. The purpose of this study was to compare the VO2 and blood lactate concentrations during active recovery immediately after intense exercise in soccer players and recreational runners.

Methods: Five college soccer players and five college recreational runners participated in this study. All subjects performed cycle ergometer exercise twice at 80% ventilation threshold lasting 12 min after 4 min exercise at 25 W. After the first submaximal exercise, defined as the control exercise, the subjects rested for 10 min before completing three 30 s bouts of an all-out sprint cycling test separated by 4 min rest. After the third sprint, the subjects performed the second low-intensity exercise, defined as active recovery. VO2 was monitored during active recovery and the control exercise. The change in the mean VO2 (delta-VO2) was calculated by subtracting the mean VO2 during the control exercise from the mean VO2 during active recovery each subject. Blood samples were taken from the fingertip during active recovery, and the blood lactate area under the recovery curve (La AUC) was also calculated.

Results: Blood lactate peaked after completing the third sprint, and then decreased during active recovery in both groups. There was a higher value of La AUC (60.6±4.3 mmol/L･min) in the soccer players than in the runners (47.5±13.2 mmol/L･min), although it was not significant ($p=0.06$). There were no significant differences in the mean VO2 during the control exercise (Soccer; 1073.8±80.9 ml/min, Runner; 1000.3±202.5 ml/min). In the soccer players, the mean VO2 during active recovery was significantly higher than in the control exercise ($p<0.001$), while it was not significantly different in the runners. The delta-VO2 in the soccer players (166.0±33.6 ml/min) was significantly greater than in the runners (57.4±59.4 ml/min, $p<0.01$). A significant correlation ($r=0.731$, $p<0.01$) was observed between delta-VO2 and La AUC when the data obtained from the two groups were combined.

Discussion: This study was particularly characterized by the fact that higher delta-VO2 was observed in the soccer players and was positively related to the La AUC. These results indicated that intermittent exercise could improve the aerobic energy system while removing the accumulated blood lactate during active recovery.

THE EFFECTS OF CALORIC RESTRICTION AND EXERCISE ON LEARNING AND OXIDATIVE STRESS MARKERS OF THE BRAIN

Szabo, Z., Jakus, J., Nyakas, C., Radák, Z..

Faculty of Physical Education and Sport Science, Semmelweis University, Hungary

It is known that caloric restriction (CR) increases both the mean and maximal life spans of laboratory rodents. Exercise enhances the caloric utilization and has subservient effects on physiological functions of the organism including brain function and oxidative metabolism too. We tested the effects of CR and exercise on brain function, brain derived neurotrophic factor (BDNF) and oxidative challenge. Wistar rats (10 months old) were assigned to control, CR (40% restriction of control), trained (1h swimming with loading, 5 times a week, for 8 weeks) and CR-trained groups. The results of passive avoidance and Morris maze tests revealed that both CR and exercise training have positive effects on brain function, however the effects of CR was more significant on memory, while exercise improved the learning more notably. Electron spin resonance data suggests that exercise significantly reduced the level of free radicals in the cerebellum of rats.

The content and mRNA expression of BDNF increased in the brain of CR trained rats compared with control animals, while the BDNF receptor TrkB did not change significantly in any group.
The results of the present study indicate that both exercise and CR have positive effect on brain function, free radical content and BDNF concentration.

THE INFLUENCE OF FATIGUE ON TEMPERATURE REGULATION DURING PROLONGED EXERCISE

Kacin, A., Golja, P., Tipton, M.J., Eiken, O., Mekjavic, I.B.

University of Ljubljana, College of Helath Studies, Slovenia

Background: Findings from our pervious studies on graded ischaemia in the working muscles (Eiken and Mekjavic, 2004; Kacin et al., 2005) and on acclimation to a hypoxic environment (Kacin et al., 2004) suggest that non-thermal physiological factors closely associated with increased relative work rate and perception of effort can modulate the regulation of sweating and skin blood flow and potentially affect regulation of deep body temperature during dynamic exercise. The present study investigated whether a fatigue-induced increase in physical strain might also affect thermoregulation during exercise.
Methods: Euhydrated subjects cycled for 120 minutes at a constant absolute work rate (WR; 50% of the initial WRpeak) in a temperate climate (23 °C; 40% humidity). During the exercise, heart rate (HR), oxygen uptake (VO2), local sweating on the forehead and back, skin blood flow and rectal temperature were measured. The fatigue-induced increase in physical strain during prolonged exercise was evaluated from the changes in rating of whole-body perceived exertion (RPBwb). In addition, peak exercise capacity (VO2peak and WRpeak) was determined both prior to and immediately after the prolonged exercise trial.
Results: Median (range) RPEwb increased (P<0.01) from 3 (1-5) at the beginning to 5 (5-9) at the end of prolonged exercise. Accordingly, mean (SD) VO2peak and WRpeak attained immediately after prolonged exercise were 9 (5) % and 10 (5) % lower (P<0.01), respectively, than the corresponding initial values. Also, during the last 60 minutes of prolonged exercise trial, moderate upward drifts (P<0.01) in heart rate (deltaHR = 13 (5) bpm) and VO2 (deltaVO2 = 0.25 (0.11) L•min-1) were observed, most likely indicating a progressive deterioration of mechanical efficiency. Despite such progressive increase in physical strain, the regulation of heat-loss responses and core temperature after the initial exercise-induced perturbation remained constant throughout the steady-state exercise.
Conclusions: A fatigue-induced increase in physical strain does not affect the level of increase in core temperature or the regulation of heat-loss responses during prolonged steady-state exercise.

EFFECTS ON THE THRESHOLD FORCE AND FREQUENCY OF HT- AND LT-MUS WITH INSTANTANEOUS COLD STIMULATION

Yona, M., Tadano, C., Seki, H., Naito, Y., Muro, M.

Tokyo University of Pharmacy and Life Science, Japan

(Introduction) Several investigators have demonstrated that subnormal muscle and skin temperature affects the recruitment and firing rate of motor units (MUs). We have demonstrated that the decrease in skin temperature to 25 degree with skin cold stimulation more markedly acted on high threshold MUs (HT-MUs) than on low threshold MUs (LT-MUs), resulting in a decrease in the threshold force of HT-MUs. However, this result indicated the effects on the MUs with decreased skin temperature over a fixed time. The purpose of this study was, therefore, to investigate the effects on the threshold force and frequency of HT- and LT-MUs with instantaneous cold stimulation. (Methods) The subjects who volunteered for this study were five healthy males. The electric signals were picked up by needle electrodes inserted on the belly of the right biceps brachii. The signals of MU were obtained in two places that changed depth below the skin (15 mm: shallow and 25 mm: depths). The force of the isometric contraction was established by a force transducer attached to the apparatus. The present experiment performed two conditions that consist of voluntary isometric ramp contraction (VIRC) (R) and sustain isometric contraction (S). The R consisted of three conditions (control; Rc, the skin temperature 25 degree; R25, cold spray; Rs) and the S consisted of four conditions (control; Sc, the skin temperature 25 degree; S25, cold spray; Ss, wind; Sw). Before each condition, 3 MVC for 2 sec were measured by the elbow flexion. The R was performed at a controlled 20%VIRC for 3 sec. The R25 was reduced gradually from Rc to 25 degree with cold air at -10 degree. In the case of S, the subjects were asked to modulate the torque during isometric contraction to identify motor units. The S was performed during a sustained isometric contraction for 10 sec. The Ss was instantaneously sprayed cold splay and the Sw was instantaneously sprayed wind on the skin of active muscle. (Results and Discussion) In the R, the threshold force of HT-MUs decreased, and that of LT-MUs did not change or increased with R25 and Rs. The result in R25 was the same as previous reports. However, the effect on the HT-MUs by spray stimulation did not have much to compare with Rs. On the other hand, the frequency of LT-MUs in S was influenced by spray stimulation. The frequency in S25 and Sw did not change. The frequency in Ss decreased just after stimulation with spray. Thereafter, the frequency returned to an original value. However, The average frequency before and after 0.5 sec of spray stimulation did not show any significant changes. Spray stimulation only affected 50% of MUs. The number of influenced MUs was different between shallow and depths. The influenced MUs in shallow were much more than that in depths. The instantaneous skin cold stimulation had an influence on the threshold force of HT-MUs and the frequency of LT-MUs for a short time. These results suggest that the influence on MUs is related to the dynamic response of cold receptors with cold spray stimulation.

THE EFFECT OF ACTIVE VERSUS PASSIVE RECOVERY IN HIGH-INTENSITY INTERMITTENT EXERCISE ON SALIVA FLOW RATE, SALIVARY SECRETORY IMMUNOGLOBULIN A AND AMYLASE RESPONSES

Naito, Y., Matsumoto, T., Yona, M., Muro, M.

Kokushikan University, Japan

High-intensity intermittent exercise is an important component of training for many athlete; few studies, however, have examined the effect of high-intensity repeated bouts of exercise on saliva parameters. Moreover, the positive effects of active versus passive recovery on high-intensity intermittent exercise training are controversial. The aim of the present study was to investigate the saliva flow rate, s-IgA concentration and alpha amylase activity in high-intensity intermittent exercise following passive and active recovery interventions. Nine active male volunteers (age 22.3(0.7)yrs, height 173.1(6.6)cm, body mass 67.3(6.1)kg, VO2max 57.3(6.2)ml/kg.min) executed two high-intensity intermittent cycling exercises. A load of 5% of body mass was applied. The exercise was composed of seven sets of maximal-effort 20-s sprint bouts with a 60-s recovery interval between sets. At the end of the first exercise bout participants were administered either active (low-intensity cycling at approximately 40% VO2peak) or passive recovery (sit quietly on the cycle ergometer). Unstimulated saliva and blood samples were collected before and after the exercise bouts and after the recovery interventions. Saliva parameters and metabolic measurements included: saliva flow rate, saliva protein, s-IgA, alpha-amylase activity, HR, and blood lactate. An ANOVA test was used to assess the difference between the conditions. There was a decrease in the mean anaerobic power and mean peak power among two tests, but there were no differences when comparing active with passive recovery. The performance of the two cycling exercise bouts affected the saliva flow rate, s-IgA concentration and alpha-amylase activity (compared with pre-exercise). However, no significant difference was found between active and passive recovery for the s-IgA concentration and secretion rate at any point. Saliva alpha-amylase activity and HR were lower in passive recovery than active recovery after the recovery interventions. At the same point, blood lactate concentration was significantly higher in passive than active recovery. The linear regressions revealed that the ratio of alpha-amylase activity between two bouts (exercise2/exercise1) was negatively correlated with the lactate concentration after the recovery intervention. Furthermore, correlation was seen between HR recovery and the change percent of the s-IgA secretion rate after recovery intervention. These results indicated that the magnitude of recovery/fatigue reflected the saliva alpha-amylase activity and do not support the benefit of active recovery when compared to passive recovery concerning s-IgA. However, the s-IgA secretion rate could be an indicator of short-term change in the activity of the cardiac autonomic nervous system.

EVALUATE THE CHANGE OF %SPO2 AND HEART RATE AT LACTATE THRESHOLD IN MALE ELITE ATHLETES DURING SPORT UNTIL EXHAUSTION

Tabatabaei, H.

Azad University, Iran

The purpose of this study was to evaluate the change of %SpO2 (saturation percent oxygen) and heart rate at lactate threshold in male elite athletes during sport until exhaustion. Also the relationship between %SpO2 and some physiologic factors such as blood lactate acid at the end of the test and the amount of oxygen used at lactate threshold was evaluated.

The sportsman in our study were national team athlete in Canoeing, Tae kwan do, Wrestling, and Middle distance running with the average age of 22.29 years, average height of 179.73 and average weight of 81.55. After explained about test, each case got on the treadmill. Once the treadmill started, each subject started walking on it. After a one-minute for warm-up with the speed of 4 km/h, they started running with the speed of 8 km/h. after each minute, the speed increased by 1 km/h up to the time until the exhaustion. During the test, %SpO2 and heart rate were recorded prior to increase in speed by the "pulse oxymeter". Meanwhile, with used gas analyzer (K4b2) some respiratory factors such as the Vo2 at lactate threshold and after the end of test blood lactate acid were evaluated.

The data were collected in forms and were analyzed using SPSS statistical software (Pearson correlation coefficient and regression).

The data revealed that there was no significant relationship between %SpO2 and heart rate at lactate threshold. Also, no relationship was detected between %SpO2 and either blood lactate acid at the end of test or Vo2 at lactate threshold.

Finally, the athletes were divided into two groups of aerobic and anaerobic sports. The statistical analysis was done again and no significant correlation was observed between the above factors.

Regarding the low regression line and reverse correlation between %SpO2 and heart rate at lactate threshold, a partial relationship or pattern may be presented like what suggested . However, presenting a more accurate table needs great subjects.

PRIOR HEAVY EXERCISE DOES NOT AFFECT PHASE II VO2 KINETICS BUT INCREASES MUSCLE OXYGENATION KINETICS DURING HEAVY EXERCISE

Marles, A., Perrey, S., Legrand, R., Blondel, N., Betbeder, D., Mucci, P., Prieur, F.

Laboratory of Multidisciplinary Analysis of Physical Activity, University of Artois, Lievin, France, France

The O2 demand in muscle at the onset of heavy exercise is more important than at the onset of moderate exercise. Therefore, the effect of prior heavy exercise on the balance between O2 delivery and O2 utilization should be different. To our knowledge, no study has investigated the relationship between kinetics of pulmonary VO2 and muscle oxygenation during a heavy exercise preceded by a prior heavy exercise. The effect of a prior exercise above the first ventilatory threshold (VT1) on the phase II VO2 kinetics and muscle oxygenation at the onset of a subsequent heavy exercise was therefore examined. We hypothesized that prior heavy-intensity exercise is sufficient to improve the O2 delivery at the onset of the second exercise. In these conditions, if VO2 kinetics is limited by O2 delivery during heavy exercise, then prior exercise would induce an acceleration of the phase II VO2 kinetics and a slowing of the muscle deoxygenation kinetics.

Ten young male adults (20 ± 2 years) performed twice the same test. This test was composed of a 6-min constant work rate exercise at a power output corresponding to 50% of the difference between VT1 and peak VO2 (Delta 50%) (CWRE 1), 6 min at 35 W and another 6-min of constant work rate exercise at Delta 50% (CWRE 2). VO2 was measured breath-by-breath, muscle oxygenation (Oxy) and blood volume (BV) were evaluated continuously by near-infrared spectroscopy. Phase II VO2 and Oxy kinetics were described with a mono-exponential model. The time delay (TD) from the exercise onset to a decrease in Oxy was also determined.

The parameters of the phase II VO2 kinetics (amplitude and tau1) were unaffected by prior heavy exercise, while the parameters of local muscle oxygenation kinetics were significantly faster (TauOxy: 10 ± 3 vs. 8 ± 2 s; $P < 0.05$, TDOxy: 7 ± 2 vs. 4 ± 2 s; $P < 0.001$). Blood lactate, heart rate (HR) and BV values were significantly higher before CWRE 2 than before CWRE 1.

These results suggest that the O2 availability was likely improved at the onset of second heavy-intensity exercise. It was however unsuccessful to accelerate the pulmonary VO2 kinetics. We have also observed that the muscle deoxygenation was faster at the onset of the second bout of exercise indicating an increase in the O2 extraction at the onset of CWRE 2 in comparison with CWRE 1. Taking together, these findings are in favour of a metabolic inertia limitation of the VO2 kinetics.

BIA-VECTOR AS A TOOL TO DETECT DEHYDRATION

Golja, P. 1, Blatnik, J. 1, Tomazo-Ravnik, T. 2

1 Nova Gorica Polytechnic, 2 University of Ljubljana, Biotechnical Faculty, Dept. of Biology., Slovenia

Background

BIA-vector (=RXc graph method), a new bioelectrical impedance method, was reported to detect changes in hydration status in renal patients and in high altitude climbers (Piccoli et al., 1994; 1996). BIA-vector derives from a classical bioelectrical impedance method, using resistance (R, Ohm) and reactance (Xc, Ohm) separately, to produce a vector in the RXc graph. The RXc graph depicts both, soft tissue hydration and cell mass, and it also presents reference values for these two parameters, thus the elliptical probability regions for a healthy population. The displacement of BIA-vector parallel to the major axis of the ellipse indicates changes in soft tissue hydration. The aim of the present study was to assess whether this method is sensitive enough to detect mild dehydration.

Methods

Sixteen young subjects (8 males, 8 females) were weighted and then rested supine for one hour in a 24°C room, to achieve equilibrium between intra- and extravascular liquid compartments. Following rest, bioelectrical impedance was determined with an alternating current of 800 microA and 50 kHz (BIA soft tissue analyzer, Akern Srl., Italy). The subjects then performed a 12.5 km walk (average speed = 5.5 km/h) outdoors in a temperate environment (ambient temperature = 20 (4)°C). During the walk, eight subjects drank water ad libitum (NH) and the other eight were not allowed to drink (DH). Following the walk, the bioelectrical impedance was determined in the same manner as prior to the walk.

Results

Body mass loss was 1.7 (0.7) kg in the DH and 0.6 (0.4) kg in the NH group, which equalled to 2.5 (1.0) % and 0.8 (0.4) % of pre-walk body mass in the DH and NH group, respectively. Despite mass loss, the classical bio-impedance showed an increase in total body water ($P<0.05$) and in extracellular water ($P<0.01$), and a decrease in body cell mass ($P<0.01$). Classical bioelectrical impedance thus did not detect dehydration in any of the groups. Similarly, vectors in the RXc graph did not lengthen following the walk in any group, as compared to pre-walk vectors, which would indicate dehydration. The BIA-vector (RXc graph method) was thus insensitive to mild dehydration.

Conclusions

Consistent with previous reports (O'Brien et al, 2002), classical bioelectrical impedance did not asses small changes in hydration status correctly. Although the BIA-vector (RXc graph method), a new bioelectrical impedance method, was reported to detect changes in hydration status of soft tissues in renal patients and in climbers at high altitude, it was not sensitive enough to detect mild (2.5 %) dehydration in healthy subjects.

SPIROERGOMETRY IN THE SWIM FLUME: STROKE RATE OF ENDURANCE AND SPRINT SWIMMERS AS A POSSIBLE INDICATOR FOR SWIMMING EFFICIENCY

Reer, R., Ramcke, C., Ziegler, M., Braumann, K.M.

University of Hamburg, Germany

Introduction: Stroke rate is considered to play an important role in swim performance. The goal of the present study was to assess if there is a difference in stroke rate between endurance and sprint swimmers.

Methods: 36 male swimmers (age: 26.64.9 years; years of practice: 13.95.2; training sessions / week: 2.30.6; training hours / week: 3.61.1), of which 18 were endurance swimmers (en) and 18 were sprint swimmers (sp), carried out a standardized stepwise spiroergometry in the swim flume (initial velocity: 0.90 m/s; increase of 0.05 m/s every 3 min; break of 1 min after each exercise step). Arm stroke rate was measured by means of a manual stop watch in the last 30 seconds of each exercise step using 3 complete arm cycles. Additionally, heart rate was measured continuously by means of a sports tester. Blood lactate was taken from the hyperemized ear lobe and respiratory parameters were measured by means of the rebreathing method, applying the exponential regression equation y=ae-bx during the 1-min break period.

Results: En showed a lower stroke rate in all exercise intensities compared to sp. If one relates stroke rate to body height, the differences increase. The ratio VO2/v, an indicator for efficiency mainly in aerobic exercise intensities, was lower for en in lower exercise intensities.

Discussion: It can be concluded that there is a characteristic difference in stroke rate between en and sp which is accentuated by relating stroke rate to body height. The lower stroke rate for endurance swimmers may be an indication for a more efficient propulsion.

PHYSIOLOGICAL ASSESSMENT AT AND ABOVE CRITICAL POWER IN CHILDREN

Williams, C.A. 1, Berthoin, S. 3, Dekerle, J. 2, McGawley, K. 2, Carter, H. 2

1 University of Exeter, 2 University of Brighton, 3 University of Lille, United Kingdom

Critical power (CP) provides the upper boundary to the heavy intensity exercise domain but to date no studies have examined the physiological responses to exercise at CP in children. The purpose of the study was to examine the physiological responses to exercise at and 10 % above CP (CP+10) in children. Six male adolescent subjects mean (SD) age 12.8 (0.3) y, stature 154.8 (11.7) cm, body mass 43.7 (10.9) kg and VO2 max 2.31 (0.24) L.min-1 performed three constant load tests of between 2 and 20 min duration to derive CP. Subjects then exercised in random order, at CP and CP+10 with heart rate (HR), oxygen consumption (VO2), rating of perceived exertion (RPE) and blood lactate (Blac) concentration measured throughout until volitional exhaustion. The mean power output for CP was 123 (10.4) W and which represented 72 (2.2) % of VO2 max. The time to exhaustion (TTE) at CP [124 (11.4) W] was 1207.7 (288) s, was longer than that at CP+10 [136 (12.5) W] being 631.3 (173.6) s. (p value). Both blood lactate and VO2 were higher in the CP+10 trial 4.8 (1.1) mM, VO2 2.15 (1.83) L.min-1) than the trial at CP Blac 4.12 (0.9 mM), VO2 2.08 (1.64) L.min-1. End exercise heart rate and RPE were similar in both trials 188 (4.8) b·min-1 and 9 (1.0) compared to 187 (4.1) b·min-1 and 8 (1.0) respectively.Although the estimated % VO2 max at CP was ~72 %, the %VO2 max attained at the end of exercise for both CP (90 (0.7) %) and CP+10 (93 (0.8) %) trial, clearly demonstrate a non steady state. Indeed, attainment of VO2 max was observed in some children (one subject attained max at CP, and two in the CP+10). Similar to some adult studies, TTE at CP was found to be ~20 minutes. Although CP cannot be continued "indefinitely" in children, these results provide information about the boundaries of heavy and very heavy exercise intensities in children.

EXERCISE AS AN ANTIOXIDANT: IT UP-REGULATES IMPORTANT ENZYMES FOR CELL ADAPTATIONS TO EXERCISE

Gómez-Cabrera, M.C., Domenech, E., Ji, LL., Viña, J.

Catholic University of Valencia, University of Wisconsin-Madison, University of Valencia. Spain, Spain

Introduction

Over the past two decades it was shown that unaccustomed exercise can increase the generation of reactive oxygen species in biological tissues specially skeletal muscle and myocardium (1). However there is increasing evidence that reactive oxygen species (ROS) are not only toxic but rather play an important role in cell signalling and in the regulation of gene expression. We have tested this hypothesis by studying the effect of inhibition of ROS production by allopurinol (an inhibitor of xanthine oxidase, a free radical generating enzyme) on cell signalling pathways in marathon runners and in rats submitted to exhaustive exercise by running on a treadmill.

Material and methods

Animals

Twenty male Wistar rats were randomly divided into three groups: rest (n =5), exercised (n =5) and exercised but pre-treated with 32 mg kg−1 of allopurinol by intraperitoneal injection (n =5) (2). Rats were exercised until exhaustion following a modification of the protocol of Davies et al. (1). The time to exhaustion was recorded for each animal. Gastrocnemius muscle was obtained by quick removal.

Subjects

Volunteers were recruited from participants in the 23rd Marathon of Valencia. Runners (n= 25) were randomly divided into two groups: placebo (n=14) and allopurinol supplemented (300 mg administered orally, 2 h before the race; n=11)(3). Blood was drawn from an antecubital vein 1 day before and immediately after the marathon. Lymphocytes were isolated from fresh whole blood. The isolated suspension of lymphocytes was subjected to whole-cell protein extraction for the determination of NF-B p50 activation.

Results

Exercise caused an activation of NF-B in lymphocytes from marathon runners which was completely prevented by allopurinol. In the rat model exercise caused an activation of MAP kinases in gastrocnemius muscle. This in turn activated the NF-B pathway and consequently the expression of important enzymes associated with defence against ROS (superoxide dismutase) and adaptation to exercise (eNOS and iNOS). All these changes were abolished when ROS production was prevented by allopurinol.

Conclusions.

In our study we report evidence that ROS act as signals in exercise because decreasing their formation prevents activation of important signalling pathways which cause useful adaptations in cells. Because these signals result in an up-regulation of powerful antioxidant enzymes, exercise itself can be considered as an antioxidant. The practical implication is that decreasing ROS levels with antioxidants may hinder beneficial cell adaptations during exercise. Therefore the common practice of taking antioxidant supplements during training should be seriously questioned.

GENDER DIFFERENCES ON FAT OXIDATION RATES DURING EXERCISE IN POST PUBERTAL ADOLESCENTS

Zunquin, G., Theunynck, D., Arhan, P., Bougle, D.

Université du Littoral & CHU de Caen, France

Evidence exist that, compared to post pubertal males, post pubertal females utilize more fat and less carbohydrate during endurance exercise performed at similar relative intensities. Skeletal muscle has an increased content of triglyceride in obese population and induces skeletal muscle defects as well as fat oxidation rates during exercise are significantly decreased compared non obese people. Are gender differences found in fat oxidation in healthy people were also found in obese population?

PURPOSE: We investigate the effect of gender on fat oxidation rates using a graded exercise test to exhaustion in sedentary obese post pubertal adolescent. METHODS: Post Pubertal adolescent (14 males, age: 14.6±0.6 yrs BMI: 31.8±6.15; 12 females, age: 14.1±0.5 yrs BMI: 28.8±3.7) underwent an incremental cycle ergometry test (20 Watts increments, 3.5 min intervals) to exhaustion with measurements of breath by breath gas exchange and heart rate. Fat rates were determined from indirect calorimetry during the 30 seconds of each stage as described previously by Achten (2001) and expressed per kilogram of Fat Free Mass (FFM). Body composition was assessed by DEXA.

RESULT: Fat oxidation rates are significantly higher in the post pubertal males at 20, 30 and 40 % of peak VO2 ($p<0.001$). When the fat oxidation rates are reported to FFM, fat oxidation rates are significantly higher in females group at 50 % of peak VO2 ($p<0.001$). Maximal fat oxidation rates occurred later for females (47.7±0.8% vs 45±0.9% of peak VO2; $p<0.001$). CONCLUSIONS: Gender differences found in non obese population is also found in obese population. This study permits to target exercise intensity which elicits maximal fat oxidation rates in obese post pubertal people. Exercise training protocol achieved at these intensities could beneficial to reduce fat mass in this population.

PROXIMAL-DISTAL SKIN TEMPERATURE GRADIENT AS AN INDEX OF PERIPHERAL SKIN BLOOD FLOW DURING EXERCISE

Kounalakis, S.N. 1, Mekjavic, I.B. 2+3, Geladas, N.D. 1

1 University of Athens, 2 Josef Stefan Institute, Ljubljana, 3 University of Portsmouth, Greece

The skin temperature difference between the forearm and fingertip (Tproximal-distal) has been demonstrated to be an index of vasomotor tone during anesthesia, and exposure to hot and cold ambient conditions. Measurements of Tproximal-distal correlate well with finger plethysmography (PPG) and laser Doppler velocimetry. Tproximal-distal is a simple, inexpensive, and easy to use method, but has not yet been validated during exercise. The aim of the present study was to determine, whether Tproximal-distal can be used as an index of vasomotor tone during steady state exercise.

For this purpose, 10 healthy young male volunteers exercised on a cycle ergometer at 58-60% of their VO2max for 30 min on three separate occasions, with at least 2 days between trials. Tproximal-distal was measured with thermistors placed on the radial side of the forearm and on the tip of the 3rd finger of the left hand. Skin blood flow (SkBF) was determined with a laser probe placed on the forearm. Pulse transit time (PTT), considered an index of arterial compliance, was calculated from the simultaneous measurements of finger pulse pressure and ECG. All measurements were taken at rest and during the last 5 min of exercise.

Upon completion of the exercise, SkBF increased significantly ($p<0.01$) from mean (SD) resting values (arbitrary units) of 5.74 (0.74) to end-exercise levels of 37.51 (1.18). Concomitant with the increase in SkBF, we observed a significant decrease ($p<0.01$) in PTT from resting values of 0.42 (0.07) to end-exercise values of 0.32 (0.07) sec, and also a significant ($p<0.05$) decrease in Tproximal-distal from resting values of -0.4 (0.2) to end-exercise levels of -1.27(0.3) oC. Tproximal-distal correlated significantly with SkBF ($r=-0.67$, $p<0.01$) and PTT ($r=-0.50$, $p<0.05$).

Based on these results, it is concluded that Tsk-diff is a valid index of vasomotor tone during exercise.

The project was co-financed within Op. Education by the ESF (European Social Fund) and National Resources.

THE EFFECTS OF VARIOUS STRENGTH TRAINING PROGRAMS UPON STRUCTURAL AND FUNCTIONAL CHANGES OF KNEE EXTENSOR MUSCLES IN SINGLE- AND MULTI-JOINT MOVEMENTS

Vinogradova, O., Netreba, A., Popov, D., Lyubaeva, E., Bravy, Y.

SSC RF - Institute of Biomedical Problems RAS, Russia

Blood restriction in contracting muscles, associated with noticeable acidosis, is considered to induce hypertrophy of muscle fibers. Blood restriction during work may be achieved either by application of occlusive cuffs or by using special type of strength training without relaxation (TwR). The latter means that during rhythmic movements the muscles do not relax at the end points of movement. The training effect of this training program in comparison with classical training (CT) is achieved using considerably lower loads. Little is known about particular effects of training without relaxation upon leg muscles during single and multi-joint movements. The aim of the investigation was to compare the effects of 10 weeks classical strength training and of low intensity strength training without relaxation upon size, strength and resistance to fatigue of leg muscles in men. Two experiments with single- and multi-joint movements (S- and M-series) were performed. The duration of each training experiment was 10 weeks. The subjects were trained three times a week: once with high load volume and twice with lower loads. Training intensity in a CT group was about 85% of maximal voluntary contraction (MVC) and in a TwR group – no more than 50% of MVC. 10 weeks strength training led to an increase of size and of maximal voluntary contraction of trained muscles. The increment of strength was noticeably higher after CT than after TwR, on the other hand strength increment related to total work performed increased after TwR more than after CT. Two training programs influenced the size of the whole muscle and of muscle fibers (MF) differently: the volume of m. quadriceps femoris increased more after CT than after TwR. CT induced a significant increase of cross sectional area (CSA) of fast MF and TwR induced an increase of CSA of slow MF. Resistance to fatigue after TwR was higher than after CT. Thus strength increments related to the total work performed were remarkably higher after TwR than after CT. The effects of TwR turned out to be more pronounced in one-joint training than in multi-joint training.

ACUTE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS RESPONSE TO THE STRESS IN SWIMMING AND RUNNING RATS

Contarteze, R.V., de Barros Manchado, F., Gobatto, C.A., Luciano, E., de Mello, M.A.

Sao Paulo State University - UNESP, Brazil

Many studies on metabolism and exercise are developed with animal models, especially with rats. Treadmill running and swimming are among the exercises most used in researches involving animals. However, doubts on which would be the most suitable exercise type to unchain to exercise responses associated to other stresses still remain. The activity of the hypothalamic-pituitary-adrenal axis, composed of adrenocorticotropic hormone (ACTH) and corticosterone hormones are important stress biomarkers. The aim of present study was compare blood ACTH and corticosterone concentrations, as stress biomarkers, during swimming and treadmill running exercises at the maximal lactate steady state (MLSS) intensity performed by rats.

For this, adult Wistar rats previously adapted to exercises in which MLSS was determined were used. For MLSS determination, the rats were submitted to 3 swimming tests with 25 minutes of duration (n=09) with loads of 5.0; 5.5 and 6.0% of their body weight (bw) or to 3 running sessions with 25 minutes (n=07) at velocities of 15; 20 and 25 m/min. Blood samples were collected from the tip tail of rats each 5 minutes of exercise for blood lactate determination. After MLSS attainment, the animals were sacrificed shortly after session of 25 minutes of exercise (swimming=09 or treadmill=07) at the MLSS intensity. For comparison purposes, a control group C (n=10) was sacrificed at rest. The Two-Way ANOVA was used in order to identify possible differences among groups ($P<0.05$).

The MLSS was obtained at 5.5% of the bw in swimming rats and at 20 m/min in running rats, at blood lactate concentrations of 5.2±0.3mmol/L and 3.8±0.1mmol/L, in swimming and running, respectively. Serum ACTH concentrations (pg/mL) were significantly

higher for the swimming group (963.3±420.4) when compared to the running (348.7±60.9) and control (179.3±46.3) groups, while the serum corticosterone concentrations (ng/mL) in swimming (2661.2±627.8) and running (1802.7±700.4) groups were significantly higher in relation to the control group (467.11±262.12). The swimming group presented higher concentrations for both hormones in relation to the running group. The swimming group presented higher concentrations of both hormones when compared to the running group.

These results allow us concluding that only acute swimming exercise induced endocrine/metabolic responses expected to stress: elevations on the serum ACTH and corticosterone concentrations.

THE EFFECT OF LIGHT INTERMITTENT EXERCISE WHILST SEATED ON PEAK FEMORAL ARTERY BLOOD VELOCITY

Hunter, S., Spencer, S.

London South Bank University, United Kingdom

The aim of this study was to compare measurements of peak femoral artery blood velocity using Doppler ultrasound during a period of prolonged sitting with and without intermittent exercise. Six healthy male subjects underwent two test conditions. The first condition, (condition A) entailed sitting as still as possible for 1 hour. The second, (condition B) of the same duration, introduced three 5-minute bouts of light foot pumping exercise during sitting. The exercise involved alternate leg action exerting enough pressure to transfer 1-litre of air from one side of an inflatable cushion to the other. In both conditions A and B measurements of common femoral artery peak blood velocity were made for three 1-minute periods during the second 5-minutes of each 10-minute period using pulsed Doppler Ultrasound spectral imaging. In condition B this immediately followed the exercise bouts. Also in both conditions heart rate (HR) was continuously recorded using two electrodes attached to a standard ECG monitor and blood pressure (BP) was determined simultaneously with the blood velocity measurements using an automated, cuff integrated wrist-type monitor. Mean peak blood velocity and mean heart rates were recorded using Spike4 data acquisition software. Despite considerable intra and inter-subject variability in the data obtained the mean peak blood velocity showed a strong tendency to increase over time in condition B ($r = 0.77$, $p = 0.07$). No such tendency was evident in condition A. It was concluded from this that light intermittent exercise is strongly indicated in effecting blood flow responses whilst sitting for prolonged periods. The results for mean HR from condition B showed higher values and a steeper increase in the upward linear trend over time compared to condition A ($r = 0.66$, $p = 0.15$). This was not significant ($p = < 0.05$). The trend in condition A was for a smaller increase over time and this was significant ($r = 0.84$, $p = 0.04$). Mean systolic BP overall was higher in condition A but increases were seen following each exercise bout in condition B. These differences were not deemed significant ($p = 0.05$). Conclusions were that HR and BP may increase with light intermittent exercise but that the observed increase in BF may be due to peripheral rather than central systemic factors.

REGULATION OF SKELETAL MUSCLE MASS IN RESPONSE TO MYOSTATIN GENE ELECTROTRANSFER

Durieux, A.C., Amirouche, A., Banzet, S., Koulmann, N., Bonnefoy, R., Mouret, C., Bigard, X., Peinnequin, A., Freyssenet, D.

University of Saint Etienne, France

Background & Significance: The cellular mechanisms that mediate skeletal muscle atrophy and functional deficits due to muscular disuse are just beginning to be elucidated. Previous studies showed that myostatin was a master regulator of muscle mass (1) and notably by inhibiting satellite cell proliferation and differentiation during embryogenesis and early post-natal growth (2).

Hypothesis: We hypothesized that gene electrotransfer of myostatin in adult rat would directly act on mature/differentiated skeletal muscle fiber and in a satellite cell-independent fashion by regulating muscle specific protein expression.

Methods: Right Tibialis Anterior (TA) muscles of 3-mounth old rats were transfected with a plasmid encoding myostatin cDNA under the control of CMV promoter. Contralateral control TA muscles were injected with the corresponding empty vector (3). Muscles were harvested 7 and 14 days after gene electrotransfer and structural modifications were determined by histochemistry. Gene expression regulation was envisaged at mRNA and protein for selected molecules.

Results: Seven and 14 days after myostatin gene electrotransfer, TA muscle weights were decreased by about 10 and 20%, respectively, when compared to control TA muscles. This was accompanied by a corresponding decrease in fiber cross-sectional area. By contrast, muscle fiber number and total DNA content remained unchanged suggesting that the decrease in muscle mass was a consequence of a reduction in myonuclear domain. Our data show that myostatin gene electrotransfer does not sensibly affect ATP-dependent ubiquitin proteasome pathway, as illustrated by the unchanged chymotrypsin-like activity of 20S proteasome and the unchanged mRNA level of E3 ubiquitin ligases, MuRF-1 and MAFbx. However, we show that myostatin gene electrotransfer induced a marked down-regulation of muscle specific gene expression and to a lesser extent, a down-regulation of the Akt-mTOR biosynthetic pathway. Indeed, we have demonstrated a down-regulation of the troponin I and MyoD promoters transactivation in myostatin-transfected muscles, a decrease in desmin, Akt and mTOR protein levels.

Conclusion: These data indicate that myostatin can trigger important regulatory mechanisms inside mature muscle fiber in a satellite cell-independent fashion. It also identifies a major role for myostatin in the control muscle mass mainly by a down-regulation of muscle-specific gene expression.

BLOOD LACTATE CHANGES DURING INDOOR CYCLING

Clijsen, R., Taeymans, J., Pfister, R., Wüthrich, M., Duquet, W.

Internationale Akademie Physiotherapie , Switzerland

Introduction

Indoor Cycling (IC) booms in European fitness centres. It is said to be an aerobic training method. Cycling frequency is determined by heavy beat music. Mostly resistance is set subjectively by the athlete while heart rate controlled training is not that common yet. The aim of this study was to investigate changes of blood lactate concentration (Lact) during an IC session with resistance set subjectively and set at a percentage of maximal heart rate (HR) estimated by the common formula 220 minus age.

Methods

Subjects (M=4;F=3) aged between 31 and 43 yrs were recruited in a Swiss fitness centre. They were familiar with IC. Informed consent was given. On 3 consecutive Saturdays following tests were conducted: a bike ergometer-test to assess lactate threshold (day1), a first IC session with resistance set subjectively (day2) and a second IC session that was HR controlled (day3). IC sessions took place in a group and were guided by an instructor (60min.). Per subject and per session 8 fingertip blood samples were analysed:1 at rest and 7 after different blocks of higher and lower intensity bouts. The Lactate Pro™LT1710 was used for lactate analyses. HR was monitored using Polar devices. Exhaustion was assessed using the Borg scale (6-20). SPSS 12.0 was used for statistics (ANOVA for repeated measurements). Significance was set at 5%.

Results

Mean HR at lactate threshold (4.0 mmol/l) was 157.0±16.8 bpm. Baseline Lact was 2.5±0.8 mmol/l at the 1st and 2.9±2.0 mmol/l at the 2nd IC session. Under conditions of subjectively set resistance mean Lact was 4.9±3.0 mmol/l after warming-up and peaked at 8.6±4.4 mmol/l ($p<0.05$). At each measurement moments mean Lact was above 4 mmol/l ($p=0.008$). Under conditions of HR controlled set resistance mean Lact was 7.0±7.3 mmol/l after warming-up and peaked at 8.0±4.3 mmol/l. However, ANOVA showed no significant changes of Lact during the IC session under HR controlled conditions ($p=0.243$). Under both conditions Borg and HR increased ($p<0.05$).

Discussion

Lact increases above 4 mmol/l directly after warming-up and remains high during the entire session period, indicating that intensity levels are too high for adequate aerobic training. Subjectively set resistance may lead to a significant increase in Lact with individual values above 14 mmol/l. It may be argued that this is an appropriate training method for not highly trained persons. Our data suggest that the use of individual HR monitoring devices may lead to a better management of the individual set resistances.

Conclusions

During an IC session the anaerobic component is dominant. Following the Indoor Cycling concept warming-up already leads to Lact concentration above the threshold. The use of individual heart rate monitoring devices may lead to a better management of the individual set resistances which may avoid significant changes in blood lactate concentration. Further research with larger numbers of participants is needed to increase statistical power.

MENARCHEAL AGE, MENSTRUAL DISORDERS AND SOMATOTYPES OF SWISS ELITE JUNIOR AND SENIOR SYNCHRONIZED SWIMMERS

Taeymans, J., Clijsen, R., Kersting, M., Clarys, P., Duquet, W.

Internationale Akademie Physiotherapie , Switzerland

Introduction

The aim of this study was to investigate menarcheal age (MA), menstrual disorders (MD) and the somatotypes (S) of the junior (JR) and senior (SR) athletes from the Swiss National Synchronized Swimming Team.

Methods

Six JR (16.4±1.6yrs) and 9 SR (20.2±2.6yrs) participated in this study. MA and MD were assessed using questionnaires. Anthropometric measurements were carried out following the ISAK guidelines. S was calculated (Heath&Carter method). SPSS 12.0 was used for statistical analysis ($p<0.05$).

Results

In JR mean MA was 12.8±1.0yrs while in SR mean MA was 13.6±1.2yrs. Oral contraceptives (OC) were used by 5 out of 9 SR, and not by JR. MD were found in 66.7% of the JR and SR not using OC. Mean height of JR was 164.1±4.9cm and mean weight was 51.0±5.4kg (BMI=18.9±1.1kg/m2). Mean S were 2.9–3.3–3.9. Mean height of SR was 164.0±6.1cm and mean weight was 54.7±4.6kg (BMI=20.1±1.0kg/m2). Mean S of SR were 3.1–3.5–3.3. Mean S of the whole sample were 3.0–3.4– 3.5. The differences in age and in BMI between JR and SR were significant. The relatively low SD of the anthropometric data indicate small variance (distribution) in these athletes. No differences between the mean values of several anthropometric variables and of the S compounds in JR and SR were found ($p>0.05$). Mean %fat in JR and SR was 21.5±2.5% and 22.8±3.1% resp.

Discussion

Mean MA (13.4±1.1yrs) is on the P50 of the "Leuven Growth Study" (1) and comparable with MA (13.0±1.3 yrs) found in the "LEGS-Study" (2). In our sample sexual maturation was normal. The absence of differences for the mean epicondylar femur and humerus widths between JR and SR indicate that skeletal maturation is completed by the age of 16 yrs. The prevalence of MD is high, with 22.2% of the athletes that are amenorrheic probably due to severe training regiments and unconventional nutritional habits. Mean BMI (19.6±2.1kg/m2) is borderline with the lower cut-off for a healthy BMI. Mean age (18.7±2.9 yrs) is above this of Olympic female stroke swimmers (17.0 yrs) (3). Although there are no differences ($p<0.05$) between the mean S of JR and SR, JR are more ectomorphic and less endomorphic than SR. The same has been found in different selections of female Olympic stroke swimmers (3). S of synchronized swimmers tend to be central, with the 3 S compounds differing from one another by no more than 0.5 units. Such athletes have well balanced bodies, which is an advantage in esthetic based sports.

Conclusion

Synchronized swimmers show normal sexual maturation but also important MD. Seen the central S and the relatively low BMI, further analyses of the administered food questionnaires will be needed for a better understanding of these relationships.

APOPTOSIS IN INDUCED SPUTUM CELLS IN LONG-DISTANCE RUNNERS: A LONGITUDINAL STUDY

Chimenti, L., Bonsignore, M.R., Paternò, A., Vultaggio, M., Bonanno, A., Bellia, V., Bonsignore, G., Morici, G.

University of Palermo, Italy

High intensity exercise induces inflammation and epithelial damage in airways. Whether, long periods of intensive training affects the response of airway cells to acute exercise in non-asthmatic athletes living in moderate climate has not been well assessed. We collected induced sputum samples for total and differential cell counts and apoptosis (TUNEL) in 9 long-distance runners (mean age±SD: 40±4 yr,

training volume: 85±26 km/week) at rest (3 days pre-race) and the morning after a race in November 2004 (Fall; 21 km, average temperature, T: 16±1°C, air humidity, H: 53±5%), February 2005 (Winter, 12.5 km, T: 7±2°C, H: 48±5%) and July 2005 (Summer; 10 km, T: 27.5±2°C, H: 48±5%). Air polutant concentrations were below attention threshold at all times. Induced sputum composition or cellularity did not vary according to season, despite large changes in outdoor T and a trend towards increased ozone concentration in Summer. Average neutrophil (PMN) counts in induced sputum of runners was 52.2% of total cells at baseline, and tended to increase after exercise (67.7%) independent of season. Total apoptosis was highest in Summer (45% of total cells) and lowest in Fall samples (11%, $p<0.05$) and apoptotic cells were mostly PMN (range 53-90% of total apoptotic cells) at all times. Bronchial epithelial cell (BEC) counts were low at all times (mean 4.3% at baseline, 3.5% post-exercise) but their contribution to apoptosis increased post-exercise (from 2% to 14% of total apoptotic cells, $p<0.05$) irrespective of season. Our data suggest that apoptosis of airway PMNs may be a mechanism to control airway inflammation in athletes living in moderate climate, whereas apoptosis of BECs may indicate epithelial damage induced by intense exercise, irrespective of season.

REMODELING AND INFLAMMATION OF SMALL AIRWAYS IN ENDURANCE TRAINED MICE

Chimenti, L., Morici, G., Paternò, A., Bonanno, A., Licciardi, A., Veca, M., Bonsignore, M.R.

University of Palermo, Italy

Studies on airways cells in well-trained endurance athletes at rest have found evidence of large airway inflammation, but the effects of endurance training on the small airways are poorly defined. We examined the integrity of bronchiolar epithelium and inflammatory cell infiltration in formalin-fixed, paraffin-embedded lung sections obtained in Swiss mice (body weight: 35 g, n=9/group) treadmill-trained (T) under standard laboratory conditions 5 days/wk for 2, 4 or 6 wks. Animals were sacrificed after 24 h rest. Sedentary controls (S) were examined at 0 and 6 wks. Daily running was progressively increased during T (fiber diameter of the tibialis anterior muscle at 6 wks: +26% in T vs. S mice, $p<0.05$). We assessed epithelial integrity of peripheral airways by counting ciliated cells/airway perimeter (range 400-1000 μm), mean epithelial thickness by measuring the area/perimeter (A/P) ratio and epithelial proliferation with an anti-PCNA antibody (Proliferating Cell Nuclear Antigen). We counted CD45+ and nuclear NF-κB+ cells (Santa Cruz) in bronchiolar walls. Ciliated cells decreased early during T (S: 0.117±0.02; 2-wkT: 0.03±0.00 cells/μm; $p<0.05$) and remained low after 6-wkT (0.03±0.01 cells/μm, $p<0.002$). The A/P ratio was 14.2±2.0μm in S mice, and increased after 4-wkT (19.4±1.1 μm, $p<0.03$) and 6-wkT (20.1±0.4 μm, $p<0.01$). Bronchiolar epithelium of trained animals showed evidence of increased proliferation respect to sedentary controls (0.060±0.040 vs 0.013±0.011 cells/μm, $p<0,001$). CD45+ cell counts in bronchiolar walls were 0.014±0.001 cells/μm after 6-wkT and 0.071±0.006 cells/μm in S mice ($p<0.001$). Finally, our results showed that endurance training decreased NF-kb nuclear activation in peripheral airways (nuclear NF-κB+cells•μm-1/ CD45+cells•μm-1: 0,730 S vs 0,303 T). Endurance training under standard laboratory conditions causes active repair processes in response to damage in the small airways, while attenuates airway inflammation. This may represent a physiological response to increased ventilation during exercise.

EFFECT OF RESISTANCE EXERCISE ON CHANGES IN MYONUCLEAR NUMBER AND FIBER SIZE IN RAT GASTROCNEMIUS MUSCLE FOLLOWING HINDLIMB-UNLOADING

Yamauchi, H., Miyano, S., Kimura, M., Shibasaki, T.

Jikei University School of Medicine, Japan

It has been documented that myonuclear number is associated with changes in cytoplasmic volume of skeletal myofibers due to hypertrophy and atrophy. The effect of myonuclear number on myofiber size is observed mainly in the slow-twitch soleus musucle, but controversy exists concerning its effect on fast-twitch muscles. Skeletal muscle atrophies in response to unloading, but mechanical stress to the muscle attenuates the atrophy. Hindlimb-unloading (HU) induces atrophy of both slow and fast muscles, and our previous study (Yamauchi et al. Jpn J Physiol 55: S222, 2005) showed that resistance exercise prevented the atrophy, especially in the fast skeletal muscles of rats. However, changes in myonuclear number in the study remained uncertain. This study investigated the effect of mechanical loading on changes in myonuclear number and fiber size of the gastrocnemius muscle. This study was conducted in accordance with the Japanese and American Physiological Society Guide for the care and use of Laboratory Animals, and approved by the Animal Use Committee at Jikei University. Adult F344 female rats were placed into either weight-bearing control (n=7) or HU group (n=14). Rats in the HU group had their hindlimbs suspended for 3 weeks. The HU group was subdivided to a group with (n=7) or without (n=7) an intermittent resistance exercise (IRE), in which the rats were put in a cylindrical wire mesh inclined 60 or 80 degree with a weight of 50-70% of body mass hung from the tail. The IRE was performed for 10 min, three times a day (total 30 min/day) throughout the HU. After the HU period, the medial gastrocnemius muscle was dissected out, weighed, and immediately frozen in melting isopentane cooled with liquid nitrogen. Frozen cross-sections of the mid-belly region were cut on a cryostat microtome, mounted on MAS-coated slide glasses, and stained. Myonuclear number inside the dystrophin-positive plasma membrane was counted, and fiber size of each fiber type identified by a myofibrillar ATPase staining was measured. The HU resulted in significant decreases in muscle mass (31%) and fiber size (30-39%) in all fiber types. The IRE attenuated the decreases of muscle mass by 49%, and fiber size by 33% to 86%. Especially, the attenuation effect of IRE on type IIa (86%) and type IIx (74%) fibers in the type I predominant region was strong. The HU resulted in significant decreases in myonuclear number (15-22%) and domain (ratio of fiber size to myonucleus) (17-25%) for all fiber types, but the decreases in myonuclear number (4-7%) and domain (0-19%) were significantly reduced by IRE. Muscle fiber size was significantly correlated with the myonuclear number ($r=0.74$) and domain ($r=0.94$). These results show that changes in myonuclear number occur in type II fibers as well as in type I fibers of the medial gastrocnemius muscle in response to mechanical stimulus, and the changes in the myonuclear number and domain are associated with changes in myofiber size.

THE EFFECTS OF 30 HOUR SLEEP DEPRIVATION ON VOLLEYBALL BASIC SKILL PERFORMANCE AND PHYSIOLOGICAL VARIABLES

Tarverdizadeh, B., Behpour, N., Safikhani, H.

Islamic Azad University,Branch of Bushehr, Iran

Introduction

The purpose of this study is to realize that sleep loss which may exit because long traveling or physical and mental factors has any effect on performance of volleyball basic skills and physical variables?

Materials and methods

To take into consideration 16 athletes of volleyball team in Kerman shah (14-17years)in tow groups of control and experimental have performed three volleyball basic skills(Windmill service .volley and Setting) and three physical variables (heart beat . blood pressure and vo2max) as pretest and posttest.

In this study the (AAHPER,1969) has used to evaluate basic skills of volleyball and physical variables.

In this study, after 8 hours of night sleep subject performed three volleyballs basic skill test and physical variables as pretest . 7days later, to determine the validity of tests and effect of learning on test results the athletes for the second time, performed the same three skills and three physical variables as posttest .in third stage, subjects sustained 30 hour sleep loss and independent variable and test performed again and the results recorded as experimental posttest and used for hypothesis testing .the obtained results compared in couple by T test and for compute used SPSS program and finally the following results gained:

Results

1)30 hours of sleep loss has a negative effect ($p<0.001$) on point of windmill service skill in volleyball.

2)30 hours of sleep loss has a negative effect ($p<0.001$) on point of volley skill in volleyball.

3)30 hours of sleep loss has a negative effect ($p<0.001$) on point of setting (volley set) skill in volleyball.

4)30 hours of sleep loss has a negative effect ($p<0.001$) on rest heart beat.

5)30 hours of sleep loss has a negative effect ($p<0.001$) on rest systolic blood pressure.

6)30 hours of sleep loss has a negative effect ($p<0.001$) on vo2max.

INFLUENCE OF THE POSITIONAL ROLE ON THE MORPHOLOGICAL AND FUNCTIONAL CHARACTERISTICS IN SOCCER PLAYERS

Olm, T., Thomson, K., Baskin, K., Herde, K.

Tallinn University, Estonia

An individuals' work rate profile during soccer competition is dependent upon the positional role of the player. The aim of this study was to determine the differences of the morphological and functional characteristics related to the positional role of soccer players.

The subjects were 46 male players of the best football clubs in Estonia. Three groups were formed from them. The first group (n=15) consisted of forwards, their average age was 22.2±2.08; the second group (n=15) consisted of defenders, their average age was 23.1±3.51; and the third group (n=16) were midfielders of age 23.8±4.05 years.

The test battery included anthropometric measurements, electro-, echo- and polycardiography, and incremental treadmill test to volitional exhaustion. Blood lactate concentration (Bla), maximum oxygen uptake (VO2max), and heart rate at anaerobic threshold were recorded. Anticipation speed and correctness, and ability to concentrate were assessed.

All mean values of the studied characteristics of the positional role groups were relatively similar, and only a small part of them differed significantly. The midfielders' height (177.1±5.33) and body mass (72.9±6,32) were significantly smaller than these of the two other groups. The tallest (184.0±6.68) and heaviest (79.0±7.92) were the defenders but their difference from the forwards was minimal. All three groups of soccer players had similar body mass indices and body fat percentages. No statistically significant differences occurred in any polycardiographic indices (E/Sm, T/St, grading points). The lowest working capacity was in the forwards' group. The mean values characterising aerobic metabolism were similar for all groups. However, their anaerobic thresholds, the ratios of the latter to the maximum heart rate, and maximum lactate indices (characterising anaerobic metabolism) were the highest in the forwards and the lowest in the midfielders' group. The ability to concentrate was also the best in the forwards, while the latter proved to be the most sensitive to fatigue: their anticipation correctness worsened twice after the treadmill test.

From the results we can conclude only a tendency to maintain the classical morphological and functional profile of the positional roles. The diminution of the differences between the characteristics of the different positional role groups might be due to the increased intensity of the soccer game over the recent years.

CHANGES IN LATENT TIME OF THE H WAVE AFTER ARM CRANK EXERCISE

Kazutoshi, S., Hidetaka, Y., Tomoyuki, I., Sho, O.

Kawasaki University of Medical Welfare , Japan

In humans, the monosynaptic H-reflex that is evoked by Ia afferents from muscle spindle to homonymous (MNs) is widely used as a tool for investigating the changes in excitability of the MN pool. There are few studies with an H reflex showing a recovery process after voluntary movement. The purpose of this study was to prove the effect of the change in latent time of the H wave during recovery examination after arm crank exercise.

Ten young males volunteered to participate in this study. After the H-reflex was elicited at time of rest, subjects performed 60％peakVO2 arm crank exercise for 10 minutes. After exercise, subjects were kept lying in the prone position, and H-reflex was measured after exercise (0, 7, 14, 21, 28, 35, 42 minutes). EMG was recorded at the medial head of MG of the right leg. H-reflex of MG was evoked by the electrical stimulation of the tibialis nerve in the popliteal fossa continuously for ten times in all of once per four second interval. Analysis of the H-reflex signal showed an average 4-6 times wave patterns, the amplitude of the M wave was maintained the same. We compared relatively evaluated latent time by the use of the value that deducted the latent time of positive peak of M wave to the latent time of positive peak of H wave because there was not a change for the latent time of positive peak of M wave each time.

The latent time of M wave did not change between pre and post exercise. But the latent time of H wave just after exercise shortened significantly as compared to the latent time of H wave of pre exercise. The latent time of H wave of post exercise was -0.43±0.21 ms and shortened significantly as compared to the latent time of H wave of pre exercise ($p<0.05$). We thought that just after arm crank exercise, the motor unit of fast muscle system was recruited remarkably, and the latent time of H wave shortened it. The latent time of H wave which shortened just after exercise with recovery time came back to the latent time of H wave at the time of rest (ANOVA: $p<0.05$). It is thought that the recruitment threshold of the motor unit changed as for the latent time of H wave returning to a previous value, and it is based on the size principle of the motor unit. This phenomenon was observed in the same experiment on different days. This study used arm crank exercise so that the position of a stimulation electrode on a tibial nerve did not change. It is clearly identified that an afference impulse from the upper limb has an influence on excitability of the motoneurons of the lower limbs. It was suggested that the lower-limb muscle group directly woke up muscle activity at the performance of exercise in the arm crank.

The latent time of H wave of post exercise shortened significantly as compared to the latent time of H wave of pre exercise. The latent time of H wave returned to a value for the latent time of H wave before exercise with time progress in recovery.

EFFECT OF TRAINING FREQUENCY ON CUTANEOUS MICROCIRCULATION IN RATS

Guerrero, F., Heylen, E., Saïag, B., Thioub, S., Mansourati, J.

Université de Bretagne Occidentale, France

Objective: Exercise training is known to improve endothelium-dependent relaxation in the coronary and skeletal muscle arteries. We previously showed that training-induced improvement of endothelium-dependent relaxation of rat aorta correlates with the frequency of training. However, the effects of exercise training on peripheral arteries, including cutaneous microcirculation, are still unclear. Therefore we investigated, in rats, whether the effects of chronic and regular aerobic exercise on cutaneous microvascular endothelial function matched those previously described on thoracic aorta.

Methods: We assessed the effect of physical training on skin microcirculation in 7 sedentary and 21 Wistar Kyoto rats submitted to a treadmill training protocol (15 m/min, 15% incline, 60 min/day, 8 weeks). Training rats were divided into three groups exercising 1 day/week (Ex1), 3 days/week (Ex3) or 5 days/week (Ex5). For all animals, cutaneous blood flow was recorded before the beginning of the training protocol, after 4 weeks and at the end of the training program. Hyperaemic responses (RH) were obtained 48h after the last exercising bout in anaesthetized animals using a Laser Doppler probe placed on middle of the calf. After baseline measurements, femoral artery was occluded for 1 min using an external circumferential garrotte. Artery occlusion was indicated by flow values reaching the occlusive zero. RH was the flow reaction obtained after sudden release of the garrotte. Caudal artery blood pressure was also monitored using non-invasive blood pressure equipment. For data analysis, cutaneous vascular conductance (CVC) was indexed as cutaneous blood flow (in arbitrary perfusion units) divided by mean arterial blood pressure (in mm Hg) and normalized to baseline values.

Results: At baseline, CVC was not different between all groups (sedentary or training) at three steps of experimental protocol. Considering RH, no significant difference was detected between all groups before the training protocol. In sedentary rats, as well as Ex1 and Ex5 animals, the maximal post-occlusive vascular conductance was not modified throughout all the protocol. Conversely, the hyperemic stimulus significantly increased normalized cutaneous vascular conductance only in group Ex3 after 4 weeks ($p<0.006$) and 8 weeks ($p<0.006$).

Conclusion: Since post-occlusive hyperaemia is known to reflect endothelium-dependent relaxation, these results indicate that exercise training exerts a generalized effect on the vasculature by increasing endothelial function in vessel beds different from central arteries. However, some differences exist since cutaneous microcirculation is modified by training at a frequency of 3 bouts weekly only.

OBSERVATION OF THE CORTICAL BMD AND URINARY PHOSPHATE EXCRETION IN THE RATS AFTER SIMULATED TAIL SUSPENSION

Kim, C., Park, G.D.

Gyeongju University, Korea, South

Introduction: Mechanical forces play a pivotal role in maintaining bone mass. Tail suspension is a ground-based model for the microgravity and cephalic fluid-shift aspects of spaceflight. This study was designed to clarify the difference of microgravity-induced bone loss between trabecular and cortical bone and changes of urinary mineral excretion.

Methods: Thirty 8-week-old female Spraque-Dawley (SD) rats randomly divided into five groups and completed tail suspension for two or four weeks: baseline control group (n=6, BC), 2 weeks vivarium control group (n=6, 2VC), 2 weeks tail suspension group (n=6, 2TS), 4 weeks vivarium control group (n=6, 4VC) and 4 weeks tail suspension group (n=6, 4TS). All rats were fed standard lab chow (CRF-1, Charles river, JAPAN) and to have same-volume-feeding for identical caloric intake. They were allowed access to distilled water ad libitum. After experimental period, rats were sacrificed and femurs were removed for analysis of bone mineral density (BMD) by dual energy X–ray absorptionmetry (DEXA, Lunar DPXL, USA) and peripheral quantitative computed tomography (pQCT, XC-960, Germany). The urine sample was collected in a glass flask with 10ml HCl during 24hrs at the end of experimental period.

Results: The femoral weights of 2TS and 4TS were decreased approximately 8% ($p<0.05$) and 9% ($p<0.05$) compared to the age matched both VC, respectively, but femoral length showed no difference among VC and TS. The femoral BMD measured by DEXA of 2VC and 4VC showed approximately 17% ($P<0.001$) and 24% ($P<0.001$) higher than that of BC, respectively. Those of the both TS, however, did not increased and approximately 12%($P<0.01$) and 14% ($P<0.001$) lower than those of VC, respectively. Also in the cortical BMD measured by pQCT, those of 2TS and 4TS showed approximately 4% ($p<0.01$) and 7 % ($p<0.001$) lower than those of VC, respectively. Similarly, the cortical cross-sectional area, bone thickness and stress-strain index (SSI), which reflect the mechanical strength, of cortical bone in both VC significantly increased, but those of TS were not ($p<0.01$ and $p<0.001$). However, trabecular BMD did not shown significant difference among any groups (NS). On the other hand, the serum calcium (Ca) concentration, urinary Ca and urinary deoxypyridinoline (Dpd) excretions of all intergroups showed similar levels (NS). The serum phosphate (P) concentrations of both TS, however, dynamically increased compared to the VC of 2-weeks ($p<0.001$) and 4-weeks ($p<0.05$), respectively, with approximately 40% decrease in urinary P excretion at both period ($p<0.05$, respectively).

Conclusion: These results suggest that the exposure to the microgravity environment induces spontaneous osteopenia in mainly cortical bone, and this osteopenia might be caused by disturbed P homeostasis.

LPS-INDUCED SICKNESS BEHAVIOR DOES NOT DEPEND ON KUPFFER CELL ACTIVATION IN MICE

Yano, H., Shiva, D., Matsumoto, T., Woods, J.A.

Department of Health and Sports Science, Japan

BACKGROUND: One characteristic of sickness behavior is demonstrated by a reduction in voluntary wheel- running activity during infection. Lipopolysaccharide (LPS), known as endotoxin, is a component of the cell wall of gram-negative bacteria that induces sickness behavior and increases proinflammatory cytokines. Additionally, it is well known that macrophages are the major cells that produce proinflammatory cytokines after LPS stimulation. Kupffer cells, which are resident macrophages in liver, constitute a large pool of macrophages. Although LPS binds to CD14/TLR4 of Kupffer cells directly, it is not clear whether Kupffer cells also are important in mediating LPS-induced sickness behavior.

PURPOSE: The purpose of this study was to determine the extent to which Kupffer cells contribute to LPS-induced reduction of running wheel behavior in mice. Our hypothesis was that LPS-induced sickness behavior is regulated by Kupffer cells via proinflammatory cytokine production.

METHODS: To clarify the effect of Kupffer cells on LPS-induced reduction of voluntary wheel-running activity, male C3H/HeN mice (n=8-9 in each group), were treated i.v. with either vehicle (PBS), GdCl3 (gadolinium chloride: inhibitors of Kupffer cells activity), or KDR (Kupffer cells

deletion reagent: provided by Prof. M. Inoue at Osaka City Univ.). We were measured changes in wheel-running activity and body weight before and after LPS (1mg/kg) or PBS injection.

RESULTS & DISCUSSION: Wheel-running activity in mice was greatly reduced after LPS injection (from 6,323+/-303 to 428+/-79 revolutions/day, 7%, p<0.01). Interestingly, wheel activity in GdCl3 injected mice was significantly lower than that in saline injected group (from 4,395+/-91 to 47+/-19 revolutions/day, 1%, p<0.01). However, in spite of non LPS stimulation, GdCl3 also induced reduction of wheel-running activity as a side effect (from 6,323+/-303 to 4,395+/-91, 70%, p<0.01). In contrast, KDR alone did not induce reduction of wheel-running activity. However, the wheel-running activity in KDR treated mice was still strongly decreased by LPS injection (from 8,609+/-1,954 to 233+/-110 revolutions/day, 3%, p<0.01). Thus, Kupffer cell activation might not regulate the response of LPS-induced reduction in wheel-running behavior.

CONCLUSION: Our results suggest that the transient reduction in physical activity after LPS injection is not mediated via Kupffer cells. Furthermore, we discuss the effect of inactivated Kupffer cells on plasma TNF-a concentration in mice after LPS injection.

THE EFFECT OF WATER IMMERSION ON ACTIVITIES OF ANTI-GRAVITY MUSCLES

Oyanagi, E., Seki, K., Lida, T., Miyakawa, T., Onodera, S.

Masters Program in Health and Sports Science, Japan

BACKGROUND: Holding the body's center of gravity steady represents the crucial variable for the stabilization of posture in the upright stance in man1). It is well known that the preservation of posture on land depends on contraction of anti-gravity muscles. However, it seems that the mechanism is different between on land and in water, because in the water condition we lose vertical force due to buoyancy. Although many previous studies showed that aqua exercise induces physiological exchanges, it is not clear whether neural muscular function affects the preservation of posture in the water. Especially, the effect of water buoyancy on response of muscular activities is still unclear.

PURPOSE: The purpose of this study was to determine the extent of the effects of activities of anti-gravity muscles. We hypothesized that water buoyancy regulates activation of anti-gravity by muscles for preserving posture.

METHODS: Six healthy adult males volunteered to participate in this experiment as subjects. Their characteristics were as follows: age; 22.0+/-1.0 years, height; 166.8+/-5.5 cm, weight; 66.0+/-5.3 kg, percentage of body fat; 21.2+/- 4.4%. All subjects were immersed up to the great trochanter-deep in the water. Furthermore, they were treated with different loads of body weight, by shouldering rucksacks. To evaluate muscle activities between on land and in water, all subjects were treated in the standing position and recorded surface EMGs (electromyograms) of TA (tibialis anterior), GAS (gstrochemious), SOL (soleus), RF (rectus femoris), BF (biceps femoris) and both left and right of MS (muscle of spine). IEMGs (integrated EMGs) were calculated by EMG signals from the 30th sec to the 60th sec after several load treatments. And then the values were expressed by percentage of IEMG in land condition.

RESULTS AND DISCUSSION: The relative IEMG of TA, GAS and SOL at great trochanter-deep in water immersion was significantly lower than that in land condition (98+/-86% vs. 165+/-136%; p<0.05, 82+/-87% vs.155+/-110%; p<0.01, and 79+/-45% vs. 110+/-26%; p<0.01, respectively). However, there was no significant difference in the relative IEMG of RF between the water immersion and the land conditions. More interestingly, although the relative IEMG of BF, left and right of MS were also not significantly changed, the relative IEMG of these muscles in the water immersion tended to be higher than that in land condition. Our results suggest that the activation of crural muscles might contribute to the preservation of posture in water immersion condition.

EFFECT OF INTERNAL WORK ON MUSCULAR MECHANICAL EFFICIENCY DURING CYCLING EXERCISE

Tokui, M., Hirakoba, K.

Kyushu Women's Junior College, Japan

【Introduction】 Exercising muscle simultaneously performs external work (Wext) as well as internal work (Wint) due to movement in exercising muscle itself. Since the Wint level during cycling has been reported to be directly related to pedal frequency (Seabury et al., 1977), a ratio of Wint to Wext would vary depending on the changes in pedal frequency even at the same Wext level. This could lead to a change in oxygen consumption (aerobic energy) at the same Wext and/ a lower muscular mechanical efficiency. This study was carried out to determine the effect of Wint on muscular mechanical efficiency during cycling under the same Wext condition. 【Methods】 Nine healthy male subjects (age; 20.7±2.4 yr, height; 170.3±4.9 cm, mass; 62.6±4.7 kg, VO2max; 47.8±6.4 ml/kg/min) performed a constant-load exercise with three pedal frequencies (40, 80 and 120 rpm) on a friction cycle ergometer. The exercise test consisted of 3-min rest and unloaded cycling for 3-min followed by 4-min constant-load exercise, which was repeated three times separated by a resting period (~20 min). Breath-by-breath pulmonary gas exchange data were measured continuously throughout the exercise test using a metabolic analysis system. Blood lactate concentration was measured at rest and immediately after each exercise test. Work (ηwork) and true efficiencies (ηtrue) were calculated as a ratio of Wext to energy expenditure (E; aerobic and anaerobic energy) above E during unloaded cycling and a ratio of the sum of Wext and Wint (total work, Wtot) to E above rest, respectively. Wint was estimated from a method of Minetti et al.(2001) and anaerobic energy from blood lactate accumulation (di Prampero and Ferretti, 1999). 【Results and Discussion】 ηwork (27-29 %) was almost remained across the pedal frequencies used in this study. In contrast, ηtrue in 120 rpm (21 %) showed a tendency to be lower than in 40 rpm (24 %) and significantly lower than in 80 rpm (26 %). The differences between aerobic energy costs to Wext and Wtot were 31.8 (40 rpm), 34.6 (80 rpm) and 100.3 J/min/W (120 rpm). The differences between total energy costs (sum of aerobic and anaerobic energy) to Wext and Wtot were 31.1 (40 rpm), 29.4 (80 rpm), 65.2 J/min/W (120 rpm). It is inferred that the greater difference between energy costs to Wtot and Wext in 120 rpm would be due to the higher energy consumption used for Wint than Wext (approximately 10 ml/min/W). This was supported by a slope (15 ml/min/W) of Wint-VO2 rerationship calculated in this study, which led to the lower ηtrue in 120 rpm. The present results suggest that muscular mechanical efficiency could be affected by the ratio of Wint to Wext during cycling under different Wint conditions. Therefore, Wint level should be taken into considertion in assessing muscular mechanical efficiency.

CARDIOVASCULAR RESPONSES TO MAXIMAL DRY BREATH-HOLDING AT REST IN PROFESSIONAL DIVERS

Perini, R. 1, Tironi, A. 1, Butti, F. 1, Moia, C. 2, Ferretti, G.1+2

1 University of Brescia, Italy, 2 Centre Medical Universitaire, Geneve , Italy

The cardiovascular effects of prolonged breath holding were evaluated in 20 professional divers (16 males and 4 females; mean 33.4+6 yrs) during voluntary maximal dry breath-holds at rest. The subjects laid supine in a room at 25-26 °C for 5 minutes for control measurements; then they performed 3 successive apnoeas, the 3rd of which was requested to be maximal, at a lung volume close to the total lung capacity. ECG and blood pressure profile (PortaPress) were continuously recorded (Biopac). Arterial oxygen saturation (SaO2) was monitored every 5 s by infrared spectroscopy (Nellcor). Beat to beat values of heart rate (HR) and of the corresponding systolic and diastolic pressures (Ps and Pd) were obtained. Maximal breath-hold duration ranged from 92 s to 319 s (mean: 210±70 s). In all subjects HR decreased from 79±15 b·min-1 to 66±13 b·min-1 within the initial 30 s of apnoea (phase I), to attain a steady state that was maintained for 131±36 s (phase II). At the end of this phase, 9 subjects interrupted their apnoea (group A; mean time of apnoea: 141±35.5 s). The remaining 11 subjects maintained apnoea for additional 96±38 s (phase III; group B; mean time of apnoea: 267.3±37.4 s). During this phase, HR decreased to a minimum of 49.2±10.3 b·min-1. A comparison of group A and B showed no differences in times of phases I and II (respectively 29±10 s and 112±34 s in group A and 27±6 s and 145±31 s in group B) and in the corresponding HR decrements (14±8 b·min-1 and 14±9 b·min-1 respectively in group A and B). Ps did not change in phase I in both groups; in phase II Ps increased above control by 24±25 mmHg in group A but did not change in group B. In this group an increase in Ps occurred in the phase III (+23±20 mmHg; p>0.05 vs group A). A significant increment in Pd occurred in phase I similar in the two groups (+9±5 mmHg); an additional increment by about 10 mmHg was found in phase II in group A and in phase III in group B. SaO2% was 100 for the initial 97±47 s in group A and 143±48 s in group B (p>0.05), i.e. for the duration of phase I and 60% and 80% of phase II, respectively for group A and B. Then, SaO2% decreased and reached at the end of phase II a value of 95±5 % in both groups. In phase III a decrement occurred to 84±11 % in group B (p<0.05). During recovery, SaO2% further decreased to 92% in group A and 79 % (p=0.03) in group B, respectively at 15th s and 20th s. The rapid decrease in HR observed with breath holding corresponds to that described as diving reflex and was coupled with increased Pd, suggesting peripheral vasoconstriction. At the end of phase II, when a given SaO2% was reached, only those who were capable to resist a breathing stimulus entered phase III. We postulate that: 1) the end of phase II corresponds to the physiological breaking point; 2) chemoreceptor stimulation may contribute to the responses observed in phase III; 3) these responses should include stronger vasoconstriction and baroreflex induced bradycardia.

THE EFFECT OF LEG VIBRATION LOAD ON EXERCISE PERFORMANCE

Masaki, T., Takayuki, K.

Institute of Exercise physiology, Japan

Muscle vibration on the leg muscles may occur in the sports activities such as alpine ski, snowboarding, mountain bicycling, climbing, basketball, soccer etc. This vibration may depress the exercise performance. Recently, it has been confirmed that the muscle vibration occurs in the leg muscles during competitive alpine skiing (Mester, 2001). In curved turns of alpine skiing especially under icy conditions and high velocity, one major part of the frequencies can be seen in the rage of 15 -18 Hz (Mester 1997). However, if this vibration could be a lowering factor for the exercise performance were of a matter of concerned. In this study, we evaluated whether the vibration of 15 -18 Hz occurred in the leg muscles affects the exercise performance in the laboratory setting.

Fourteen men, aged 22.6±0.8 were participated in this study. All subjects were competitive athletes playing alpine ski, basketball, and soccer. Their sports career was 8 -11 years. Exercise performance test items were vertical jump, back strength, single leg balance with eyes closed, whole body reaction time, trunk flexion, and posture maintaining ability such as crouching were measured in both conditions of with 15 -18 Hz's vibration and without vibration. We defined the muscle endurance as the time to reach to the level of ratings perceived exertion (RPE)'s 17, i.e., fairly hard in which the subject had to maintain the crouching posture as long as possible to reach to this level. Moreover, to evaluate the muscle fatigue during crouching, electrromyographic (EMG) activities were measured on the 10 muscles including the buttocks, quadriceps and the gastrocnemius during crouching posture for 30 seconds and compared the mean power frequency (MPF) for every 5 seconds interval in the both conditions of with vibration and without vibration. Subjects were tested on the plate of vibration machine that was able to generate artificial vibration. The frequency of vibration was set at 15 -18 Hz and the direction of vibration was vertical. Measurements were conducted at first under the without vibration and, 1 day after, same performance tests were conducted with 15 -18 Hz vibration.

Vertical jump (52.7±6.6 vs. 54.4±6.0), single leg balance with eyes closed (23.2±22.2 vs. 83.3±5.1), and crouching (85.4±24.4 vs. 106.3±30.1) were significantly lower in the condition with vibration compared to without vibration. Particularly differences were remarkable in the equilibrium function and the muscle endurance. Significantly lower MPF was observed in 8 of 10 muscles. There were no significant differences in back strength, whole body reaction time, and trunk flexion. No beneficial effects of vibration on exercise performance were observed. From the results of this study, we conclude that 15-18 Hz's vibration load on the leg muscles could cause in the depression in exercise performance.

MUSCLE AND CEREBRAL OXYGENATION CHANGES DURING ISOKINETIC LEG EXERCISE

Mookerjee, S., Weller, B., Welikonich, M., Matsuura, C., Bhambhani, Y.

Bloomsburg University, Bloomsburg, PA; Universidade Gama Filho, Rio de Janeiro, & University of Albe, United States

Muscle contraction is initiated in the cerebral motor cortex. This efferent signal traverses the spinal cord to recruit motor units in proportion to the intensity and velocity of contraction. Near infrared spectroscopy (NIRS) is a non-invasive optical technique that has been used to evaluate both cerebral activation and muscle performance during exercise. This study examined the relationship between isokinetic exercise at three velocities and cerebral as well muscle oxygenation/blood volume responses measured simultaneously using NIRS. Eleven healthy volunteers (mean age = 23.5 ± 3.3 yrs, height = 171.3 ±14.4 cm, mass = 68.5 ±12.3 kg, % fat= 15.9 ± 6.1 %) completed a 15-repetition leg extension/flexion protocol on an isokinetic dynamometer (Biodex System 3; Shirley, NY) after 2 min rest. Subjects exercised with the right leg at 150, 300 and 450 deg∙sec-1 in random order. NIRS measurements were recorded at rest and during the test from the left pre-frontal lobe and right vastus medialis muscle simultaneously using a dual wave spectrometer (MicroRunman, NIM Inc, PA). The difference in hemoglobin absorbency between the 850nm and 760 nm wavelengths was an index of oxygen extraction,

while the sum signal was an index of blood volume. Delta values of cerebral and muscle oxygenation/blood volume were calculated as the difference between the peak exercise and resting values prior to the initiation of contraction. Repeated measures analysis of variance indicated a significantly (p<.05) greater peak extension/flexion torque at 150 deg∙sec-1 compared to 300 and 450 deg∙sec-1. Cerebral oxygenation and blood volume exhibited a significant increase at all three velocities implying increased neuronal activation. These increases were significantly different (p<.10) between the contraction at 150 deg.sec-1 compared to the two faster velocities. Muscle oxygenation and blood volume decreased at all three velocities implying greater oxygen utilization despite a reduced blood volume. The decline in muscle oxygenation at 150 deg.sec-1 was significantly greater (p<.10) compared to the two faster velocities. Correlations between peak torque and delta values of cerebral oxygenation/blood volume were not significant with the exception of knee flexion torque and cerebral blood volume at 450 deg∙sec-1 (r2 = 0.68, p<0.04). However, statistically significant correlations were observed between peak extension torque and muscle oxygenation at 150 deg∙sec-1 (r2 = 0.63, p<0.04), and 300 deg∙sec-1 (r2 = .67, p<0.02). These NIRS findings support the well accepted torque-velocity principle and demonstrate the ability of NIRS in improving our understanding of the physiological factors that influence resistance exercise performance.

EFFECT OF ACUTE HYPOXIA ON FUNCTIONAL STATUS, RESOURCES AND PERFORMANCE OF MOUNTAINEERS

Kulnazarov, A., Ivanov, A., Sukhov, S.

National Research and Practical Center of Physical Culture, Almaty, Kazakhstan, Kazakhstan

Introduction

Mountain climbing involves the effect of a set of extreme natural factors; hypoxia being one of the main of them. Goal of the study is to assess the effect of acute hypoxia on the functional status, reserve resources and physical performance of mountaineers.

Methods

In the resting state and at submaximum and maximum aerobic load on the cycle ergometer, there were determined the indicators of respiration and gas exchange, lactate concentration and acid-base state of blood, registered ECG, and assessed performance. Ten males were tested twice, with interval of one day. During the first test the athletes breathed ambient air, while during the second one they inhaled hypoxic mixture with oxygen content 11.2% that corresponds to 5000m above the sea level.

Results

It was revealed that at breathing ambient air the respiratory minute volume (RMV) of in resting state was 7.20.61 l, while in the hypoxic conditions – 12.60.85 l. Heart rate prior to and after changing to hypoxic mixture was 72.13.5 and 84.42.7 beats a minute, respectively. Oxygen debt of in resting state was 247±8 ml/min, while in the hypoxic conditions – 278±14 ml/min. In hypoxia the maximum tolerable load decreased by 28.72.6%, and its total volume – by 39.23%. In hypoxic conditions, the PWC170 declined by 34.53.5%. At submaximum load in hypoxic conditions RMV increased by 427.9%, while at maximum load there was no difference in RMV. Oxygen debt at submaximum hypoxic load has decreased by 19.54,5%, and by 38.53.4% at maximum load. At the first and second examinations, the coefficient of correlation between the maximum oxygen consumption (VO2max) and PWC170 was 0.60. Submaximum load in hypoxia was accompanied with the growth of lactate concentration by 60.619.5%, in comparison with breathing ambient air. There was no difference in lactate concentration at maximum load. Physical load in the conditions of hypoxic mixture led to more expressed disbalance of blood acid-base status. Acidosis shift of pH at submaximum load in the hypoxic conditions was 0.160.01, and at breathing ambient air – 0.0710.02 conventional units. pH indices did not differ at the maximum load. Breathing the hypoxic mixture resulted in more expressed elimination of carbon dioxide from the blood. Thus, in breathing ambient air the рСО2 dropped to 37.53 1.31mm mercury at maximum load, while in hypoxic conditions – down to 31.190.99 mm mercury.

Conclusion

Use of such testing allows to assess the tolerance of athletes to locomotory and high-altitude hypoxia, and to forecast their performance in extreme high-altitude conditions.

THE STRESS OF CHESS PLAYERS. A MODEL TO STUDY THE EFFECTS OF PSYCHOLOGICAL STIMULUS ON BIOLOGICAL RESPONSES. AN EXAMPLE ON ENERGY EXPENDITURE IN MAN

Troubat, N., Gluck, M.-A., Dugue, B.

EA 3813 - University of Poitiers, France, France

Aim: We have studied the following stress model: the tension caused by playing chess.

Material and subjects: Eighteen subjectively healthy male chess players from the Limousin chess league participated in this study. Contests were arranged against players of similar levels (similar ELO chess rate). Heart rate (HR), O2 consumption (V.O2), CO2 production (V.CO2), breathing frequency (BF) were recording during the game using a portable metabolic cart (Metamax, Cortex, Germany) and a heart rate monitor (Polar Accurex, Finland). Indirect calorimetry was used to determine energy expenditure.

Results: The results were analysed between the 4th and the 20th minute of the game. Significant increase in HR (mean and [extreme values]: 86 [69-114] to 91,7 [68-124] bpm), V.O2 (4,5 [3,4-5,9] to 5,0 [3,8-7,8] ml.kg.min-1), BF (16,4 [9,6-24,9] to 17,1 [11,5-23,8] breath.min-1) and significant decrease in V.CO2 (4.2 [2.2-6.2] to 4.1 [2.9-7.0] ml.kg.min-1), and respiratory exchange ratio (RER) (0.9 [0.7-1.2] to 0.8 [0.7-0.9]) were observed. When calculating the oxidation rate, the lipid oxidation was found to significantly increase (from 0.6 to 1.7 g.min-1), whereas glucide oxidation significantly decreased (4.5 to 2.3 g.min-1). All together, total energy expenditure significantly increased during the game (22.9 to 24.8 Kcal.l-1).

Conclusion: We here describe an interesting real-life stressor that seems a useful stress model in that it has significant effects on the the metabolism. Considering the amount of energy used while sitting and playing cards for amusement, the extra energy due to a twenty min chess match is comparable to a 10 min walk at 5 km.h-1.

DIFFERENT ERGOMETRIC RESPONSE AFTER CAFFEINE INGESTION IN TRAINED AND UNTRAINED MEN

Olcina Camacho, G.J., Maynar, M., Caballero, M.J., Muñoz, D., Timón, R., Maynar, J.I.

Sport Science Faculty, Spain

Introduction: caffeine is an alkaloid, which may improve physical human performance due to different physiological mechanisms. Sport training generates physiological adaptations to itself, so, does caffeine act equally in trained men with adaptations as well as in non trained ones?.

Objectives: the aim of this study is to analyze the differences generated between trained and untrained men after caffeine ingestion in aerobic activities.

Material and Methods: A double blind randomized study with 5 mg/bw of caffeine was performed. Twenty non trained males and 15 trained cyclists had to cycle with two different protocols: progressive protocol until exhaustion and 30' steady state at 80% VO2 max under two conditions caffeine (CAF) and placebo (PLA). Ergospirometric response was measured with a Medical Graphics gas analyser and lactate values were analysed before and after all trials from vein blood using an YSI system. Statistical analysis was carried out using a statistical package for social sciences (SPSS 11.0 for windows). ANOVA was used for repeated measures to determine the significance of the differences, considering $p<0.05$ statistically significant.

Results: In incremental maximum tests, non trained subjects after caffeine ingestion showed an increase in total time of exercise (PLA: 11'35" ± 1'45 vs. CAF: 12'08" ± 1'59) $p<0.05$, VO2 max in ml kg/ min (PLA: 38.47 ± 4.99 vs. CAF: 41.59 ± 6.50) $p<0.05$, maximum heart rate (PLA: 184 ± 5 vs. CAF: 190 ± 6) $p<0.01$ and a decrease maximum RER values (PLA: 1.46 ± 0.14 vs. CAF: 1.40 ± 0.13) $p<0.05$, while, in trained cyclists there were only differences in maximum heart rate after caffeine ingestion (PLA: 182 ± 6 vs. CAF: 190 ± 5) $p<0.05$. With regard to the steady state trials, caffeine didn't change ergoespirometric parameters or lactate values in non trained subjects. In trained cyclists a better metabolic efficiency after caffeine ingestion with a decrease in VO2 and in RER values after 10 minutes of exercise was shown.

Discussion: caffeine ingestion improves maximal aerobic power in untrained men and it could enhance aerobic efficiency in trained men. Due to these different findings in trained and untrained men, caffeine would actuate by different ways depending on training level. In non trained men, changes in effort perception or nervous system stimulation could be the caffeine action mechanisms, while in trained men would be different, more related to metabolic aspects.

MUSCLE OXYGENATION, BLOOD VOLUME, LACTATE AND HEART RATE RESPONSES DURING CONCENTRIC AND ECCENTRIC CONTRACTIONS

Moalla, W., Dupont, G., Ahmaidi, S.

Faculté des Sciences du Sport, Université de Picardie Jules Verne, Amiens, France

Introduction: Understanding muscular action mode is of importance to improve training programs for athletes and patients (Styf et al 1995). It has been reported that eccentric contraction (Ecc) produces less cardiovascular stress and was fatigue resistant than concentric contraction (Conc) (Durand et al 2003). This difference would be due in part to a better oxygenation which may reduce metabolic demand. The aim of this study was therefore to investigate the effects of Conc and Ecc contractions on peripheral muscle oxygenation (MO2), blood volume (BV), blood lactate concentration [Lac] and heart rate (HR) in comparable work.

Methods: Twelve men aged 21 to 26 years performed Conc and Ecc maximal voluntary contractions (MVC) and 100 s endurance tests of the knee on Cybex isokinetic dynamometer at a velocity of 60°.s-1 between 6° and 84° according to the protocol of Kay et al (2000). During endurance test, MO2 and BV were assessed continuously by near infrared spectroscopy NIRS (RUNMAN, USA) on the vastus lateralis muscle. An arterial occlusion was applied to determine changes in MO2. Then, we calculated the mean rate of decrease in MO2. To assess changes over time, we divided into 10 s epochs the endurance test. Likewise, maximal HR was recorded and [Lac] was determined 3-min after the endurance test (Dr Lange miniphotometer).

Results and Discussion: Compared to Ecc, Conc contraction showed a significantly lower MVC (201.8 ± 40.3 N.m vs. 268.4 ± 47.7 N.m; $p<0.01$), higher HR (132.7 ± 19.6 vs. 117.0 ± 14.9 beats.min-1; $p<0.05$), and higher [Lac] (6.92 ± 0.86 mmol.l-1 vs. 4.64 ± 0.83 mmol.l-1; $p<0.01$). These results confirms the hypothesis of reduce energy cost of Ecc contraction. MO2 kinetics showed a progressive deoxygenation in both Ecc and Conc contraction which is significantly pronounced in Conc ($p<0.001$) until 60 s. Surprisingly, we showed a better oxygenation during Conc from 70 s until the end of exercise. The mean rate of decrease in MO2 during the test was significantly faster in Conc compared to Ecc contraction (0.72 ± 0.03 %.s-1 vs. 0.67 ± 0.05 %.s-1, $p<0.01$). This better oxygenation could be due to the viscoelastic properties of the muscles fibres during Ecc contraction. Furthermore, no difference in BV was found between Ecc and Conc contraction at the beginning of exercise (from rest to 10 s), and from 50 s to the end of exercise. However, significant reduction in BV was observed in Conc than Ecc contraction at 20, 30 and 40 s ($p<0.001$) which could be explained by the lowest intramuscular pressure reported on Ecc contraction (Styf et al 1995).

Conclusion: Our results demonstrate that vastus lateralis muscle deoxygenate less during Ecc contraction compared to the Conc contraction. Moreover, Ecc generates a higher MVC, lower HR and [Lac] than Conc contraction.

ACUTE INTERLEUKIN-6 ADMINISTRATION DOES NOT ALTER PLASMA SOLUBLE INTERLEUKIN-6 RECEPTOR CONCENTRATION FOLLOWING AN ACUTE BOUT OF EXERCISE

Robson-Ansley, P., De Milander, L., Collins, M., Noakes, T.

University of Portsmouth, Portsmouth PO1 2DT, UK, United Kingdom

Fatigue is a predictable consequence of physical activity; yet its biological cause remains ambiguous. During exercise, a polypeptide messenger molecule interleukin-6 (IL-6) is actively produced. We previously reported that administration of recombinant IL-6 (rhIL-6) to healthy trained runners prior to a 10 km time trial induced a heightened sensation of fatigue and a significant decrement in performance (Robson-Ansley 2004). Plasma soluble IL-6 (sIL-6R) receptors in association with IL-6 can render almost all cells sensitive to IL-6. In patients with elevated plasma IL-6 concentrations, administration of anti-IL-6 receptor antibodies reduced the symptoms of previously debilitating fatigue (Nishimoto et al., 2000). We hypothesise that the increased sensation of fatigue following exercise following rhIL-6 administration is due to a concomitant increase in sIL-6R concentration. The effects of exogenously provided rhIL-6 following an acute bout of exercise on plasma sIL-6R concentration in healthy trained male runners have yet to be reported. Thus, the purpose of this study was to determine if plasma soluble IL-6 receptor concentrations were increased following a low dose of rhIL-6 administered to trained male runners following a repeatable exercise challenge. Seven healthy, trained male runners completed an exercise challenge, which consisted of a 10 km time trial on a motorized treadmill on two occasions under two different treatment conditions i) a placebo (saline) ii) rhIL-6 subcutaneous injection at a dose of 0.05µg per kg body mass. Each trial was separated by one week and treatment was randomly assigned in a double-blinded manner. RhIL-6 administration had no significant effect on plasma soluble IL-6 receptor concentration post-exercise (P>0.05) despite (as previously reported) the fact rhIL-6 administration significantly impaired 10 km time trial running performance compared to the placebo 10 km time trial (P<0.01). In conclusion, rhIL-6 administration did not increase sIL-6R concentration post-exercise. Hence, we hypothesize that the rhIL-6 administration impaired exercise performance and increased sensations of generalized fatigue by altering CNS serotonergic activity.

CHANGES OF URINE 8-OHDG LEVELS OF A SINGLE BOUT OF EXERCISE UNDER HEAT OR COLD ENVIRONMENT IN HUMANS

Saito, Y., Nagashima, K., Suda, K., Kanosue, K., Tanaka, H.

Waseda University, Japan

Purpose: 8-OHdG has been recognized as a biomarker of oxidative DNA damage by endogenously generated oxygen radicals. The urinary excretion of 8-OHdG is a reflection of the integrated rate of oxidative DNA damage and the whole body repair of DNA1). The aim of this study was to examine whether evaluation in 8-OHdG content after a single bout of exercise under different environment in humans is affected by heat or cold exposure. Methods: We have determined the urinary 8-OHdG levels of six healthy male volunteers (Age; 21.3±1.0 years, Height; 172.7±5.8cm, Weight; 72.0±13.4kg, BMI; 24.1±4.5kg/m2). They wore T-short and half pants during the period of the study. All subjects in each experiment gave their informed consent. The procedures for these studies conformed to the guidelines. So, we studied five condition tests; Change on urinary 8-OHdG levels 1)when they don't experiment (Baseline), 2)when HRmax 60-70% of a single bout of exercise for 60 min in a room maintained at 25℃ (neutral environment ; Neutral EX), 3)when HRmax 60-70% of a single bout of exercise for 60mins in a room maintained at 35℃(heat environment ; Heat EX), 4) when HRmax 60-70% of a single bout of exercise for 60 min in a room maintained at 0-5℃ (cold environment ; Cold EX), 5) when immersed leg at 43℃ water temperature for 60 min in a room maintained at 30℃ (Heat BATH). The urine 8-OHdG was used at selected time points; pre-, just post-experiment, 2 hr post-experiment and 6 hr post-experiment. Results: Urinary 8-OHdG excretion was increased all experiment compared to the each experimental control (p＜0.0１). But, only heat EX was not significant (pre-;11.36±4.09ng/h/kg, just post; 13.99±6.57ng/h/kg, 2 hr post; 15.42±5.53ng/h/kg, 6 hr post; 11.24±3.54ng/h/kg). Rectal temperature during the experimental load was rose Heat EX from 30 min point, and it was getting over 38℃ from 50 min point. Discussion: These results indicate that a single bout of exercise in a room maintained at heat environment, getting over 38℃ on thermoregulatory response in humans, was rose heat shock protein, so increased antioxidant enzyme, oxidative DNA damage was decreased, and oxidative DNA repair enzyme was activated. Our results suggest that the promotion of body tissue injury by the oxidative stress may cause the influence in rectal temperature. We conclude that urinary 8-OHdG content increases after short-term and a single bout of exercise.

EFFECT OF TIME OF DAY ON VO2 KINETIC RESPONSES DURING SEVERE INTENSITY EXERCISE IN TRAINED CYCLISTS

Santana, M.G., Tufik, S., Passos, G.S., Santee, D.M., Denadai, B.S., Mello, M.T.

Federal University of São Paulo, Brazil

The kinetic analysis of the has been suggested to be an important parameter in the evaluation of aerobic capacity, as well as the capacity to tolerate exercise (Jones and Carter, 2000; Jones and Poole, 2005). As regards the tolerance to exercise and the diurnal variation, studies have shown that there is a longer exhaustion time at high intensity exercise in the afternoon and morning periods (Reilly and Baxter, 1983; Hill, 1996). The aim of this study was to evaluate a possible influence of the time of day on the parameters of oxygen uptake VO2 during severe intensity exercise. Nine trained cyclists, male (age 25 +/- 3.8 yrs., body mass 66.8 +/- 4.6 kg, height 174.4 +/- 6.7 cm and VO2max. 63.0 +/- 2.73 ml/kg/min), performed an incremental test to exhaustion (11:00 h) on a cycle ergometer and repeated bouts of exercise at constant loads (08:00, 13:00 and 18:00 h) on different days. These bouts of exercise were performed twice on each occasion, with an interval of 1 h between them. The intensity of the load used was 75%Delta (75% of the difference between the VO2 lactate threshold and the VO2max.). Prior to the bouts of constant-load exercise, the subjects rested in supine position for 20 min. Oral temperature was measured by a clinical digital thermometer inserted sublingually for 3 minutes after the period of rest. The oral temperature observed at 08:00 h (36.2 +/- 0.2ºC) was significantly lower than that at 13:00 h (36.5 +/- 0.2ºC) and at 18:00 h (36.6 +/- 0.2ºC) ($p < 0.05$). The values of the time constant of the VO2 primary component (19.3 +/- 2.5 s, 18.4 +/- 3.0 s and 19.7 +/- 3.9 s) and of the amplitude of

the VO2 slow component (735 +/- 81 ml/min, 764 +/- 99 ml/min and 680 +/- 121 ml/min) did not present significant differences at the different times (08:00, 13:00 and 18:00 h), neither did the other parameters of the VO2 kinetics. In summary, the data suggest that the VO2 kinetic responses of trained cyclists, exercising at severe intensity (75%Delta), were not influenced by the time of day exercise took place (either 08:00, 13:00 and 18:00 hours). This characteristic increases the time availability for the kinetic evaluation of the VO2 in cyclists.

EFFECTS OF SOME PHYSIOLOGICAL PARAMETERS ON SPECIFIED MOTOR SKILLS IN WATER POLO PLAYERS

Radovanovic, D. 1, Stamenovic, L. 2, Aleksandrovic, M. 1

1 Faculty of Physical Education Nis, 2 Faculty of Medicine Nis, Serbia and Montenegro

Introduction

Water polo requires a high level of physiological adaptation due to the game characteristics and aquatic envioronment. The aim of the present investigation was to determine the effects of some physiologic parameters on specified motor skills in young waterpolo players.

Methods

The investigation inlcluded 68 male subjects (age 11.8 yrs.±0.4, height 157.24cm±8.36, body weight 49.62kg±7.82). Subjects were junior water polo players of 4 Serbian water polo clubs with at least two years' training and competition experience in the league and tournament competitions. Functional abilities were determined according to absolute and relative VO2max values, forced vital capacity (FVC), forced expiratory volume in 1 second (FEV1.0), and heart rate frequency at rest. The level of specified motor skills was determined by means of the following variables: 25 m front-crawl swimming (S25), 50m front-crawl swimming (S50), 100m front-crawl swimming (S100), 4x5m back-crawl swimming (S4X5), 3x5m leading the ball (S3X5), and throwing the water polo ball (TWB). The level of investigated dimensions in water polo players was determined by applying the basic statistical parameters. The establishment of the space structure of specified motor skills was performed using Hotelling's method for factor analysis of the main components. The effect of the tests for latent space functional ability of specified motor skills was determined by regression analysis.

Results

One main component was obtained–a general factor of situational motor skills (GFSM) using factorization of 6 tests for specified motor skills in the investigated water polo players. The projections of variables on the main component are bipolar. The connection of the whole predictor system of functional ability variables and GFSM is relatively high (R= .460), and common variability between them approximates 21% (R^2= .212). In particular, FEV1.0 has the highest statistically significant effect on GFSM (BETA= - .293).

Discussion/Conclusion

The presence of one main component (factor) of the specified motor skills in water polo players is a consequence of optimal selection and homogenous sample, as well as the adequate selection of a battery of tests. The applied battery of tests can be recommended for monitoring specified motor skills in water polo players at the age of 12 years. A significant effect of FEV1.0 on GFSM points to the interdependence of functional adaptation and specified motor skills even this early in a water polo player's sports career. Since 5 out of 6 test for situational motor skills lasted longer (S25, S50, S100, S4X5, S3X5), the effect of this parameter is expected.

CHARACTERIZATION OF A PERIPHERAL MARKER FOR THE IDENTIFICATION OF THE PREVAILING SKELETAL FIBER TYPE

Fontes Ribeiro, C.A., Tavares, P., Cabrita, S., Santos, A.C., Rosado, M.F., Fontes Ribeiro, G., Oliveira, A.

University of Coimbra, Portugal

The characterization of the skeletal fiber type can only be performed through a biopsy which is not available for routine use without personal and ethical concerns. Therefore, another method is needed.

The main objective of this work was to test if the aerobic training capacity might be assessed through the determination of the expression of nitric oxide synthase (NOS) isoforms in platelets. To verify this, Wistar rats were used for: a) Characterization of skeletal muscle fiber type in the following muscles: soleus, vastus lateralis and rectus femoris (both of the quadriceps muscles) and gastrocnemius; b) Determination of NOS isoform expression [constitutive (cNOS), which can be endothelial or neuronal, or inducible (iNOS)] through Western blotting in the same muscles; c) Determination of the expression of the same NOS isoforms in platelets; d) Determination after 28 days of aerobic training (treadmill of increasing velocity) of the expression of cNOS and iNOS in the same muscles and platelets.

Muscles were analysed histochemically for mATPase (with alkaline (pH 9.40) and acid (pH 4.35) pre-incubation) and succinic dehydrogenase (SDH) activities. NOS expression was determined by Western blotting, by using specific antibodies against the constitutive and inducible isoforms of the enzyme. Training was performed in a treadmill (LE8706 model, Panlab s.l., Barcelona, Spain) controlled by computer, starting with the velocity of 6 cm/sec and finishing at 54 cm/sec (after 6 weeks of continuous and progressive training).

The following results were obtained:

The principal type of muscle fiber in soleus is oxidative (slow-twitch oxidative fibers or type I fibers) whereas the other muscles are mixed (with type I, and type IIb and IIa fibers (fast-twitch glycolytic fibers and fast-twitch oxidative glycolytic fibers)). In the principal oxidative muscle – soleus - of sedentary rats there was no cNOS expression, the same occurring for cNOS and iNOS in the gastrocnemius muscle. However, after aerobic exercise there was a significant expression of these two enzymes in both muscles. In sedentary rats there was a high expression of cNOS and iNOS in the rectus femoris and principally in the vastus lateralis. After training there was an increase of 10-30% of the cNOS and iNOS expression.

In platelets, cNOS and iNOS are significantly expressed. After training there was a significant increase of both isoforms, of the same magnitude of the increase in muscles.

These results suggest that the skeletal muscle nitric oxide expression (cNOS and iNOS) may be obtained through the determination of the cNOS and iNOS expression in platelets. Moreover, aerobic training may increase the expression of both enzymes in muscles and platelets, in a parallel way. Thus, platelets may be used to determine the training effect on the nitric oxide system and may reflect the aerobic capacity of the subject.

CASE STUDY OF SHORT-TERM HEART RATE VARIABILITY CHANGES WITH TRAINING LOAD IN A 16-YEAR-OLD MALE SWIMMER DURING PRE-COMPETITION AND COMPETITION

Matos, N., Winsley, R.

University of Exeter, United Kingdom

Introduction

To optimise training and preparation for competition athletes need to balance training and rest. Failure to provide adequate recovery may result in the athlete becoming overreached or eventually overtrained. The latter may be reflected by decreased performance, constant fatigue, altered mood states, depressed immune function, or changes in the autonomic nervous system activity (Halson et al., 2004).

Heart rate variability (HRV) analysis arguably provides an indication of autonomic sympathovagal balance. Acute changes in training load have been shown to influence HRV profile of trained athletes, with a reported increase in sympathetic drive (Hedelin et al., 2000), therefore HRV analysis may offer a non-invasive assessment of cumulative exertion and related fatigue (Earnest et al., 2004).

It has been suggested that competitions are physically and psychologically stress-inducing (Lehman et al., 1998), and whether changes in HRV profile are evident during a short-term (<1 week) competition period remains unclear. Hence, the purpose of this study was to examine the effects of quantifiable levels of exertion (TRIMPS) and resting HRV in a swimmer, assessed during pre-competition training and competition.

Methods

A 16 year-old national-level swimmer, 76.0kg body mass and stature 1.90m, who was currently in a 6-month training cycle, volunteered to participate. He was evaluated weekly during 3 weeks of mid-season pre-competition training and during a 3-day competitive gala (best score of 733 - International Points Score, IPS). A 5-minute resting HRV sample was measured at the end of each evaluation period. TRIMPS were calculated for each week of evaluation, assessed from both the duration of effort and its relative intensity. HRV data was analysed using frequency domain analyses.

Results

During week one, training load was high (74.8 TRIMPS) and this was accompanied by a LF/HF ratio of 4.8, indicating a predominance of sympathetic modulation. Interestingly, when training load reduced (week 2, 42.6 TRIMPS) LF/HF ratio declined to 0.4, with LFnu reducing by 64% and HFnu increasing by 300%, which suggests a rebound recovery of parasympathetic modulation during phases of lightest training. Return to higher training loads in week three again saw LF/HR ratio increase. Importantly during competition, although total TRIMPS were reduced, the swimmer gave close to his best performance (IPS=700), resulting in LFnu increasing by 8.7% (42.5) and HFnu decreasing by 5.6% (57.5), suggesting that stressors of competition may be reflected with a change in HRV profile towards increased sympathetic modulation.

Conclusion

HRV profile indicates an increased sympathetic modulation with increased training load and competition.

PEAK OXYGEN UPTAKE, LACTATE, BODY MASS IN SWIMMERS AND NON-SWIMMERS

Colantonio, E., Barros, R.V., Peduti Dal´Molin Kiss, M.A.

University of São Paulo, Brazil

Maximal oxygen uptake (VO2max) is an important indicator of aerobic fitness so much for athletes as for non-athletes. Due to methodological aspects related for his determination, the peak oxygen uptake (VO2peak) is also used. In swimmers is common to find high values of this variable as for absolute as for relative values, in spite of the competitive swimming performance is associated, predominantly, to glycolytic anaerobic metabolism. Knowledge of metabolic and functional responses during exercise and sport still has some questions related to physical training in children and adolescents. The aim of the present study is to analyze the VO2peak behavior and lactate concentrations ([La]) in children and adolescents swimmers (Sw) and non-swimmers (Nsw). Seventy one male volunteers served as subjects in this study, ranging in age from 7 to 17 years (35Sw and 36Nsw). They were arrangement in age-groups from 7-10, 11-14 and 15-17 years, making six under groups, respectively: Sw1 (n=13), Sw2 (n=13), Sw3 (n=09), Nsw1 (n=12), Nsw2 (n=15), Nsw3 (n=09). Anthropometrical data: Stature, Body Mass (BM) and Sum of seven Skinfolds were realized. The VO2peak values were attained through the VO2000® gas analysis system and Inbrasport ATL® treadmill, using adapted Bruce (1973) protocol. Capillary blood samples were collected from ear lobe at the end of the test and they were analysed immediately using Accutrend® analyzer for blood [La]. The results of the [La] showed lactate absolute delta for Sw1 = 3.44 + 1.79, Sw2 = 5.44 + 2.28, Sw3 = 5.89 + 2.01 mM and Nsw1 = 1.79 + 0.96, Nsw2 = 3.85 + 1.96, Nsw3 = 4.23 + 2.52 mM. The mean values of the VO2peakabs (l.min-1) were: Sw1 = 1.60 sd 0.45; Sw2 = 2.59 sd 0.65; Sw3 = 3.86 sd 0.44; Nsw1 = 1.00 sd 0.16; Nsw2 = 1.98 sd 0.51; Nsw3 = 2.78 sd 0.39. The mean values of the VO2peakrel (ml.kg-1.min-1) were: Sw1 = 46.15 sd 6.66; Sw2 = 57.03 sd 6.75; Sw3 = 56.28 sd 6.28; Nsw1 = 36.50 sd 5.12; Nsw2 = 43.46 sd 6.35; Nsw3 = 44.44 sd 8.64. The mean values of the VO2peakrelcor (ml.kg-0.67.min-1) were: Sw1 = 147.66 sd 24.90; Sw2 = 200.23 sd 30.00; Sw3 = 226.61 sd 19.51; Nsw1 = 108.74 sd 14.77; Nsw2 = 152.24 sd 22.50; Nsw3 = 173.37 sd 28.68. Statistical differences in both VO2peak were observed among the age groups ($p<0.05$). These finds point that both VO2peak rise between age groups for Sw and Nsw, and still it suffers influence from the age group and total BM, in special the body fat. The absolute lactate delta depends of the age group and the state training. In all age groups both VO2peak was greater for Sw than Nsw.

Bruce et al (1973). Am Heart J 85:546-2.

DOES LOW INTENSITY ISOCAPNIC HYPERPNEA ENHANCE BLOOD LACTATE ELIMINATION AFTER EXHAUSTIVE ARM EXERCISE?

Perret, C., Mueller, G.

Swiss Paraplegic Research, Switzerland

Introduction: Increased lactate concentrations compromise exercise performance. Therefore to regain maximal exercise capacity a fast elimination of accumulated lactic acid is important, particularly if several high intensity exercise bouts have to be performed within a short period of time. In general, blood lactate elimination is enhanced by active recovery at moderate in-tensities using the previously loaded muscle groups. In doing so glycogen resynthesis in these muscles is compromised and might impair subsequent exercise performance. Respiratory mus-cles have the ability to metabolize lactate and may therefore be used for recovery purposes without affecting glycogen resynthesis in previously stressed limb muscles. The aim of this study was to investigate the impact of moderate isocapnic hyperpnea (IH) on blood lactate elimination after exhaustive arm exercise in comparison to passive and active recovery using the previously loaded muscles.

Methods: 18 healthy male subjects (age: 30±5yr; height: 178±7cm; weight: 72±9kg; VO2peak: 42±7ml•min-1•kg-1) performed three arm cranking tests to volitional exhaustion on 3 different days at least 48h apart. Arm exercise was randomly followed by 30min of passive re-covery (PR), ventilatory recovery (VR) by means of IH at 30% of 12s maximal voluntary venti-lation, or active arm cranking (AC) at a moderate intensity. Blood lactate concentrations were measured at rest, immediately after the exercise test and every 2min until the end of the re-covery period. Furthermore peak power, peak oxygen uptake and rate of perceived exertion were determined at the end of the arm cranking test. Heart rate was measured continuously throughout the test.

Results: No significant differences for blood lactate concentrations were found between inter-ventions PR, VR and AC during the whole measurement period (peak lactate concentrations: 11.09±1.98mmol•l-1 (PR), 11.25±1.93mmol•l-1 (VR), 11.13±1.44mmol•l-1 (AC); lactate concen-trations at the end of the recovery period: 4.35±1.56mmol•l-1 (PR), 4.09±1.35mmol•l-1 (VR), 3.77±1.60mmol•l-1 (AC). All other parameters measured were not significantly different be-tween interventions, with the exception of higher mean recovery heart rates during VR (111±7bpm) and AC (116±9bpm) compared to PR (93±11bpm).

Conclusion: Low intensity IH seems not to enhance blood lactate elimination after exhaustive arm exercise compared to passive or active recovery using the previously loaded muscle groups.

THE INFLUENCE OF FUNCTIONAL CLOTHING ON THE THERMOREGULATION OF AN ATHLETE

Jack, A., Thoma, S., Rossi, R., Niess, A., Schmidt, W.

Empa St. Gallen (CH)/ Universität Bayreuth Sportwissenschaft (D), Switzerland

Human beings are homoeothermic, which means that they have to maintain their core temperature within close limits around 37°C. During every activity, the body produces a certain amount of heat lying between 80 W while sleeping and over 1000 W during most strenuous activities. The surplus energy can be transferred to the environment via three channels: respiration and release of dry (radiation, convection and conduction) and evaporative heat through the skin. Evaporative cooling is a very efficient means of heat dissipation, as one litre evaporated sweat removes about 670 W/h from the body. The body evaporates from at least about 22 g/h so-called perspiration insensibilis, up to 4 l/h during short periods of time. In order to avoid heat stress, the heat loss to the environment should be as high as the heat production. In many sports activities, the heat production of the muscles is higher than the heat release and therefore the body will overheat. Marathon runners, for instance, show core temperature of 40°C or even higher at the end of the run. If the ambient temperature is high, the heat and moisture transport through the garment should be as high as possible to avoid heat stress. In order to develop sports clothing with optimal thermo physiological properties, all thermo physiological parameters have to be considered. In summertime, the thermal insulation should usually be low and the clothing should allow efficient water vapour transfer. During very strenuous activities, it is also very important that the liquid sweat produced can evaporate near the body. If the liquid sweat produced drops down, it will not contribute to cooling the body. Any liquid sweat that does not evaporate near the body will, on the contrary, correspond to an additional physiological load, as the body has to produce more sweat to compensate the run-off. For this reason we aim to develop new textiles, which help to improve human thermoregulation in order to achieve an enhancement of the physical performance. For this purpose we carried out a series of human subject tests on a treadmill. We chose environmental conditions similar to those we will find at the summer Olympic Games in Peking 08. The goal of our study was to look at the influence of running suits on the evaporation cooling process and the thermo physiological parameters of the human body, compared to a nude athlete. This investigation shows that the thermoregulation of the human body works best without clothes, as could be expected. Even if the garments can store additional sweat, they could not increase the evaporative cooling process in comparison to the nude body. However, the lower core temperature reached with one garment shows that a garment with fast wicking properties can efficiently help the thermoregulation of the body.

PERFORMANCE OF VOLUNTARY ISOMETRIC CONTRACTIONS AFTER DOWNHILL RUNNING IN FEMALES AND MALES

Willems, M.E., Northcott, S.R.

University of Chichester, United Kingdom

Downhill running results in injury of knee extensor muscles [i.e. force loss (Martin et al. 2004), disorganization of the myofibrillar ultrastructure (Féasson et al. 2002)] and alterations in motoneuron pool excitability (Bulbulian and Bowles 1992). Injured skeletal muscles that are part of a synergistic group may allow continued performance with different contributions from the individual muscles. PURPOSE: Gender differences for muscle performance and surface electromyograms (sEMG) of knee extensors 1hr after downhill running were examined. METHODS: Maximal voluntary isometric force (MVIF), steadiness and sEMG of vastus lateralis (VL) and vastus medialis (VM) muscles during 50%MVIF were measured in six males (22 ± 4 yr, mean ± SD) and six females (29 ± 9 yr) before and 1 hr after downhill running [(5x8 min, -12%, 60%Vmax (females: 7.5 ± 0.2 km/h; males: 10.5 ± 0.6 km/h)]. EMGworks software (Delsys, Boston, MA, USA) was used for bandpass filtering (20-500 Hz) of the raw EMG signals and calculation of the EMG parameters root mean square (RMS) and median frequency (MDF) for each muscle. RESULTS: Males had larger MVIF values (658.2 ± 58.9 N versus 460.4 ± 36.9 N, $P<0.05$) and longer endurance times during 50%MVIF than females (84.3 ± 25.3 s versus 54.4 ± 13.5 s, $P<0.05$) before downhill running. After downhill running, MVIF deficits were similar (males: 12.5 ± 3.3%, females: 9.1 ± 3.2%, $P=0.487$) with no changes in endurance times and steadiness during 50%MVIF. After the downhill run, females, but not males, increased the ratio for the root mean square (RMS) values of the VL and VM muscles during MVIF testing by 33% ($P<0.05$) and lowered the change in RMS for VM during 50%MVIF from 47.2 ± 35.6% to 29.6 ± 34.6% ($P<0.05$). In males and females, no changes were observed for the change in median frequency in VL and VM during 50%MVIF.

After downhill running, females, but not males, altered for knee extensor muscles the vastus medialis and vastus lateralis contributions to maximal isometric force production and the activity pattern of the vastus medialis during submaximal isometric fatigue. CONCLUSION: Downhill running causes acute neuromuscular adaptations to perform voluntary isometric contractions of knee extensor muscles in females, but not in males.

THE EFFECT OF AN ACTIVE RECOVERY PROGRAM ON NEUROMUSCULAR AND BIOCHEMICAL MARKERS BETWEEN TWO ELITE FEMALE SOCCER MATCHES IN FOUR DAYS

Andersson, H., Raastad, T., Nilsson, J., Kadi, F.

Sport Sciences, Sweden

The aim of the study was to investigate the effect of an active recovery program on neuromuscular and biochemical markers during a simulated tournament match schedule for elite female soccer players (matches every 3rd day).

Methods: 20 elite female soccer players (23±4 years, 65±6 kg and 54±3 ml.kg-1.min-1) were randomly assigned to one of the following groups; active recovery group (n=10) and control group (n=10). The players in were evenly distributed into two teams that played two matches in four days. During the two days between the matches (22 and 46 hrs after match 1) the recovery training took place and consisted of 30 minutes of submaximal cycling (60% of HFpeak) and 30 minutes of low resistance training, while the control group was inactive. Before match 1, directly after, 5, 21, 27, 45, 51, and 69h after match 1, 20m sprint, countermovement jump, maximal isokinetic knee extension and flexion were measured. Creatine kinase (CK) was analysed from the blood plasma before match 1, directly after, 21, 45 and 69h after match 1. Total distance covered, distance covered in high intensity running and heart rate measures were recorded during the match. The food intake was standardised for all players during the 4 days and secured an optimal intake of macro nutrients for all players.

Results: No differences were found between the groups in recovery of performance, biochemical markers or match data. 20m sprint performance was reduced by 3.1±0.5 % after match 1 but was not significantly different from baseline level after 5hrs. Jump ability was decreased by 4.4±0.8% after match 1 and did not return to baseline levels before match 2. Peak torque in leg extension was reduced by 6.8±1.8% after match 1 and returned to baseline levels 27 hrs after match 1. Peak torque in leg flexion was reduced by 9.1±1.8% directly after match 1 and returned to baseline levels 45 hrs after match 1. CK levels were increased after match 1 with a peak concentration of 451±59 U/l 21 hrs after the match and returned to baseline levels 69 hrs after match 1. The total distance and, distance covered in high intensity running and mean heart rate was 9.4±0.3km, 1.1±0.2km and 81.7±0.7% of HRpeak respectively.

Conclusion: The active recovery program had no effect on recovery of physical performance or biological markers following a soccer match compared to complete rest. All physical and biological markers had recovered 45 hrs after match 1 except for jump ability that did not recover at all before match 2. The results indicate that 72 hrs is a sufficient recovery period between two elite soccer matches for neuromuscular and biochemical markers. Moreover, despite that the distance of high intensity running was in the normal range for elite female soccer matches, the total distance covered and mean HR were in the lower range, which may imply that a longer time for recovery is needed for matches with higher intensity, such as competitive international matches.

ELITE FOOTBALL ON ARTIFICIAL TURF VERSUS NATURAL GRASS: MOVEMENT PATTERN, TECHNICAL STANDARD AND PLAYER OPINION

Andersson, H., Ekblom, B., Krustrup, P.

Sport Sciences, Sweden

The purpose of the present study was to examine whether the movement pattern and ball skills of elite football players during competitive matches are different on artificial turf compared to natural grass. Another aim was to investigate the players' impression of the physical and technical performance in football matches on these surfaces. Six male and two female teams from the Swedish top league took part in the study. Technical analyses were performed for all out-field players during five male artificial turf games and five male natural grass matches against the same opponent. One male team that had artificial grass home ground were analysed in all 10 matches (5 home and 5 away matches). Three opposing teams, that had natural grass home ground, were analysed during 6 of those 10 matches (3 home and 3 away matches). In total, 8 team observations were performed for each surface. Ten players were video filmed during 1-4 games on each surface for computerized time-motion analyses. Questionnaires were filled out by 72 players with natural grass home ground and 21 players with artificial turf home ground. The players˝ match impression was registered via a "better(0)-equal(5)-worse(10)" visual analogue scale. The total distance covered and the amount of high-intensity running were not different during artificial turf compared to natural grass matches (10.190.19 and 1.860.10 km vs. 10.330.23 and 1.870.14 km, respectively). Moreover, no difference was observed between the surfaces in number of sprints (211 vs. 222), headers (81 vs. 81) and standing tackles performed per game (101 vs. 111), whereas the number of sliding tackles was lower (P<0.05) on artificial turf compared to natural grass (2.10.5 vs. 4.30.6). The number of short passes per game (218±14 vs. 167±12) and the number of midfield-to-midfield passes per game (148±11 vs. 107±8) was higher (P<0.05) on artificial turf than on natural grass. The number of long passes per game was not different between surfaces (87±5 vs. 82±6), but the proportion of unsuccessful long low passes was higher (P<0.05) on artificial turf than on natural grass (37±4 vs. 27±3%). The male players reported a negative overall impression of artificial turf (8.3±0.2) and stated that it was physically harder (7.0±0.2) and more difficult to control the ball (7.2±0.3) on artificial turf compared to natural grass. In contrast, the female players had a neutral overall opinion about artificial turf (5.4±0.5). In conclusion, the movement pattern of elite football players was observed to be similar on artificial turf and natural grass, except that fewer sliding tackles were performed on artificial turf. During games on artificial turf, much more short-passing was performed with no difference in the success rate of the short passes, but a lower success rate for long low passes. The female players reported a neutral impression of artificial turf, whereas the male player opinion was negative.

OBTAINING THE BASIC RESPONSE PATTERN OF PHYSIOLOGICAL TIME SERIES DATA USING FOURIER LOW-PASS FILTERING

Zakyntinaki, M., Stirling, J.

Universitat Autonoma de Barcelona, Spain

The derivation of a smooth curve describing the basic response pattern of physiological time series data is of great importance in the process of modeling the kinetics of such data, as well as in understanding the underlying dynamics of the physiological system under study. Currently simple noise reduction techniques, such as 3-rolling averaging, or averaging over repeated bouts of exercise are extensively used. In nonlinear systems such as the physiological systems under study, however, the characteristic high frequency oscillations do not only correspond to noise, but can also be inherent features of these systems. Therefore, the use

of such noise reduction techniques do not necessarily result in an enhancement of the basic response pattern; features not contained in the original data set might also be introduced, such as the time delayed transition to different phases in the 3-phase models of oxygen uptake and heart rate. The aim of the present work is to introduce Fourier low-pass filtering as an alternative curve smoothing technique, as well as an easy and very effective way for obtaining the basic response pattern from noisy physiological data. Fourier low-pass filtering is not only able to enhance the basic response pattern, by reducing the noise level of the data, but also to provide a smooth underlying curve about which any high frequency oscillations in the original time series of the data, including stochastic noise, are distributed. The application of such a filtering technique shows that the kinetics of such data can easily be described by a smooth curve (see for example Stirling et.al.), in contrast to the currently used 3-phase model which describes the kinetics of physiological variables in a non smooth manner. Fourier low-pass filtering can be successfully applied not only to physiological time series data corresponding to exercise of constant velocities, but also to any data obtained from varying exercise intensities providing a smooth curve that can be used further for modeling purposes. We will present the application of Fourier low-pass filtering to non-averaged, non-interpolated heart rate data sets of different exercise intensities. Averaging, as well as 3-rolling averaging is applied to the same data sets for a comparison. We believe that Fourier low-pass filtering can be successfully applied to data sets of any physiological variable (such as the V̇O2), not only to provide a smooth function describing the basic response pattern of the kinetics of these variables, but also to throw doubt onto the existence of different phases and time delays.

THE EFFECT OF PEDALING RATE ON CARDIAC OUTPUT AND STROKE VOLUME DECLINE IN PROLONGED EXERCISE

Kounalakis, S.N., Nassis, G., Koskolou, M.D., Geladas, N.D.

University of Athens, Faculty of Physical Education and Sport Science, Greece

Classical factors such as dehydration and hyperthermia do not fully explain the observed drop in cardiac output (CO) and stroke volume (SV) during prolonged steady state exercise, a phenomenon which has been named as cardiovascular drift and seems to be worse in cycling than in running. It has been speculated that a diverse active muscle mass and a more efficient muscle pump may partially explain the differences in cardiac output drop. PURPOSE: To explore the role of pedaling rate on CO and SV decline during steady state prolonged cycling. METHODS: Twelve subjects (24.3±3.8 yrs) cycled for 90 min at 126±15Watts (58-60% of VO2max), on two occasions: a) with a pedaling rate of 40 revolutions per minute (40rpm), and b) with 80 revolutions per minute (80rpm). Oxygen consumption (VO2), cardiac output (CO2 rebreathing method), heart rate (HR), rectal temperature (Tre), and mean skin temperature (Tsk) were recorded at various time points during exercise. Integrated EMG (iEMG) of vastus lateralis (VL) and skin blood flow (SBF; laser Doppler flowmetry) were also measured. Plasma and blood volume changes from rest (PV%, BV%) were calculated from hemoglobin and hematocrit values taken before exercise, at the 30th and 90th min of cycling. RESULTS: Despite the identical work rate performed, mean values of VO2, VLiEMG, HR, and CO were significantly higher during steady state exercise (20th min and onwards) with 80rpm than with 40rpm. Throughout the exercise protocol, the rate of decline in SV and the respective rate of rise in HR were significantly greater in the 80rpm than in the 40rpm condition. For instance, at the 85th min of exercise ΔSV was -16.21±0.85 ml/beat in the 40 rpm and -25±0.79 ml/beat in the 80rpm; similarly, ΔHR was +18.33±0.88 beats/min and +24.5±0.74 beats/min, in 40rpm and 80rpm, respectively ($p<0.01$). Overall, at the end of exercise CO decreased, from the steady state values, by 1±0.26 L/min in 80rpm ($p<0.01$), whereas no changes were observed in 40 rpm (ΔCO = -0.23±0.1 L/min, p=ns). Percent PV drop was greater during high than low frequency pedaling ($p<0.05$). Thermal variables (Tre, Tsk, SBF) were not significantly different between experimental conditions ($p>0.05$). CONCLUSION: During steady state prolonged cycling with high pedaling rate, cardiovascular drift is exaggerated compared to low pedaling rate, despite equal mechanical work being performed in both conditions. Thermal and hydration status of participating subjects cannot entirely explain the observed differences. It appears that muscle input may play a role on cardiovascular regulation during steady state exercise performed with different speed.

The project is co-financed within Op. Education by the ESF (European Social Fund) and National Resources.

EFFECTS OF INSPIRATORY MUSCLE FATIGUE AND BLOOD FLOW OCCLUSION ON EXERCISING MUSCLE

Lomax, M.E., McConnell, A.K.

Brunel University, United Kingdom

The existence of a inspiratory muscle metaboreflex has been demonstrated in the resting leg when inspiratory muscles are subjected to external loading sufficient to induce fatigue (Sheel et al., 2001), as well as during heavy exercise with inspiratory muscle loading (Harms et al., 2000). When evoked, this reflex induces sympathetically-mediated vasoconstriction that is capable of diverting blood away from locomotor muscles (Sheel et al., 2001; Harms et al., 2000). The influence of the inspiratory muscle metaboreflex upon limb muscle performance is unclear. We examined the effect of prior inspiratory muscle fatigue and manual occlusion of limb blood flow upon calf fatigue during sub-maximal plantar flexion exercise (PF).

Eight subjects performed 5 isometric voluntary PF trials: 1 control trial, 2 occlusion trials (cuff inflation of 50mmHg and 140mmHg), and 2 trials preceded by inspiratory muscle loading. The loading trials were identical, except that the first preceded 4 weeks of inspiratory muscle training (IMT; pre-IMT) and the second after IMT (post-IMT). Loading consisted of breathing against a flow resistive load equivalent to 60% of pre-IMT maximum inspiratory mouth pressures with a duty cycle of 0.7, breathing frequency of 15 per min (Sheel et al., 2001). PF was undertaken at 85% maximum voluntary contraction torque (MVC; 3-sec 'on', 2-sec 'off'). MVC was measured at 1-min intervals (5 sec

sustained contraction) with superimposed electrical stimulation. PF continued until subjects failed to generate 50% baseline MVC on 3 consecutive contractions (Tlim). Statistical comparisons were made using ANOVA.

The control trial produced the longest Tlim (mins) (9.67 ± 2.02). The 140mmHg trial produced the shortest Tlim (4.37 ± 1.74), followed by pre-IMT (6.12 ± 2.18), 50mmHg occlusion (7.52 ± 1.82), post-IMT (9.41 ± 1.82). The Tlim for the 140mmHg trial was significantly shorter than all trials (P<0.01) except the pre-IMT trial (p = 0.571). Similarly, pre-IMT Tlim was significantly shorter than all other trials (P<0.01) except the 50mmHg (p = 0.817). Inspiratory muscle training significantly increased inspiratory muscle strength (P<0.01).

When blood flow is restricted by manual occlusion, PF Tlim is significantly reduced. Furthermore, the greater the severity of the occlusion, the greater the decline in Tlim. Similarly, Tlim appears to be shortened by prior IMF. However, if the inspiratory muscles are strengthened by IMT this response is attenuated. Together, these findings are consistent with the notion that IMF elicits vasoconstriction in the working limb and that strengthening the inspiratory muscles attenuates this response.

THE EFFECTS OF GRAVITY ACCELERATION ON THE CARDIOPULMONARY RESPONSE TO EXERCISE

Bonjour, J., Tam, E., Grazzina, F., Antonutto, G., Capelli, C., Montmerle, S., Linnarsson, D., Ferretti, G.

CMU, Genève, CH; Uni Udine, IT; Uni Brescia, IT; Karolinska Institute, Stockholm, SE, Switzerland

Models of internal work of cycling predict that the oxygen consumption (V'O2) at any given work rate should be higher the greater the gravity acceleration (ag). If so, assuming that the relationship between cardiac output (Q') and V'O2 be unchanged, then Q' also should be a function of ag. We tested these predictions by measuring, on 14 male subjects (age = 26 + 5 years, body mass 76 + 8 kg), V'O2, carbon dioxide output (V'CO2), pulmonary ventilation (V'E), heart rate (fH) and Q' at rest and at the steady state of submaximal exercise carried out at a pedalling frequency of 60 min-1 in the human centrifuge at 1 (centrifuge still), 1.5, 2 and 2.5 G (1 G = 9.81 m/s2). V'O2, V'CO2 and V'E increased linearly with the mechanical power. As ag was increased, these lines were displaced upward. The linear relationship between V'E and V'O2 was unchanged, indicating that the ventilatory equivalent was the same at all ag. At any investigated power, V'O2 was linearly related to ag. These results are coherent with the first tested hypothesis. They allow predictions of the oxygen cost of exercise on planets with different masses than the Earth. fH increased linearly with both power and V'O2. The relationship between fh and power was displaced upward when ag is increased, such that the relationship between fh and V'O2 was unaffected by ag. By contrast, because the increase in fh did not correct the decrease in stroke volume, the relationship between Q' and power was unaffected by ag, despite the increase in V'O2. As a consequence, the relationship between Q' and V'O2 was displaced downward by increasing ag, contrary to the tested hypothesis. The increase in V'O2 with ag was supported by greater oxygen extraction by the tissues. These results imply that the maximal aerobic power should be lower, the higher the ag, in spite of a potentially unchanged maximal oxygen consumption.

INVESTIGATION OF POSTURAL STABILITY, REACTION TIME AND BODY MEASURES IN BASKETBALL PLAYERS

Téczely, T. , Ángyán, L.

University of Pécs, Medical Faculty; University of Pécs, Faculty of Adult Education and Human Resou, Hungary

Objective The aim of this study was to determine if any relationship between balancing functions, reaction time and body measures. Subjects The subjects were 11 professional basketball players (complete team) aged 22.2±1.5 years. Methods The body height, weight, and fat (%) were measured; the body mass index (BMI) was determined. The postural sways were recorded during standing on two legs on the stabilometer for 30 seconds. Static balance was measured on one leg on a beam 50 cm long, 4 cm high, and 3 cm wide. The subject should keep balanced in this position for one minute. Each time the subject lost his equilibrium, a new attempt was started. The number of attempts needed to keep in balance was computed. The time elapsing between the onsets of either a light or a sound stimulus and pressing an electric push button was measured as reaction time. Descriptive statistics and regression analysis were used for data analysis. Results The average height was 193±2.6 cm, the body mass index 23±0.6, and the body fat (%) 11.5±1.37. The reaction time to the light and sound stimulus was 183.6±8.8 msec and 149.3±6 msec, respectively. The body sways to left side were significantly higher than to the right side (difference: 1.75◦, p<0.03). Moderately high correlations were found between body mass index and attempts to maintain equilibrium on one leg (r=0.599, p<0.003). Higher correlation was found between the body sways and the body mass index (r=0.685, p<0.01). A close correlation was shown between body sways and the force of back muscles (r=0.7, p<0.01). Moderately high correlation was found between the reaction time to light stimulus and the body sways to left side (r=0.54, p<0.05). Conclusions The higher body mass index the higher body sways appeared. No significant correlation was found between body measures and the reaction time. The moderately high correlation between body sways and reaction time indicates the responsiveness of the subject to kinaesthetic and to the light stimuli.

QUANTIFICATION OF TRAINING LOADS BY USING THE CRITERIONS OF EXERCISE PULSE COST

Savelev, I.A., Popov, O.I., Voitenko, Y.L.

Russian State University of Physical Education, Russia

Adaptation to influence of physical loads in sports training may be quantitatively described by relationship "dose-effect" . The value of trained function increase for the period of observation is assumed as a parameter of achievable effect. A dose of influence of physical load is defined as the product of intensity of exercise energy expenditure on the period of the physical load action. This period assumed to be the sum of exercise time, the rest pauses time, and part of the recovery time that is related with the fast component of the oxygen debt. The absolute values of a heart rate usually used in practice of sports for an estimation of a level of exercise energy expenditure, find out linear relationship with a level of aerobic energy production only in the limited area of the exercises, that are not exceeded critical power value where the maximum of oxygen consumption is achieved. For wide range of exercises will be more correctly to use overall pulse criteria, such as the pulse sum of work, the pulse debt, the pulse cost of exercise which are derived from the time course analysis of the heart rate kinetics during periods of the work and recovery.

26 well-trained male swimmers, middle-distance runners and skaters (age 18-24 years, height 162-186 cm, body mass 62-83 kg), ranging from club to international level, volunteered to take part in the study. All subjects performed 5 all-out tests – 10 s, 30 s, 60 s, 120 s and

360 s duration without preliminary warm-up. The gas volume, the O2 and CO2 fractions in the expired air were measured using a monitor system (Sensormedics V-max 29 C). O2-intake, O2-debt, O2-requirment, aerobic and anaerobic energy output were calculated with a special computer program. The blood lactate concentration is determined using an enzymatic method Dc Lange. Acid-alkaline balance parameters were determined using a pH and blood gases microanalyzer (Instrumentation Laboratory IL-213).
Changes of parameters total pulse cost in dependence with values of exercise limiting time close reproduce appropriate relationships for parameters oxygen requirement and energy cost of exercise. Thus, pulse cost indices may be used as objective criteria for quantification physical loads as well at the development of programs of optimization of training in various kinds of sports. As a criteria of achived training effect is used a increase of physical performance and as a criteria of physical load dose is used a product of relative power and total pulse cost of exercise.

INTENSITY OF INITIAL ECCENTIC EXERCISE AND THE MAGNITUDE OF REPEATED BOUT EFFECT

Nosaka, K., Chen, T., Sacco, P.

Edith Cowan University, Australia

The underlying mechanisms of the protective effect conferred by a bout of eccentric exercise, often referred to as the "repeated bout effect," are not fully understood. A shift in the angle-force curve toward longer muscle lengths after eccentric exercise, which is speculated to result from an increased number of sarcomeres in series, has been posited to play a role in the repeated bout effect (Proske and Morgan 2001). However, it is not known whether there is an identifiable relationship between alterations in the muscle length tension relationship and the level of protection associated with an initial exercise bout. This study investigated the effect of initial eccentric exercise intensity (40, 60, 80, and 100%) on the joint angle/strength relationship, and the extent of the protective effect conferred against maximal eccentric exercise (100%). Fifty-two male students (20.7 ± 1.9 yrs), who had not performed regular resistance training, gave informed consent in conformity with the Declaration of Helsinki. Based on the baseline maximal voluntary isometric strength (MVC) of the elbow flexors at the elbow joint 90°, subjects were placed into one of the four groups; 100%, 80%, 60%, or 40% group (13 subjects per group). Subjects performed the first eccentric exercise (ECC1) with the non-dominant arm using a dumbbell adjusted to 100%, 80%, 60%, and 40% of each individual's MVC. Subjects lowered the dumbbell from an elbow flexed (50°) to an elbow extended position (170°) in 4~5 s every 45 s for 30 reps. All subjects performed the second bout of eccentric exercise (ECC2) with the same arm using a dumbbell equivalent to 100% MVC 2-3 weeks after ECC1. The protocol for ECC2 was the identical to that of ECC1, except for the dumbbell weight for the 40%, 60%, and 80% groups. MVC at six elbow joint angles (50°, 70°, 90°, 110°, 140°, 160°), range of motion, upper arm circumference, serum creatine kinase activity, myoglobin concentration, and muscle soreness were measured before and for 5 days following ECC1 and ECC2. The higher the intensity of ECC1, the greater the subsequent change in the criterion measures. A rightward shift of optimum angle following ECC1 was significantly ($P<0.05$) greater for the 100% and 80% groups than the 60% and 40% groups. Changes in the criterion measures following ECC2 were significantly ($P<0.05$) greater for the 40% group compared with other groups. Although the magnitude of repeated bout following ECC2 was significantly ($P<0.05$) smaller for the 40% and 60% groups, all groups showed significantly ($P<0.05$) reduced changes in criterion measures following ECC2 in comparison to the 100% group. These results suggest that the magnitude of the repeated bout effect was dependent on the magnitude of muscle damage in the initial bout; however, a shift of optimum angle does not play a main role in the repeated bout effect.

INFLUENCE OF DIFFERENT TYPES OF STRENUOUS TRAINING ON INDUCED FATIGUE CHANGES OF CARDIORESPIRATORY RESPONSIVENESS IN ENDURANCE ATHLETES

Mishchenko, V., Tomiak, T.

Academy of Physical Education and Sport, Gdansk, Poland, Poland

Fatigue induced changes of CO2 sensitivity and primary cardiorespiratory (CR) kinetics may be an integral reflection of overall fatigue of athletes and were related to the stage of overall fatigue of high performance athletes [1]. There have been limited researches of CR responsiveness changes induced by fatiguing training of different types. The purpose of this study was to determine the effect of different types strenuous training sessions on response to CO2, hypoxia and the CR primary kinetics in endurance athletes.
Twelve male elite rowers (18-26 yrs old) were tested prior to, 13-15 hours and 37-39 hours after different type of strenuous training sessions (mainly intermittent or continuous bouts of exercises). Power output, blood lactate, primary kinetics of ventilation (VE), oxygen uptake (VO2), carbon dioxide production (VCO2) and heart rate (HR) in 6 min max rowing test and 5 min test (0.7 VO2 max, transition from 25 w) were measured breath by breath (T50, monoexponential function). In rebreathing tests ventilatory response sensitivity to CO2 (∆VE /∆ PACO2) and HR response sensitivity to normocapnic hypoxia (∆HR/∆SaO2) were also measured.
Results showed decrease lung ventilation response to CO2, increase HR response to hypoxia and decrease in CR primary kinetics 13-15 hours after the strenuous training session relative to baseline in both types of training. The results showed significant decrease in response to CO2 (1.33±0.11 vs. 1.53±0.13 l.min-1 per 1 mm Hg in baseline, $p<0.05$) after intermittent type of strenuous training session. There was also tendency to higher level in HR sensitivity to hypoxia (1.32±0.13 vs. 1.22±0.14 beat.min per 1%) and primary kinetics VO2 (29.7±1.4 vs. 27.3±1.3 s, $P<0.1$) 13-15 hours after intermittent in comparison with continuous type of training session. Data collected 37-39 hours after the intermittent type of training session only showed decrease in sensitivity to CO2 (-8.9±1.7%) and primary kinetics VE (-7.6±1.2%, $p<0.05$) relative to baseline. Blood lactate level in 6 min max test increased significantly more 13-15 hours after intermittent training in comparison with continuous type training (5.9±0.4 vs. 2.8±0.2%, $p<0.01$).
We concluded that temporary effects of fatiguing training session related to hypo-kinetic features of CR response in both type of training sessions (mainly intermittent or continuous exercises) of highly trained rowers; CR sensitivity to CO2 and primary kinetics were decreased at 15-13 hours after strenuous intermittent training session but showed relative better recovery by 37-39 hours in the continuous type of training lesson. Impaired performance and specific fatigue induced different types of sport specific training may be attributed not only to exhaustion in energy sources but to temporarily impaired CR responsiveness also.

EFFECTS OF PHYSICAL TRAINING ON THE GH/IGF-1 GROWTH AXIS IN DIABETIC RATS

Gomes, R.J., Caetano, F.H., Rogatto, G.P., Pauli, J.R., de Mello, M.A., Luciano, E.

State University of São Paulo, Brazil

The aim of the present study was to examine the influence of moderate physical training on the GH/IGF-1 growth axis in diabetic rats. Male Wistar rats were divided into 4 groups, sedentary control (SC), trained control (TC), sedentary diabetic (SD) and trained diabetic (TD). Diabetes was induced by Alloxan (35 mg/kg b.w.) The training program consisted by swimming 5 days/week, 1h/day, supporting a load of 5 % body weight for 6 weeks. At the end of the training period, the rats were sacrificed and the blood was collected for determinations of serum glucose, insulin, GH, and IGF-1. Samples of liver and skeletal muscle were used to evaluate glycogen content. Tibias were collected for determination of total area. Diabetes decreased serum GH, IGF-1, total tibia area and liver glycogen stores in SD group ($P<0.05$). Physical training promoted increases in serum IGF-1 (SC=82±18, TC=90±8, SD=59±11, TD=80±9 ng/ml) and in tibia area (SC=1.73±0.05, TC=1.74±0.14, SD=1.41±0.14, TD=1.67±0.14 cm^2) in trained groups ($P<0.05$). It was concluded that in diabetic rats, moderate physical training induces important metabolic and hormonal alterations that are associated with an improvement in glucose homeostasis and an increased activity of the GH/IGF-1 axis.

SURVEY THE EFFECT OF SLEEPLESSNESS ON AEROBIC AND NON-AEROBIC PERFORMANCE OF PHYSICAL EXERCISES AND SPORT SCIENCE MALE STUDENTS

Molanaei, N., Boroujerdi, S.S.

Kurdestan University, Iran

This research is a survey the effect of sleeplessness on aerobic and non–aerobic performance of physical exercises and sport science male students.

The statistical sample of this research is the male students of physical exercises and sport science in Open University of Medical Science of Kurdestan University. There were 54 students as a whole of which 21 students have been chosen as research samples.

This is a descriptive research in which physical power; heart endurance, speed and muscular power are studied by means of one-mile running (1609m), 5 Yard running and vertical jump Sarjent in two levels of pre-test and post–test. Analysis of the data of the research has been done according to descriptive static and ANOVA one way. And it has been considered at the level of p< %5.

The results of this research show:

1. There was a distinctive difference of the records of 1609m endurance running between the time they were sleepless and the second time which shows that sleeplessness has some effect on aerobic performance.
2. There was a distinctive difference between the medium of records of second normal time and other situations.
3. There was a distinctive difference between the medium of records of the second normal time and the sleeplessness one that shows the effect of sleeplessness on non-aerobic performance.
4. There was a distinctive difference between the records of the speed running of 45m in the first time and in other conditions.
5. There was a distinctive difference between records of vertical jump in the first normal time and the time of sleeplessness and it shows the sleeplessness affect the muscle power of feet.
6. There was a distinctive difference between the medium of the records of vertical jump in the second normal time and other conditions.

INFLUENCE OF PHYSICAL TRAINING ON BONE METABOLISM IN EXPERIMENTAL DIABETIC RATS

Luciano, E., Gomes, R.J., de Oliveira, C.A., Luciano, E.A., de Mello, M.A.

Sao Paulo State University, Brazil

Purpose: The purpose of this study was to verify the effects of physical training on protein and DNA levels in bone and the histology of epiphysis in diabetic rats. Methods: Male Wistar rats were distributed into sedentary control (SC), trained control (TC), sedentary diabetic (SD) and trained diabetic (TD) groups. Diabetes was induced by alloxan administration (30mg/kg b.w.). The training consisted of daily swimming with load of 2% b.w., 1 h/d, 5d/w, for 4 weeks. At the end of the experiment the rats were sacrificed and blood samples were collected for glucose, insulin and GH determinations. Fragments of epiphysis of the right tibia were excised for protein and DNA evaluation. The left tibias were fixed in formol (10%) and decalcified in TCA for histology. Results: One-way ANOVA indicated that glucose was elevated among the diabetics ($p<0.05$) and improved in the trained diabetics (SC=118„b20, TC=122„b19, SD=415„b35, TD=362„b24mg%). Physical training did not have influence on insulin and GH levels. Protein/DNA ratio were increased in diabetic rats and recovered in trained diabetic rats (SC= 2.9„b0.6, TC=2.5„b0.6, SD=4.5„b0.8, TD=3.2„b0.5). Conclusions: The histology reveled decalcification in epiphysis of tibia in sedentary diabetic and improvement in trained diabetic. Therefore, physical training is important for the maintenance of protein metabolism and recovery of the developmental pattern of bone tissue in diabetic organisms.

OXYGEN UPTAKE KINETICS AT THE ONSET OF MODERATE-INTENSITY EXERCISE IN TRAINED BOYS BETWEEN 12 AND 15 YEARS OLD

Millet, G., Solano, R., Borrani, F.

Aspire, Academy for Sport Excellence, Doha, Qatar

The VO2 response to the onset of exercise provides a useful assessment of the body's ability to match change in metabolic demand and is viewed as complementary to the traditional variables measured for assessing the aerobic fitness; i.e. VO2max, ventilatory threshold. Despite it has been generally shown that prepubertal children have a more rapid exponential rise in VO2 than adults, the effects of growth on VO2 kinetics are still unclear: it is unknown if the puberty period leads to change in VO2 kinetics in moderate-intensity exercise.

Four groups of 20 trained boys of calendar age respectively of 12 (height 147.6 ± 6.7 cm; weight 36.6 ± 5.4 kg), 13 (156.8 ± 10.0 cm; 44.4 ± 10.5 kg), 14 (165.2 ± 9.4 cm; 52.2 ± 9.6 kg) and 15 years (168.3 ± 9.9 cm; 55.2 ± 10.8 kg) performed an incremental test (1 km.h every min) to exhaustion on treadmill and a transition from rest to a 6-min constant-load exercise at moderate intensity, slightly below the ventilatory threshold. Gas exchange was measured using a breath-by-breath analyzer (Oxycon Pro, Jaeger, Hoechberg, Germany). The ventilatory threshold was determined by the method of the O2 equivalent. The VO2 kinetics of the rest-to-exercise transition was modelled by a single exponential function described by its amplitude, time constant and time delay. The first 15 s were removed from analysis. These

parameters were calculated by an iterative procedure by minimizing the sum of the mean squares of the differences between the modelled and the measured VO2. The inclusion of a second exponential was tested but did not improve the fitting. The variability (CV: coefficient of variation) of the modeling parameters was calculated by the means of the 'bootstrap method' (1).

VO2max was similar in the four groups (54.0 ± 5.1, 53.6 ± 3.9, 54.3 ± 5.6 and 54.9 ± 4.9 ml.kg.min for the 12, 13, 14 and 15 respectively; P = 0.85) whereas the velocity associated (vVO2max) was greater (P<0.05) in the 15 than in the 12 or 13 (14.3 ± 1.4, 15.1 ± 1.4, 15.4 ± 1.4 and 16.4 ± 1.5 km.h-1). The time constant of the exponential rise increased (F = 11.1, P < 0.001) from 12 to 15 [15.9 ± 3.9 (CV = 14.6 ± 6.2%); 19.8 ± 2.9 (11.8 ± 5.0%); 21.7 ± 4.5 (11.8 ± 4.8%) and 24.0 ± 6.9 s (11.3 ± 3.7%)] whereas its amplitude [31.3 ± 4.1 (1.3 ± 0.5%); 30.1 ± 2.3 (1.4 ± 1.1%); 28.6 ± 3.4 (1.2 ± 0.4%) and 29.7 ± 4.9 ml.kg.min (1.2 ± 0.5%)] was not significantly different (P = 0.16) between groups.

The present study confirms in moderate-intensity exercise the results of Fawkner and Armstrong (2) who reported that the time constant of the primary phase were increased over a 2-yr period in prepubertal children. Moreover, despite that theoretically the signal-to-noise ratio is low in children (3), the variability of the present parameters are lower than in previous adults studies (1).

THERMOREGULATION AND HORMONAL RESPONSES DURING COLD EXPOSURE IN WHEELCHAIR ATHLETES

Sugawara, M., Taimura, A., Nakagaichi, M.

Faculty of Education, Nagasaki University, Japan

The purpose of this study is to clarify the characteristics of thermoregulation and physiological responses during exercise in a cold environment in wheelchair athletes. The subjects were male wheelchair athletes with spinal cord injury and healthy male college students. The maximal oxygen uptake as a parameter of endurance exercise ability was higher in the wheelchair athletes than in the college students. Measurements were performed at an environmental temperature of 12 Åé with a mean relative humidity of 60% at a mean air stream of 0.5m/sec. After rest for 30 minutes, the subjects performed arm cranking exercise at 20 watts(50 rpm) for 60 minutes. The measurement items were tympanic temperature, mean skin temperature, heat production, catecholamine, and cold-induced vasodilation. During exercise under exposure to cold, the tympanic temperature, heat production, and catecholamine more markedly increased in the wheelchair athletes than in the college students. The resistance index as a value of cold-induced vasodilation were higher in the wheelchair athletes than college students during cold exposure. On the other hand, the decrease in the mean skin temperature was slighter in the wheelchair athletes than in the college students. The thermoregulation sensitivity and heat production responses to exercise in a cold environment were more markedly increased in the wheelchair athletes than in the college students.

PREVENTION OF UNLOADING–INDUCED ATROPHY BY VITAMIN E SUPPLEMENTATION : LINKS BETWEEN OXIDATIVE STRESS AND SOLEUS MUSCLE PROTEOLYSIS?

Desplanches, D., Letexier, D., Servais, S., Pequignot, J., Duchamp, C.

UMR 5123 CNRS, Université Lyon I, France

Exposure to reduced activity induces skeletal muscle atrophy (1, 2). Oxidative stress might contribute to muscle wasting via regulation of proteolysis (3). This study was designed to test two hypotheses in rats. Firstly, long-term supplementation of the lipid-soluble antioxydant vitamin E, prior and during the phase of unloading, would partly counteract unloading-induced soleus muscle atrophy. Secondly, prevention of oxidative stress would decrease the rate of muscle proteolysis by reducing expression of different protease systems : calpains, caspase-3, -9, -12 and E3 ubiquitin ligases (MuRF1 and MAFbx). Soleus muscle atrophy (- 50%) induced by fourteen days of hindlimb unloading was reduced to only 32 % under vitamin E. Vitamin E partly prevented the decrease of type I (- 59 % vs – 38 %) and IIa (- 42 % vs – 32 %) fibre size. Supplementation suppressed the rise in muscle level of thiobarbituric acid-reactive substance caused by suspension but failed to modify the lower ratio of reduced vs. oxidized glutathione and the higher antioxydant enzyme (superoxide dismutase, catalase, glutathione peroxidase) activities observed after unloading. Vitamin E treatment abolished the upregulation of calpain 1 (+ 30 %), caspase- 3,- 9 and - 12 transcripts (+ 110, + 35 and + 50 % respectively) in unloaded muscle and decreased the large upregulation of both genes encoding ubiquitin ligases. In conclusion, vitamin E supplementation partly prevents muscle atrophy via redox control of proteolysis.

IMPACT OF AN INCREMENTAL EXERCISE ON THE PAIN

Grancharska, K., Pencheva, N., Nikolova, E., Kotcev, C.

South-West University , Bulgaria

Introduction

Exercise of sufficient intensity and duration has been shown to activate endogenous opioid and adrenergic systems and modulates the pain perception (Pencheva, Bojkova 2004). The object of this study was to investigate the effect of an incremental cycle ergometric test to exhaustion on pain threshold (PT) and pain tolerance using tourniquet ischemic pain technique. The total activity of creatine kinase (CK) as a marker protein for skeletal muscle injury, was also determined.

Methods

Two groups of healthy men (mean age 23, range 21-24) were studied. The first group of six untrained persons (UTr) had no limitations to exercise and were not involved in any specific training. The second group comprised six trained persons (Tr) - short-distance runners with middle level of training. The Tr and Utr males were evaluated before and 10-15 min after maximal incremental cycle test to exhaustion (30 W/1.5 min; W0=60 W) on ischemic pain test for both: (i) PT (mm Hg) for absence of pain (APT), poor pain (PPT), powerful tolerable pain (PTPT) and powerful intolerable pain (PIPT); the thresholds were determined cumulatively after inflation of the tourniquet to the level (mm Hg), corresponding to the verbal estimation of the subject; and (ii) pain tolerance by verbal rating scale (VRS) after 3 min ischemia with a constant pressure (BPd+50 mm Hg), comprising: intolerable pain, powerful pain, moderate pain, soft pain and absence of pain. The

blood samples were obtained from all participants about 15 min before and 30-40 min after the exercise test. CK activity (U/L) was analysed by measuring the rate in NADH, using commercial kits.

Results

The Wmax for Tr and Utr males was 300+/-12 W and 190+/-14 W respectively. All kinds of PT after exercise were significantly higher ($p<0.05$) as compared with pre-exercise values, for both Tr and Utr participants. The APT was increased with 16.5+/-3.2 % in both groups, but PPT increase was 22.4+/-3.2 % for Utr and 13.7+/-2.6 % for Tr. The post-exercise increase (%) of PTPT and PIPT in Tr males was 30.0+/-1.8 and >30, respectively, while for Utr was 15.9+/-1.8 and 15.5+/-1.9. Thus, the more pronounced increase in Tr concerns the powerful pain stimuli. Pain ratings according to VRS were decreased with 2-3 degree after exercise for all subjects (Tr and Utr). The plasma CK activity in Utr males was increased 4 times as compared with the pre-exercise value, but in Tr subjects was not significantly changed.

Discussion/Conclusion

These findings allow to conclude that the incremental exercise to exhaustion produces a pronounced hypoalgesic effect, which increases the pain tolerance. The changes, probably mediated by endogenous opiate release (Sgherza et al.2002), concern the total pain perception during and immediately after exercise.

ISOKINETIC STRENGTH AND JOINT MOBILITY ASYMMETRIES IN STROKE AND BOW SIDE OARSMEN

Riganas, C.S., Vrabas, I.S., Papadopoulou, Z., Vamvakoudis, E., Mandroukas, K.

Aristotle University of Thessaloniki , Greece

Competitive rowing is a strenuous sport which requires high levels of dedication. There are two types of rowing: Sculling where the sculler uses two oars, and sweep oar where the oarsman uses one. Sweep rowing is an asymmetric activity which involves loading the back in a rotated and flexed position. Therefore imbalances can occur between the agonist and antagonist muscles, as well as, bilateral asymmetry. The purpose of this study was to investigate oarside and non-oarside lower extremity asymmetries in isokinetic strength and joint mobility of oarsmen.

Peak torque of the right and left quadriceps (Q) and hamstrings (H) in 12 bow side (Mean ± SEM) (BS; age 18.6 ± 0.5 yrs, height 181.6 ± 1.4 cm, weight 77.6 ± 2.5 kg, training age 5.5 ± 0.5 yrs) and 14 stroke side (SS; age 20.6 ± 1.3 yrs, height 182.2 ± 1.8 cm, weight 78.8 ± 1.6 kg, training age 6.1 ± 0.9 yrs) Greek national level male rowers were measured on a Cybex II isokinetic dynamometer at 60 and 180°s-1. Three repetitions were carried out at each angular velocity and the best torque value was used. A 30 sec rest period was taken between each trial and a 60 sec rest period between each velocity measurement. Mobility of the hip, knee and ankle joints was measured using the Myrin flexometer, a modification of the Leighton flexometer. All measurements were made on an adjustable bench and were evaluated passively without causing pain, at the same time of the day and at uniform environmental conditions.

Considerable left/right and agonist /antagonist asymmetries, as well as, differences between oarside and non-oarside in both isokinetic strength and joint mobility were observed. Peak torque of the right Q was significantly lower in BS compared to SS at both speeds (216.7±15.8 vs. 286.2±8.8 and 144.9±7.6 vs.182.5±8.1 N∙m, $p<0.01$). Peak torque of the left Q was significantly higher in BS compared to SS at both speeds (271.0±14.0 vs. 233.5±10.9 and 182.1±8.0 vs. 158.1±5.6 N∙m, $p<0.05$).

Peak torque of the right H was significantly lower in BS compared to SS at both speeds (113.1±6.4 vs. 131.5±6.1 and 71.3±5.3 vs. 93.21±4.2 N∙m, $p<0.01$). No differences were observed in Peak torque of the left H between groups. Mobility of the right hip and ankle was significantly less in BS compared to SS (79.6±2.3 vs. 86.0±1.1 and 32.2±1.4 vs. 35.5±1.0 degrees, $p<0.01$) where mobility of the left hip and ankle was significantly larger in BS compared to SS (87.4±1.9 vs. 78.0±1.5 and 36.2±1.6 vs. 27.9±1.2 degrees, $p<0.01$). No differences were observed in right and left knee joint mobility between groups.

These results indicated a significant effect of sweep side on isokinetic strength and joint mobility of oarsmen.

LIGHTWEIGHT AND OPEN CLASS ROWERS: DIFFERENCES IN PHYSICAL PERFORMANCE AND ANTHROPOMETRIC CHARACTERISTICS

Riganas, C.S., Vrabas, I.S., Papadopoulou, Z., Vamvakoudis, E., Mandroukas, K.

Aristotle University of Thessaloniki , Greece

Competitive rowing is a strenuous sport which requires high levels of dedication. The anthropometric profile of rowers has been reported to be closely related to the level of sports performance (Jürimäe et al., 2000). The purpose of this study was to compare the possible differences in anthropometric, metabolic and performance variables between lightweight and open class rowers. Eighteen lightweight (LW; training age 6.8 ± 0.7 yrs) and 16 open class (OC; training age 7.4 ± 1.4 yrs) Greek national level male rowers were subjected to two exercise sessions on a rowing ergometer (Concept IIc, Nottingham, UK). An incremental exercise test to determine the anaerobic threshold (AT) and maximal oxygen uptake (VO2max), and a 2000 metre "all-out" test to evaluate performance indices. In addition underwater weighting (Vacu·Med, Ventura, CA, USA) was performed for body fat percentage calculation (Brozek: 100x[(4.570/BD)-4.142]).

Results revealed significant differences between groups. Anthropometric characteristics was significantly different between LW and OC rowers (Mean ± SEM) (Height 179.81 ± 1.07 vs. 184.78 ± 1.07 cm; Weight 72.44 ± 0.90 vs. 88.22 ± 2.2 kg; BSA 1.91 ± 0.11 vs. 2.11 ± 0.16 m2; BMI 22.50 ± 0.39 vs. 25.87 ± 0.46 kg•m-2; Body fat 10.71 ± 0.32 vs. 14.6 ± 0.53 %; Lean Body Mass 64.64 ± 0.96 vs. 75.29 ±1.78 kg; Fat Weight 7.79 ± 0.20 vs. 12.93 ± 0.68 kg; $p<0.001$). Physical performance characteristics was also significantly different between LW and OC rowers (VO2max 4705.09 ± 60.01 vs. 5237 ± 231.68 ml•min-1; VO2max 65.03 ± 1.03 vs. 59.37 ± 2.07 ml•kg-1min-1; VEmax 145.45 ± 5.29 vs. 165.42 ± 9.28 l•min-1; T2000 410.96 ± 1.70 vs. 393.05 ± 4.52 sec; P2000 323.72 ± 3.75 vs. 378.85 ± 2.79 Watt; SPM 29.90 ± 0.34 vs. 28.85 ± 0.14 strokes• min-1; LAmax 10.35 ± 0.39 vs. 11.81 ± 0.43; $p<0.01$). No differences were observed between groups in HRmax (200.45 ± 1.29 vs. 198 ± 2.04 beats•min-1), Dyspnea Index (0.87 ± 0.26 vs. 0.92 ± 0.31), BFmax (56.81 ± 2.05 vs. 57.28 ± 4.23

Breaths•min-1), RERmax (1.15 ± 0.12 vs. 1.19 ± 0.11), EqO2 (30.56 ± 0.70 vs. 31.38 ± 1.54), AT (178.27 ± 1.81 vs. 176.42 ± 2.49 beats•min-1), LA2000max (14.68 ± 0.62 vs. 13.64 ± 0.68 mmol• lt-1)

In conclusion the antropometric, metabolic and performance characteristics of lightweight rowers differ from those of open class rowers.

PHYSIOLOGICAL DEMANDS OF 4 V 4 AND 8 V 8 GAMES IN ELITE YOUNG SOCCER PLAYERS

Drust, B., Jones, S.

Liverpool John Moores University, United Kingdom

Small-sided games are time efficient as training activities since they present an opportunity for technical, tactical and physical development of players. Changes in the structure of training sessions may have consequences for the physical and technical demands placed on individuals. The impact of these changes has not been systematically investigated especially with young children. The aim of the current investigation was to evaluate the physiological and technical demands associated with 4 v 4 and 8 v 8 games in elite young soccer players.

Eight elite male soccer players from a Premier League Soccer Academy (Mean ± S.D. age 7 ± 1 years, height 1.3 ± 0.2 m, body mass 25.3 ± 3.8 kg, playing experience 2 ± 1 years) completed three 4 v 4 and three 8 v 8 games. Match duration was restricted to 10 min. The physiological responses to match-play were determined for each player by recording the heart rates during all games (Polar Electro, Kempele, Finland). Each player was also filmed using a video camera (Sony CCDTRV218, Japan) for the determination of individual work-rate profiles. These tapes were analysed using a hand notation system for both locomotor actions and ball contacts.

Mean ± S.D. heart rate responses to 4 v 4 and 8 v 8 matches were not significantly different (4 v 4, 175 ± 10 beats.min-1; 8 v 8, 168 ± 6 beats.min-1). Total distance covered, estimated by calculating stride length at the various velocities, during games were also similar (4 v 4, 778 ± 160 m; 8 v 8, 693 ± 103; $P>0.05$). The total distance covered walking, jogging and sprinting did not significantly differ with the number of players included in the game. Significant differences were noted for utility (backward and sideways) movements ($P<0.05$) with greater distances covered in 4 v 4 (140 ± 68 m) than 8 v 8 (107 ± 51 m) games. When expressed as a percent of the total distance covered the overall activity profile of players was similar in both forms of game. Walking, jogging, sprinting and utility movements accounted for 24 %, 44%, 19% and 13 % in 4 v 4 games and 27%, 48%, 10% and 15 % in 8 v 8 matches. The technical requirements of the game, as illustrated by the mean ± S.D. number of ball contacts, was dependent on the number of players involved. Reductions in the number of players significantly ($P<0.05$) increased the number of individual ball contacts per game from 13 ± 7 in 8 v 8 to 36 ± 12 in 4 v 4.

The data from this investigation suggest that small-sided games impose substantial physical demands on young players. The number of players involved in these activities does not seem to be a crucial determinant in these demands at this age. This observation is in contrast to more technically related actions that are significantly influenced by player number. This would suggest that activities that include smaller numbers of players can deliver a more effective multi-component training stimulus whilst maintaining the same cardiovascular stresses as large group activity.

TRAINING PREPARATION FOR AND PHYSICAL RESPONSES TO AN ULTRA LONG TERM HANDBIKE RACE

Abel, T., Lindschulten, R., Schneider, S., Strüder, H.K.

German Sport University Cologne, Germany

Introduction: Handbike as a wheelchair sport has gained increased popularity in Germany. It is a very attractive sport and important for the prevention of cardiovascular diseases. During the last 5 years race performance has increased enormously. Aim of this study is to measure the physical responses during a race from Trondheim to Oslo (540 km). The race will take part from 24.6 – 25.6.2006. Results will be really new.

Method: One spinal cord injured subject (lesion level Th4 ASIA B, gold medal winner in Paralympics and European Champion in handbiking) is going to perform the race in between a time window of 45 hours. Before, during and after the race blood samples will be taken to determine hormonal and immune system parameters as well as the metabolic situation (catecholamines, cortisol, leukocytes, lymphocytes, granulocytes, monocytes, CD3+ T-cells, CD19+ B-cells, CD4+ T-cells, CD8+ T-cells, CD56+ NK-cells, lactate). The handbike of the athlete will be equipped with a SRM system to register work load, speed, cadence and heart rate continuously. Body temperature will be measured by skin electrodes. Daily energy intake will be determined as well as distribution of carbohydrates, fat and protein. Water consumption and intake of vitamines and minerals will be documented.

Results: The athlete is in preparation for the race since October 2005. First training camp started on the 6th of December and was terminated on the 29th of January. Work load at metabolic threshold (4 mmol/l lactate) was inclined by 44 % from 90.0 watts to 128.8 watts by cycling 2.852 km. Maximum oxygen uptake per kilogram body weight increased by 14.6 % from 36.9 ml/kg to 42.28 ml/kg. The training was registered using as well the SRM system (average speed 18.1 km/h, average heart rate 132.1 bpm, average cadence 57.1 rpm). The training intensities were dedicated to metabolic situations of a laboratory staged test: 56.5 % with an intensity lower than 2.6 mmol/l lactate (> 60 watts), 10.2 % in between 2.6-3.4 mmol/l lactate (60 - 80 watts), 15.1 % in between 3.4 – 5.2 mmol/l lactate (80 – 105 watts), 8.5 % in between 5.2 – 6 mmol/l lactate (105 – 125 watts); 9.7 % > 6 mmol/l lactate (> 125 watts). A second training camp will start on the 26th of March ending 22nd of May. Planned are again approx. 3.000 km. The race will be accompanied by mobile medical laboratory equipment. All relevant parameters will be analysed in the first week after the race.

Conclusion: The influence of a systematic training period of nine months on an ultra long term race in handbiking will be shown. The profile of such an extended load and the physical reactions will be shown. The hypothesis is that moderate intensities during the training with great volumes will increase the performance capacity best.

EXPLOSIVE LEG STRENGTH AND LEG STIFFNESS AS PREDICTORS OF 100M SPRINT PERFORMANCE IN ELITE CROATIAN SPRINTERS

Vueti, V., Babic, V., Markovic, G.

Faculty of Kinesiology, University of Zagreb, Croatia

Introduction

It has been demonstrated that sprint performance is dependent on several qualities of the muscular system, explosive leg strength in particular1,5. In addition, it has been suggested that the stiffness of the legs also represents an important factor responsible for successful sprinting performance, particularly in the maximum velocity sprint phase1,2. Leg stiffness is one of the elastic components of the muscle-

tendon complex behavior that influences the mechanics and kinematics of body's interaction with the ground3. Both explosive leg strength and stiffness can be successfully determined by means of various jump tests1,3. The purpose of this study was to relate, in national level track sprinters, explosive leg strength and leg stiffness to the 100m sprint performance.

Methods

Eleven regional to national level male sprinters (100m sprint performance: 10.9 ± 0.4s (mean ± SD); range: 10.3-11.5s) participated in the study. Best 100m sprint performance (R100) during an official competition in the present season for each sprinter was considered as a criterion. Explosive leg strength was assessed from the height of the squat jump (SJ), countermovement jump performed with both legs (CMJ), as well as CMJ performed with each leg separately (CMJR and CMJL, respectively)4. All vertical jumps were performed on a force plate. Leg stiffness was assessed from maximal hopping in place test, as previously suggested2. Each subject performed ten maximal hops in place on a force plate. Mean jumping height (HOP) and leg stiffness (K; half-period method4) were calculated. Stepwise regression analysis (backward model; SRA) was used to calculate the relationship between jumping variables and R100.

Results

Performance in SJ, CMJ, and HOP correlated significantly to R100 (r = -0.76 to -0.83; p<0.02). No significant relationship between K and R100 was found (r = 0.14; p = 0.72). SRA revealed a simple solution with only CMJ as a significant predictor variable, which explained 69% of R100. For comparison, full regression model (i.e. all five jumping variables included) explained only 5% more variance in R100.

Discussion and conclusions

Although jump heights in both concentric and stretch-shortening cycle (SSC) movements were significantly related to R100, the best predictor of R100 in trained sprinters is CMJ. These data suggest that CMJ explains both concentric and SSC muscle function relevant to sprint performance. In contrast to previous data1, we found no relation between K and R100. Future studies should examine specific influence of jumping performance on each particular sprint phase. We conclude that CMJ represents the best jumping indicator of R100 I trained sprinters.

ENERGETIC COST AND D-TE RELATIONSHIP IN SWIMMING

Dekerle, J., Zamparo, P., Capelli, C., di Prampero, P.E.

University of Brighton, United Kingdom

Introduction. The concept of critical velocity (CV) has been criticized on different grounds (e. g. di Prampero 1999) especially for such sport activities, as is the case for swimming, in which the energy cost (C) is not constant but increases with increasing velocity (v). In sports for which C does not change as a function of v (e. g. running), the relationship between distance (d) and minimal time taken to cover it (te) is linear and CV can be calculated as the slope of this relationship, the y-intercept being associated to the anaerobic work capacity (AWC): d = AWC + CV te. Even if the slope and the intercept of this relationship do not represent CV and AWC in swimming, these two parameters can be calculated also for swimmers as described below.

Methods. During maximal exercise, the total energy expenditure (Etot) is given by the sum of the anaerobic (An) plus the aerobic (Aer) capacity. The latter can be calculated as the product of maximal oxygen uptake (O2max) and the time of exhaustion (te, s): Etot = An +  O2max . te (where Etot and An are expressed in kJ and  is the energy equivalent for O2). Etot can also be expressed as the product: Etot = C . d (where C is expressed in kJ m-1 and d is the distance covered, in m). By taking into account that, in swimming, C = a . vn (e. g. Capelli et al. 1998) and dividing all terms by C, one obtains: d = (An / a . vn) + ( O2max / a . vn) . te. In this equation the first term (An / a . vn) represents the distance that can be covered by exploiting the anaerobic energy sources (AWC) whereas the second term ( O2max / a . vn) represent the critical velocity (CV).

Results and discussion. Based on data published by Capelli (1998), AWC and CV were calculated for three elite male front crawl swimmers whose O2max was known (4.09 ± 0.54 l . min-1) and for which the C vs. v relationship was experimentally determined (C = 0.607 . v1.614). The values of AWC and CV were then compared to the intercept and the slope of the d vs. te relationship as obtained over 4 distances (46, 91, 183 and 366 m). CV (e. g. the ratio  O2max / a . vn) turned out to be 1.33 ± 0.07 m . s -1, e. g. 0.11 m s -1 smaller that that obtained from the d vs. te relationship (d = 1.44 . te + 16.8, R2 = 0.999, n = 12). AWC (e. g. An / a . vn) was found range from 18 (over the shorter distance) to 42 m (over the longest distance). These data show that the slope of the d vs. te relationship is not a measure of CV in swimming and that to calculate this parameter the subject's O2max and his/her C vs. v relationship should be known. Moreover, these data show that the intercept of the d vs. te relationship is not a measure of AWC which, in turn, is not a constant but increases as a function of the distance covered.

PHOSPHATE INGESTION LOWER BLOOD LACTATE CONCENTRATION AFTER A MAXIMAL OXYGEN CONSUMPTION TEST

Frøyd, C.

Sogn og Fjordane University College, Norway

Ingestion of phosphate for athletes in sports is not advised by nutritionists due to lack of effect on performance. Athletes using the sports drink FOZ, containing sodium dihydrogenphosphate report that they like the beverage and believe the phosphate increase performance and recovery in endurance sports.

PURPOSE: Compare the effect of a sports drink containing phosphate and the same sports drink without phosphate. The effect on performance was measured during a VO2max-test (VO2max, time to exhaustion and lactate concentration) and recovery (10 minutes) after the VO2max-test for athletes. METHODS: 29 athletes (men n=23, women n=6, age 20-27 years, VO2max 61.2±7.8 ml O2 kg-1 min-1) ran two test sessions on a treadmill with four hours rest period between the test sessions. Each test session contained of 15 min warm up

running, a VO2max-test (4-8 min), 2 min rest and 10 min recovery running. Heart rate (HR) (Polar, Finland) were measured during the whole test, VO2 (MetaMax I, Cortex, Germany) were measured during the VO2max-test, and lactate concentration in blood (cLa) (YSI, USA) were measured 1 minute (cLa0) after the VO2max-test, and after 3 (cLa3), 5 (cLa5) and 10 min (cLa10) recovery running. Between the two test sessions, all subjects ate the same light meal, drank water and 1 liter of sports drink. Half of the subjects (n=14, VO2max 61.5±7.4 ml O2 kg-1 min-1) drank a sports drink containing sodium dihydrogenphosphate (PHOS) and the other half (n=15, VO2max 60.9±8.3 ml O2 kg-1 min-1) drank the same sports drink without sodium dihydrogenphosphate (PLACEBO). All results are reported as mean ± SD. RESULTS: Time to exhaustion or VO2max were not significantly different between test 1 and 2 for PHOS or PLACEBO. cLa were significant lower for PHOS for all cLa-measurements between test 1 and 2: cLa0: 8.8±1.8 mmol l-1 (test 1) – 7.4±1.8 mmol l-1 (test 2) p<0,001, cLa3: 8.4±1.9 mmol l-1 (test 1) – 7.3±1.4 mmol l-1 (test 2) p<0.01, cLa5: 6.9±2.2 mmol l-1 (test 1) – 6.0±1.5 mmol l-1 (test 2) p<0.05, cLa10: 4.5±1.9 mmol l-1 (test 1) – 3.3±1.3 mmol l-1 (test 2) p<0.05. For PLACEBO, only cLa10 were significant different between test 1 and 2: cLa10: 4.5±1.5 mmol l-1 (test 1) – 3.6±1.1 mmol l-1 (test 2) p<0.05. CONCLUSION: Ingestion of sodium dihydrogenphosphate in a sports drink with sodium and D-glucose result in lower lactate concentration in blood 1 minute after VO2max-test and after 3 and 5 min recovery running after the VO2max-test. However ingestion of sodium dihydrogenphosphate did not alter time to exhaustion or VO2max during a VO2max-test. This is surprising since it is usually assumed that a reduction in cLa would be associated with increased performance. The mechanism which lowers cLa is unclear.

ACCURACY OF SUB MAXIMAL CYCLO-ERGOMETRY IN SENIOR ROWERS AND RUNNERS - WHAT CAN WE CONCLUDE BASED ON THE STATISTICS?

Ruzic, L., Mikulic, P., Sporis, G.

University of Zagreb, Croatia

Astrand cycle ergometry test is probably the most famous and most frequently used sub maximal test aimed at evaluation of the aerobic capacity. In this research the accuracy of test was evaluated based on results comparison with the results obtained during maximal ergometry test, the test which is considered to be an objective indicator of functional status of the individual. The sample consisted of 46 rowers and 22 runners. All the examinees are males in their middle age (35-65 yrs), who are at least twice per week active in rowing or running recreational training sessions. The maximal ergometry test was conducted using the rowing ergometer for the sample of rowers, and treadmill for the sample of runners. Basic statistical parameters were calculated followed by Pearson correlation coefficient. Simple regression analysis was performed and Student T-test and Fisher F-test were used to verify the obtained results. The results pointed out statistically significant, but low to moderate relationship between Astrand test results and maximal ergometry results (r=0.68 for rowers and r=0.56 for runners). Simple regression analysis pointed out statistically significant prediction of true VO2max based on the Astrand test results, but the shared variance turned out to be relatively low (R2=0.46 for rowers, R2=0.31 for runners). T-test results pointed out no statistically significant difference between Astrand and maximal ergometry results in both of the observed groups (p=.42 for rowers and p=.27 for runners), while stronger F-test proved otherwise (p=.00 rowers; p=.01 runners). Acquired results confirmed that Astrand test can not be considered an accurate test for evaluation of the aerobic capacity in recreational rowers and runners. For further research, it remains to be investigated can these results be translated to a broader population of the physically active men in their middle age.

FROM INTENTION TO ACTION: TOWARD PROFESSIONALISM IN TENNIS

Leitão, M.T., Bergamo, V.R., Loschi, L., Lemos, E., Campos, K.

ESEFJ/PUCC, Brazil

The practice of tennis is considerably increasing in Brazil, and many juvenile players have expressed intent to become pros. With the evolution of sports, other aspects have been exhaustively studied, and nevertheless the coaches seem not to be following that evolution, since factors like biomechanics, nutrition, injury prevention, or sports psychology are not receiving due attention. Research show that the number of juvenile players who give up sports during this complex transition phase is high, and they mention pressure with travel, training, ranking, injuries, and sponsors as reasons for giving up. It is true that players who aspire to this higher level need more training - at the risk of premature specialization as pointed out in some studies - but not all of those who engage in broader training as suggested become a professional. Other players do not train so much and do not reach a professional level. In order to investigate the type of training being offered at tennis clubs and academies, and if the players are also being prepared out of court, a questionnaire with 20 questions was submitted to 28 juvenile players of both sexes between 12 and 16 years of age, from Jundiai, Sao Paulo. Of the 28 subjects, 14 want to become pros, and the average training is two hours a day three times a week. None of them has psychological counseling with a specialist, 10 do not have nutritional counseling, 09 have a physical trainer, and none of the teachers use audiovisual aids in their training. They play an average of 03 tournaments per month, mostly at local and state level. When questioned about their weak and strong points in tennis, most of the answers were about technical aspects and 03 mentioned tactical and mental skills as weak points. Many of them said that they watch friends, opponents and professional players in order to improve. The results show that few of these juvenile players are having adequate out of court support to achieve their goals. Players 10 to 12 years of age should train with less intensity and frequency, and also play fewer tournaments; after 14 training may be adapted to the characteristics of this age group and to the demands of competitive sports. Besides the stress inherent to the game and the weariness resulting from playing more than once a day or during several hours, they need focus, motivation and emotional control, as well as good nutrition. While some players overtrain and give up before achieving their goals, others want to achieve them without training enough. We believe that training should be reconsidered and restructured, and new studies should be carried out so even if many of them do not become professionals, they continue to have adequate training and continue to play quality tennis during a long term, which helps them lead active and health lives.

THE DEVELOPMENT OF WOMEN'S BASKETBALL AFTER BALL SIZE REDUCTION: A STATISTICAL ANALYSIS OF PARTICIPATING PLAYERS OF 2003 AND 2005 EUROPEAN CHAMPIONSHIP AND CONSEQUENCES FOR THE TRAINING PROCEDURES

Ohanian, J., Michna, H.

Faculty of Sport Science Technical University Munich , Germany

Introduction:Changes of rules in sports were introduced to vitalize the game for spectators. Due to reduction in possession time in offence (Schmidt et. al., 2003) basketball already gained speed. 2004 a further change took place in european women's basketball, as the ball size was reduced to enhance game speed and create more offences.

The aim of this study is to determine whether the change of ball size had an effect on shooting quotas and overall offences (game speed) and to consider consequences for the training procedure.Methods:The detailed shooting quotas of 41 female players who participated in the 2003 and 2005 final round of the European Championship in Basketball were analysed using t-test for paired groups in order to discover significant changes in the shooting performance. The data were retrieved from FIBA. The detailed shooting performances (made shots, attempted shots and shooting percentage) of 2 point field goals (FG), 3 point shots (3 PtS) and free throws (FT) of 2003 were compared to those of 2005. In addition, ball handling skills such as assists, turnovers and steals were analysed. Results:
In 2005 the 2 point FG attempts as well as the number of assists, steals, turnovers and minutes played were significantly higher. The individual over all points and the point averages were higher in 2005. Although there are more attempts and made shots, the 2 point FG and 3 point quota went down in 2005. However, the FT quota increased in 2005.Conclusions:
Following up some interpretations on 2005's shooting quotas: The number of attempted shots is an indicator for overall offences. Hence, this significant increase in attempted shots in 2005 may be a consequence of the ball size reduction. A rise in shot attempts should lead to the detected increase in overall points and points on average. However the rise of playing time of these players along with their progression from 2003 to 2005 should also be considered. The fact that there are more made and attempted 2 and 3 point shots but a lower quota can be explained by the not yet fully adapted shot to the ball. Nevertheless, the increasing intensity on defence should also be discussed. The improved free throw quota in 2005 can be interpreted as a faster adaptation to the smaller ball of undisturbed shots than shots in motion and against opponents.The significant higher number of assists can be the result of adaptation to the ball since passing is easier with a smaller and lighter ball. However, dribbling and ball handling is more difficult. Thus both, turnovers and steals, have increased since these two parameter correlate. Consequences for training are as follows: the increased game speed can be enhanced by emphasizing fast break and offence transition. In order to adapt to the increase in defence intensity all shots should be performed in full speed and against opponents to create game like situations. References:

STUDY OF THE EFFECTS OF BRIEF AND LONG TERM OF STIMULATION METHOD IN THE KICK BOXING

Villani, R. 1,2+3, Tomasso, A. 1+3, Fratarcangeli, M. 1, Distaso, M. 1+3
1 TMA.Combat Sport, M.Sc.Faculty, Univ.Cassino, 2 IUSM Rome, 3 CSRSC Combat Sport Research, Italy

Introduction: In the kick boxing the speed of kick is a fundamental quality, but hard to train. The most interesting method of rapidity training is the stimulation one (Verchoshanskij) where a rapidity exercise is replaced by an "intense loading of strength".
We want to verify the methods effects in a brief and long term in a month of training.
Methods
The method of stimulation is based on the connection of two exercises: one general (squat 85%; 3 set X 4 reps; rec. 3 min) and one specific, the medium round kick executed with a backward leg position (3 set X 4 kicks, right and 4 left; rec. 1 min.) performed against the punching bag with the maximum explosive force (rec. squat-kicks: 4 m.)
This experiment was practised with twenty-two kick boxing trainees (age 17/30; w.60/88kg; h.168/185cm; practise: 2/7years) of different competitive levels (provincial and national).
All the athletes had to do a modified version of the SOK TEST (Villani et al.,2004) in which the time of execution of the kick (4 right, 4 left) was evaluated in both conditions of before and after the definite squat loading. The reliability of the testing was verified repeating the exercises in two following sessions (test-retest correlation).
Two uniform groups have been formed with athletes with a comparable quality both physical and technical:
11 athletes (experimental team), trained four weeks with the stimulation method;
11 athletes (control team) trained four weeks with a standard training: the squat session was executed an hour after the specific training with the punching bag.
After the training, the test was repeated to evaluate the effects of both training methods. We compared the pre-load and post-load test to study the short term method; we compared the SOK TEST results in both teams to study the long term method effects .
Results
The test reliability pointed out values of the r between 0,79 and 0,89 ($p<0,01$) for the round kick, in conditions of pre and post-load.
In the experimental team, the SOK TEST results improved in the evaluation of pre-training, while the control team decreased the improvement and not always was significant (20-28% vs. 10-14%). In the comparison of the SOK TEST results, before and after the squat, both teams had a higher speed of the execution of kicks after the overloading stimulation, but after the month of training, the experimental athletes team had a higher difference between the pre-squat and the post-squat test (from 11-15% to 19-21%); the control team didn't have such significant variations.
Discussion
The stimulation method applied to the kick boxing techniques can be considered an efficient system of training of speed and specific explosive force. The results indicate an increasing efficiency of the method proceeding with the training. Our future studies will evaluate these aspects on higher competitive level athletes

90S ALL-OUT TEST AND AEROBIC FITNESS IN CHILDREN

Dekerle, J., Williams, C.A., McGawley, K., Berthoin, S., Carter, H.
Unversity of Brighton, United Kingdom

The purpose of this study was to establish the validity of an all-out test for the estimation of the power associated with peak VO2 during a ramp test (P-VO2peak), and sub-maximal aerobic ability as represented by critical power (CP). Based on the 2-parameter CP concept, it was hypothesized that the power output at the end of the 90s test (EP) would correspond to CP due to a complete depletion of the anaerobic capacity. Seven active children (mean ± SD: 12.8 ± 0.3 years; 43.7 ± 10.9 kg) carried out a series of physiological performance trials: (i) an incremental ramp test to determine P-VO2peak; (ii) three tests to exhaustion to determine CP and (iii) a 90-s all-out isokinetic test to measure EP and end VO2. The VO2 at the end of the 90-s trial (2266 ± 485 mL.min-1) reached 92 to 106% of VO2peak (mean ± SD:

99 ± 5%). Mean ± 95% limits of agreement was equal to 40 ± 233 mL.min-1 giving limits of agreement of -194 to 273 mL.min-1. EP in the last 10-s (168 ± 44 W) was related to (r=0.91; SEE = 22 W; P=0.05) but was not significantly different from P-VO2peak (173 ± 42 W; P =0.75). Mean ± 95% limits of agreement was equal to 3 ± 38 W giving limits of agreement of -35 to 40W. These two variables were not statistically significantly different from CP (123 ± 24 W; P =0.05). CP was significantly correlated with EP (r=0.96; SEE = 16 W; P=0.01) and P-VO2peak (r=0.94; SEE = 16 W; P=0.02). In conclusion, VO2peak determined from a ramp test can be assessed from the performance of a 90s all-out test in children. While the end power of an all-out test is not different from and highly correlated with P-VO2peak, the level of agreement between the two variables is too high to use these variables interchangeably. Based on the 2-parameter CP concept, it could be concluded that 90s is not of sufficient duration to totally exhaust the anaerobic capacity in children. Further investigations are required to corroborate these findings, as the 90s all-out test seems a useful tool to assess aerobic and anaerobic potentials in children.

INFLUENCE OF EXERCISE DURATION ON RESTING HEART RATE VARIABILITY FOLLOWING EXERCISE IN ACTIVE WOMEN

James, D.V., Reynolds, L.J.

University of Gloucestershire, United Kingdom

INFLUENCE OF EXERCISE DURATION ON RESTING HEART RATE VARIABILITY FOLLOWING EXERCISE IN ACTIVE WOMEN

JAMES, D.V.B. AND REYNOLDS, L.J.

FACULTY OF SPORT, HEALTH & SOCIAL CARE, UNIVERSITY OF GLOUCESTERSHIRE, OXSTALLS CAMPUS, OXSTALLS LANE, GLOUCESTER, UK

Few studies have investigated the resting heart rate variability (HRV) response following a single exercise bout (James et al., 2002; Pober et al., 2004). The aim of the present study was to examine the influence of exercise duration on the 24 h post-exercise HRV response in active women.

Twelve active healthy women were recruited who undertook two conditions in a randomised order: a 20 min bout of walking (W20) and a 60 min bout of walking (W60). Walking was performed on a level motorised treadmill at 6.5 km.h-1. Participants visited the laboratory once prior to (-1 h) and twice following (+1 h; +24 h) the walking exercise interventions to allow determination of resting HRV. Participants also visited the laboratory prior to any testing for a familiarisation session. Resting determination of HRV involved participants sitting for 20 min whilst breathing at a controlled rate of 0.2 Hz. Successive R-R intervals were measured in the final 5 min using a heart rate monitor (Polar 810i) and transmitted telemetrically to a PC for storage. Time domain variables included average R-R interval (AVRR) and standard deviation of the R-R interval (SDRR) and frequency domain variables included total power (TP), low frequency (LF) power (0.04 – 0.16 Hz), high frequency (HF) power (0.16 – 0.24 Hz) and LF/HF ratio.

A significant (p = 0.05) interaction (condition x time) for AVRR was observed. AVRR was significantly higher (p = 0.017) at +1 h in W20 (889ms) compared with the W60 (832ms). A main effect for time (p = 0.056) was observed for SDRR in W60, with post-hoc tests revealing a significant increase between –1 h (51 ms) and + 1 h (65 ms). However, by +24 h, SDRR was not significantly elevated from the –1 h value. Similarly, a main effect for time (p = 0.047) was observed for LF power in W60, with post-hoc tests revealing a significant increase between –1 h (847 ms2) and + 1 h (1316 ms2). However, by +24 h, LF power was not significantly elevated from the –1 h value.

The main finding is that AVRR responded quicker (i.e., after 1 h) in W20. Coupled with the finding that LF power was not significantly increased after 1 h in W20, this suggests that in the short-term (+1 h) W20 confers a positive change in extending the R-R interval, without any change in LF power. Although W60 was able to induce an increase in SDRR after only 1 h, this change was associated with an increase in LF power.

GOAL SCORING PATTERNS OF THE GREEK NATIONAL SOCCER LEAGUE

Katis, A., Kati, F., Kellis, E.

Aristotle University of Thessaloniki, Greece

Introduction

The low frequency of goals scored during a soccer game compared to other team sports gives greater importance and value to each goal. Goal scoring pattern is defined as the time at which the goals are scored during a game (Abt et al., 2002). The purpose of the present study was to examine the goal scoring patterns of the Greek national soccer league.

Methods: Five seasons (2000-01 to 2004-05) of the Greek soccer league were totally analyzed. For each game, the time at which the goals were scored and the goal scoring technique which was used were recorded. A 90min game was divided into two 45min, six 15min and eighteen 5min time periods. Goals scored at the extra time of each half, goals scored per month and goals scored per place of playing were also analyzed. The kick, the heading, the free kick, the penalty and the owngoal were the goal scoring techniques which were further examined.

Results: In total, 2318 goals from 1804 games (1.28 per game) were totally analyzed. Chi-square analysis indicated a significant ($P < 0.01$) increase of goals scored at the second half. An upward trend was revealed across the 5 and 15min time periods. Significantly ($P < 0.01$) more goals were scored on May and at the home conducted games. The kick was the most effective goal scoring technique (67.08%), followed by heading (18.55%), penalties (8.33%), free kicks (4.06%) and owngoals (1.98%).

Discussion/Conclusion: The present results suggest that more goals were scored at the end of each half, at the home conducted games and at the last months of the league, while a significant number of goals were scored after the implementation of the regular time of each half. Similar results were reported for the Australian and the Scottish soccer league (Abt et al., 2002; Ekblom, 1994) and for the 14th World Soccer Cup (Jinshan et al., 1993).

ELABORATION OF A SPECIFIC TEST FOR THE EVALUATION OF PUNCHES FREQUENCY SPEED OF BOXING

Villani, R. 1,2+3, Tomasso, A. 1+3, Tucciarone, G. 1, Distaso, M. 1+3

1 TMA.Combat Sport, M.Sc.Faculty, Univ.Cassino, 2 IUSM Rome, 3 CSRSC Combat Sport Research, Italy

Introduction

The rapid execution of punches is a determining factor in order to excel in the sport of boxing and above all in amateur boxing,
A few authors studied the speed of action and the speed of frequency of the attack's combinations (Alonso & Lopez, 1983).
In order to observe the development of the frequency speed, we invented a new kind of specific test called FSP (Fre-quency Speed of Punch), a valid and economic test that allows us to study the speed of a simple combination (jab-cross) and the number of punches hitting the sack in defined unities of time.
Methods
To carry out the FSP test, we used a footboard with piezoelectric cells connected to a computer (ergotester Globus) and put around a boxing sack. The test had 3 procedures: jab-cross (speed of the single punch), number of punches in 5" (speed of frequency) and number of punches in 15" (resistance to the speed of frequency). The experimentation was tried on a group of 20 boxing athletes, sorted out from the age of 16 till the age of 33: 10 amateurs (non agonists) (weight 74±14, h 176±8) and 10 agonists (weight 65±9, h 175±9).
For the FSP jab-cross mode each athlete had to repeat the test for 3 times (and we considered just the best one), while for the other two modes (number of punches in 5" and in 15") we repeated the test just once. In FSP 15" we considered and observed the frequency of punches and the heart frequency (post-test recovery). In order to check the validity of the test itself, it has been repeated after 2 days (test-retest correlation).
To study the test validity and to verify the capacity of distinction among athletes of different level, we made a transverse comparison between the group of agonists and the group of amateurs.
Results
The results of the reliability of the test (test-retest) for the 3 modes in both groups, put in evidence values of r between 0,84 and 0,95 ($p<0,01$). The transverse comparison (validity study) put in evidence a greater speed of frequency in the group of agonists than in the amateurs. In fact the agonists had a 20% best result in the 5" and a 12% best result in 15" ($p<0,01$). In the jab-cross mode the difference was only of 5% ($p=0,47$ n.s.). Analyzing the rhythm of punches in FSP 15" we noticed a greater regularity in the agonists if compared to the amateurs. The agonists also resulted as the best in the post-test recovery of the heart frequency.
Conclusions
The FSP test resulted as a reliable test (test-retest correlation) and as a valid one (transverse comparison). As a conclu-sion, this test can be considered a valid means in order to obtain a precise and economical valuation of the frequency's speed of punches in the sport of boxing and in fighting sports in general. But, to obtain final conclusions is important to analyse with the FSP test also top level athletes. It will be the subject of our next study.

RELIABILITY AND VALIDITY OF AN ACCELEROMETER-BASED FOOT SENSOR IN RUNNING

Niessen, M., Hartmann, U., Laukkanen, R., Kinnunen, H.
Technical University Munich - Faculty of Sport Science, Germany

Novel innovative technologies provide tools to monitor continuous running velocity (vrun). For outdoor running purposes e.g. global-positioning systems (Witte & Wilson 2004, Terrier & Schutz 2005) have been developed. Accelerometer-based technology provides tools measuring acceleration or deceleration in both indoor and profiled outdoor terrain. Attached on top of one shoe, the sensor (FS) can determine distance and vrun based on frequency, length and height of strides. Aim of the study was to verify the reliability and validity of FS-technology under standardised laboratory conditions.
A group of 27 male (31±6 yrs, 181±6 cm, 78±7 kg) & 23 female (28±6 yrs, 167±5 cm, 59±5 kg), divided into low (VO2max: 49-53 ml/kg/min) and high fit (VO2max: 57-65 ml/kg/min) competitive endurance runners, completed pre & post training phase standardised maximal graded load tests (GLT 1 & 2) on a treadmill. Starting speed was 2 or 2.5 m/s, step duration 5 min, increase 0.5 m/s, rest 30 s and incline 1%. Before tests FS was calibrated running on a track for minimum 400 m with individual extensive vrun-intensity. Sensor data were memorised by running computer S625x (Polar Electro) with 12Hz. Maximum of 3 min data within each 5 min step were extracted. Descriptive and group-specific parametric statistics were applied.
Mean vrun results of 373 steps (n=12340 data points) showed a strong linearity (r=0.983, p≤0.001) between predicted and derived FS-vrun (2-5.5 m/s) for both GLTs. Underestimation in vrun as well as increased negative deviances of FS- compared to treadmill-vrun were found with risen speed (Δ: -0.1 m/s (2%) at 2 m/s; -0.3 m/s (5%) at 5 m/s). There was no significant difference between more or less fit endurance runners or genders. Individually slightest deviations were -0.2% to 0.6%. Paired t-tests pointed out high sig. diff. (p≤0.001) between GLT 1&2 vrun. In contrast to sig. (p≤0.01) deviations of predicted and derived vrun in GLT 1 for all steps, GLT 2 showed only low sig. diff. (p≤0.05) for two steps.
Familiarisation to FS, calibration modus as well as better running economy due to regular training leaded to more precisely vrun and definite lower intraindividual variances (-1.7 %) in GLT 2. Despite slight variations between runners and/or shoes there was a good reproducibility (<1% error) of vrun per step. Prospective including a categorisation of moderate, medium and high vrun zones into product software to better adjust a correcting factor for FS values would be needed. In summary accelerometer-based FS gave reliable instant vrun results under standardised conditions. Further field tests and real speed / distance comparisons on various in- & outdoor surfaces are necessary to verify suitability & accuracy of this technology in varying running terrains.

RELATIONSHIP BETWEEN MOTOR PERFORMANCE ABILITY AND PERCEIVED PHYSICAL STATES IN YOUNG ELITE SOCCER PLAYERS

Kornmayer, A., Steinbacher, A., Spitzenpfeil, P., Kleinert, J., Hartmann, U.
Technical University of Munich, Faculty of Sport Science, Germany

Introduction: The motor performance in soccer depends on different variables. Beside technical-tactical, coordinative to physical condition abilities as well as constitutional qualities, the mental parameters, like motivation, mood states also perceived physical states (PPS) play a determining role.

Within the project soccer interdisciplinary performance-diagnostics are carried out regularly for injury prophylaxis with young elite soccer players. Beside the motor performance ability and the physical comfort are collected in this study. Purpose of the study is to find out coherences between the PPS and objectively measured data of motor performance.

Methods

81 young elite soccer players (U17) of the highest German league were tested. After measuring the PPS (activity, fitness, flexibility and health) by the questionnaire Perceived Physical State (PEPS; Kleinert 2004), twelve physical performance variables were tested via the talent diagnostic system (TDS; Werthner 2000). By means of factor analysis four categories were built: speed (sprints of 0-10m, 10-20m and 0-20m), agility (shuttle run, steeplechase and slalom run), reaction (match, flash jump, rhythm run and drop jump) and jump strength (squat jump and counter movement jump). Nonparametric bivariate correlations (according to Spearman) have been used to determine the behaviour between the perceived physical state and the motor performance factors.

Results and Discussion

Over all analysis did not show significant results in all parameters for all players of all teams. However, a significant correlation of single factors appeared within single teams. The perceived activity showed a correlation with the factor speed (r = 0,54, p ? 0,05). This means the more actively the players have subjectively felt, the faster they were. Furthermore the factor agility correlates with the area perceived fitness (r = 0,60, p ? 0,05) which indicates that the sense of fitness resulted in better values of the shuttle run, steeplechase and slalom run.

Those first results show a possible assessment of physical performance abilities by psychological data. Are there any further variables which have an influence on the relation between the motor and the mental performance?

THE RELATIONSHIP BETWEEN EXERCISE INTENSITY AND TIME TO EXHAUSTION DURING SHORT INTERMITTENT RUNS: IMPACT OF EXERCISE BOUTS DURATION, CARDIORESPIRATORY FITNESS, EXPLOSIVE STRENGTH OF LOWER LIMBS

Buchheit, M., Pactat, F.

Laboratoire de Recherche Adaptations Réadaptations (APS et conduites motrices), France

The relationship between exercise intensity and time to exhaustion during short intermittent runs: impact of exercise bouts duration, cardiorespiratory fitness, explosive strength of lower limbs and anaerobic capacity.

Purpose: The purpose of this study was to use, during short intermittent runs, the slope of the time to exhaustion (TE) vs running intensity relationship as an index of intermittent endurance (IE), and to observe its association with exercise bouts duration, cardiorespiratory fitness, explosive strength of lower limbs and anaerobic capacity. Methods: 12 athletes (24.5 ± 4.1 yrs) took part in six maximal shuttle intermittent runs (100%-95%-90% of V30-15IFT [1] during 15 or 30sec, intersected with 15 (Int15) or 30sec (Int30) of passive recovery, respectively) on a synthetic track (40 m). Cardiorespiratory fitness was estimated by the V30-15IFT (VO2est). Explosive strength of lower limbs was evaluated in all subjects through counter movement jump (CMJ), drop jump (DJ), and 10m sprint time (10m). Anaerobic capacity was estimated by the MART test [2] that is aimed to provide maximal lactate production ([la]max). TE data was log-transformed and all calculations were adjusted on age and body mass index. Results: TE vs. running intensity relationship obtained with the three exercise sets for each subjects was linear for all (r = 0.98 ± 0.2 and r = 0.98 ± 0.2 for Int15 and Int30 respectively). Although TE was significantly higher during Int15 than during Int30 for all intensities, IE indexes did not differ between the two exercise conditions (6.7 ± 1.2 vs 7.1 ± 1.7 for Int15 and Int30). In Int15, IE was not related to VO2est or [la]max, but was negatively correlated with CMJ and DJ ($P<0.05$) and positively with 10m ($P<0.05$). Concerning Int30, IE was not related to VO2est, 10m or [la]max, but was positively associated with CMJ and DJ ($P<0.05$). Conclusions: cardiorespiratory fitness and anaerobic capacity may not constitute relevant predictors of IE during short intermittent runs. Explosive strength may have distinct incidences on IE, depending on exercise bouts duration. Although a high explosive strength level, often synonym of a limited peripheral oxidative background, may not be beneficial for a high IE during Int15, it could be hypothesized than during the Int30 with its longer runs, a higher explosive muscular fitness could help decreasing the energy cost of running and thus maintaining IE.

EFFECTS OF 6-WEEK RESISTANCE TRAINING PROGRAM USING "RESISTOGYM" ELASTICATED TUBING ON PHYSIOLOGICAL PERFORMANCE INDICES IN AMATEUR MALE SOCCER PLAYERS

Donne, B., McGowan, M.

Trinity College Dublin, Ireland

Resistance training (RT) plays a role in improving athletic performance by increasing muscular strength, power and speed, inducing hypertrophy, and improving local muscle endurance. Recently studies have investigated the effect of short-term RT using elasticated tubing in the elderly (Mikesky et al., 1994; Damush and Damush, 1999) and in collegiate tennis players (Treiber et al., 1998). Elasticated RT stresses single or multiple joints making exercises more functional, and facilitating training in a more effective weight bearing functional position. The aim of this study was to investigate if the addition of a simple six-week RT intervention using elasticated tubing (Resistogym Ltd.) at low/medium load and high repetitions would affect physiological indices relative to control.

Amateur male soccer players in mid-season training, resistance group (R: n=10, mass 83±11 kg, height 184±6 cm, body fat 19±4 %) and control group (C: n=7, mass 80±9 kg, height 182±8 cm, body fat 17±5 %) participated. C performed only standard soccer training and competitive matches; R supplemented their standard training and matches with a graded RT program 3 day.week-1 using low/medium

load and high repetitions. Each RT session consisted of repeated sets (2-3 sets of 15-20 reps) of 10 discrete lower limb exercises and was completed in approximately 45min. Aerobic, anaerobic and specific strength indices were assessed pre- and post-intervention. Data was analysed using a two factor ANOVA with time as the repeated measure, values of $P<0.05$ were considered statistically significant.

No significant intra-group differences in assessed variables were observed pre-training and no significant inter-group differences were observed in C following standard soccer training. However, significant improvements in maximum voluntary isometric force (682±49 vs. 797±47 N, $P<0.01$) and isometric endurance capacity (41.3±3.9 vs. 62.0±8.3 kN.s, $P<0.05$), vertical jump height (49.5±2.2 vs. 55.6±1.4 cm, $P<0.01$), standing broad jump (232±5 vs. 242±4 cm, $P<0.05$), 10 x 5m sprint agility data (14.8±3 vs. 14.3±3 s, $P<0.05$) and 20 MST performance (99±6 vs. 108±7 shuttles, $P<0.05$) were recorded following RT. In addition, RT had no significant negative effects on aerobic performance indices assessed during either an incremental treadmill test to volitional exhaustion (VO2 max, vVO2 and velocity at Dmax) or 12 min Cooper Run and no significant improvement in 30 or 50 m sprint velocities were observed.

In conclusion, a six-week RT program using low-cost elasticated tubing supplementing regular soccer training resulted in significant improvements in many of the performance indices assessed which could potentially benefit on-field soccer performance without the need for complex and expensive gym-based RT regimes.

EFFECT OF INITIAL PACING STRATEGY UPON 10-KM RUNNING PERFORMANCE

Edwards, B.J., Currell, K., Waterhouse, J., Atkinson, G.

Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, United Kingdom

Pacing strategies have been found to influence athletic performance in a number of events. However, few researchers have investigated the effects on overall time taken of manipulating pace, especially during the first part of the event. Purpose: We examined the effect upon overall performance of three enforced pacing strategies during the first 3 km of a 10-km run. Methods: Eight male participants completed two initial trials at a self-selected pace. The mean running speed was then used to calculate the enforced pacing strategy for the first 3 km. The pacing strategies were "fast" (velocity 5% above the mean), "slow" (5% below the mean) and "even" (equal to the mean); the last 7 km were run as quickly as possible. Ratings of perceived exertion (RPE), split times and heart rate were recorded every km, and stride length and frequency were measured at 2, 5 and 8 km. Haemoglobin, haematocrit and blood lactate were measured before and after the runs, as was time taken to complete them. Results: A significant effect was found for times to completion (fast trial 2747 ± 598 vs even trial 2796 ± 629 vs slow trial 2851 ± 601 s respectively; $P<0.05$), with the "fast" trial being faster than the "slow" ($P<0.05$) but no difference between slow and even trial ($P>0.05$). Split times and RPE showed significant effects of the pacing intervention ($P<0.01$) and significant interactions between pacing intervention and distance ($P<0.01$). No significant effects of pacing intervention were observed for the other variables. A 5% increase in running velocity during the first 3-km of a 10-km running time-trial led to an improved overall performance, with ~90% of this improvement explained by the first 3-km. Conclusion: It was concluded that a sustained aggressive approach in the early stages of a 10-km run would be of overall benefit to performance.

THE INFLUENCE OF STRENGTH TRAINING IN ISOKINETIC STRENGTH AND IN THE PERFORMANCE OF SOCCER PLAYERS IN JUMP, SPRINT AND AGILITY TESTS

Alves, J., Rebelo, A.

Faculdade de Desporto - Universidade do Porto, Portugal

The purpose of this study was to analyse the effect of a strength training program in isokinetic strength and in the performance in physical actions involved in soccer: jump (Squat Jump), sprint (5 and 15 meters velocity) and agility ("505" test).

Twenty three young elite Portuguese soccer players (average age: 17, 36±0, 57 years) were divided in three groups: two experimental groups (G1, n=9, e G2, n=8) and a control group (G3, n=6). G1 and G2 have done the strength training program. The average weekly training sessions were one session for G1 and two sessions for G2. Besides the strength training program, G1 and G2 have performed their regular soccer training program. G3 has kept their regular soccer training program.

After the strength training program the following results were mostly observed: i) an increase in the average of peak torque (PT) and in the average power (AP) of G2 on knee extension at 90°.s-1 and 360°.s-1 ($p<0,05$); ii) a reduction of the sprint times over 5 and 15 meters for G1 and G2 (9,17% and 6,19% for G1 and 7,03% and 3,11%, for G2; $p<0,05$); iii) an increase on Squat Jump for both groups (12,6% for G1 and 9,63% for G2; $p<0,05$).

The training program was effective to increase the PT and AP only in group G2, which was submitted to a frequency of training sessions of two sessions per week. The increasing perfomance observed on jump and sprint tests after the strength training program didn't reveal being statistically influenced by the number of weekly training sessions used (one or two sessions/week).

20-HZ WHOLE BODY VIBRATION TRAINING FAILS TO COUNTERACT THE DECREASE IN LEG MUSCLE VOLUME INDUCED BY 14 DAYS OF 6° HEAD DOWN TILT BED REST

Zange, J., Liphardt, A.M., Müller, K., Mester, J.

DLR, German Aerospace Center, Germany

Atrophy of leg muscles caused by long term unloading is still a major health problem in the scope of human space flight. Training countermeasures currently performed in space can only partially conserve muscle volume and strength. A common model to study the effects of space flight conditions on leg muscle is a permanent 6° head down tilt (HDT) bed rest.

Vibration training (VT) has been shown to improve muscle performance in training studies with little time effort per day. Thus, it was hypothesized that VT could be a potential measure to counteract the negative responses of human body to bed rest. This abstract focuses on leg muscle volume. In a cross-over design 8 healthy male subjects (78.1 ± 9.5 kg; 179 ± 9.6 cm, 26 ± 5 years) took part in two study phases in the metabolic ward of the DLR-Institute of Aerospace Medicine. Study phases were divided into a 4-days adaptation period, a 14-days intervention period in 6°- HDT bed rest, and a 5-days recovery period. During bed rest each subject performed either VT or the control intervention. VT was performed twice daily on a Galileo 900 vibration plate (20 Hz / 2-4 mm). Subjects walked a defined

distance to the plate and performed 5 intervals of 1 min vibration in an upright standing position with 30° knee angle and 15% body weight extra load interrupted by 1 min sitting. The control intervention included exactly the same procedure except the vibration plate was not turned on. Subjects were mobile in the adaptation period and the recovery period. Both study phases were identical with respect to environmental conditions, study protocol and diet. At day 4 of the adaptation phase and at day 1 after bed rest muscle volumes in upper and lower legs were determined using magnetic resonance images recorded at 1.5 Tesla. Axial images showed a pixel resolution of 0.78 mm x 0.78 mm. Two sets of stacked slices without inter slice distance were recorded from the upper and the lower leg each over a distance of 20 to 25 cm. Before measurements subjects laid for minimum 20 min in horizontal position to allow a sufficient equilibrium of blood volume. The feet were kept at an angle of 90°. Bed rest combined with control intervention caused a significant ($P<0.05$) decrease in muscle volume in all examined muscle groups. The relative changes for the sum of muscles in both legs was -5.6 ± 1.9% in m. quadriceps, -4.3 ± 2.0 % for the hamstrings (m. biceps femoris + m. semimembranosus + m. semitendinosus), -6.5 ± 2.0 % for the m. triceps surae, and -3.6 ± 2.9 % for the m. tibialis anterior. Vibration training failed to cause a significant reduction in the volume loss of any examined muscle. Instead the volume reduction was significantly amplified by VT in the hamstrings (-6.2 ± 1.2 %, $P<0.05$). Whole body vibration at 20 Hz combined with an isometric loading at body weight + 15% failed to counteract leg muscle atrophy induced by 14 days 6°-HDT bed rest.

STUDY ON THE IMPROVEMENT OF TAKE OFF HEIGHT IN 13-14 YEARS OLD GIRLS AND 14-15 YEARS OLD BOYS

Gloria, R., Bogdan, R., Marinela, R., Gheorghe, B.

Universyti of Bacau, Romania

Starting from the hypothesis that going through a training program of localized physical exercise, which would use certain muscular groups, improves the vertical leap (the height of vertical take off) over the level of normal development, we have initiated an experiment. The experiment was organized on two groups: an experiment group and a witness group, and each group was formed of 12 girls (6 of 13 years old and 6 of 14 years old) and 12 boys (6 of 14 years old and 6 of 15 years old). The work methodology relied on performing a training system for 10 weeks. During the first and the last week control tests were held: drap jump (jump/100 in depth from 40 cm followed by a quick take off), countermovement jump (vertical jump preceded by quick flexion), squat jumps (vertical jumps from a semiflexed position) and 15 consecutive jumps. During the 8 weeks, they followed a training program made of exercises localized at ankle, knee and hip level and global training exercises. The means were used in an approach from easy to difficult, in a structure of three training sessions a week. The results analysis pointed out the value evolution for: unitary strength, take off height, repetition speed, the duration of ground time, the duration of air time, and take off power. Comparing the increases of the three jump types, we can notice that the best progress was achieved in drap jump of 3.9 cm and the lowest in countermovement jump of 3 cm. The conclusions point out significant increases for the experiment group, over the normal limits that were registered for the witness group. We also underline that the progress made is due to the specific work, localized with simple plyometric-type means, with light loads; to the usage of pendular balance which led to the increase of the bi-articular muscle strength; and to the improvement of performing manner to the nervous command at the level of the motor unit. The differences among the four jump types are bigger from the dynamic movement to the static.

STROKE QUALITY WITH YOUTHFUL CADRE PLAYERS OF THE INTERNATIONAL TOP CLASS IN TENNIS

Pieper, S., Denke, I., Weber, K.

Institute of Movement Science for Games in Sport , Germany

Introduction: The modern elite tennis has developed in last decades to a faster play. Thus, for instance, advancements of the stroke technique, the athletics and the racquet material cause a clear increase of the stroke velocity. The following contribution shows the diagnostics of stroke velocity and precision of cadre tennis players of the youth world rankings. Ones, the stroke quality were measured by service, forehand and backhand winner. To the other the influence from this was examined on the ranking list position.

Method: To the analysis of the quality of winners and service a total of 33 participants are at the age of 13 to 14 years (height 172±7.3 cms; BMI 20±1.8 kg/m²) diagnoses of the international Tennis Youngsters Cup in Cologne by means of a test battery to the stroke velocity. The test protocol exists of a service, forehand and backhand winner test. The passing with the winner test occurs through a ball throw machine. This was placed on the T-line. For the test realization all balls should be hit at high velocity on target fields.

Results: The service speed of the youngsters lies between 140 and 190 km/h (156±11 km/h). The players reach a strokes rate for the respective service field from 28%. In the forehand winner test the cadre players show a maximum stroke velocity from 113 to 151 km/h (135±9 km/h). On this occasion, they place possibly every third stroke in the field and everybody fourth on the target field. Besides, the stroke hardness of the backhand from 115 to 142 km/h (128±6 km/h) is slightly lower; indeed, the precision rises in comparison to forehand by 15%. The maximum service speeds (S) show in the ranking list comparison (R) no test-statistical differences ($p=.064$) (SR12-62 168±13 km/h; SR81-197 157±9 km/h; SR206-627 162±9 km/h). With the forehand winner (FH) merely significant differences appear in the stroke precision (target) between FHR12-62 35±15 and FHR206-627 19±10. With regard to the height (H) the maximum service speed differs high significantly (SH≥1.75 171±12 km/h; SH 1.70-1.74 160±8 km/h; SH≤1.69 156±9 km/h). Nevertheless, the forehand ($p=.708$) and backhand ($p=.137$) remain uninfluenced by the height.

Conclusion: The study shows that the stamping degree of the stroke quality takes in particular the stroke velocity already with youthful cadre athletes in the international top tennis a high meaning. As already in early works (Ferrauti and Weber 2000) shown, the service speed of the present study also shows a bigger connection to the ranking on than the forehand velocity. Hence, the stroke velocity should be coached in the training intensively in combination with an improvement of the stroke technique (intra-and intramuscular coordination) as well as the behaviour (e.g. Return) by fast or hard strokes forced.

EFFECTS OF DIFFERENT BODY POSITIONS ON BIOELECTRICAL IMPEDANCE ANALYSIS

Knuth, S., Yue, Z., Mester, J.

Institute of Training Science and Sport Informatics, Germany

Introduction

Bioelectrical impedance analysis (BIA) is a widely used method to assess body composition. Recently, there are several automatic devices available which can be simply used for daily measurements. To get accurate and reproducible assessments, it is necessary to standardize the measurements of BIA. Several factors, such as fluid balance of the body, physical exercise and the stage of menstrual cycle, have

been proved to affect the measurements of BIA. The goal of the present study was to analyze the possible influences of different positions of the arms or the legs on the measured values of the whole body and segmental composition.

Methods

Eight healthy subjects (age: 30.0 ± 5.5 years, height: 173.4 ± 7.2 cm, body weight: 69.2 ± 12.5 kg) participated in this study. The subjects carried out three trials with four different body positions on a BIA single-frequency scale (TANITA BC 418 MA, TANITA Europe GmbH, Sindelfingen, Germany), which had eight pressure-contact electrodes. Four stainless steel foot pad electrodes were fixed on the weighing platform to connect to the toes and heels respectively. Another four electrodes were fixed on the two handles to connect to the finger tips and the palms respectively. Thus, different connections of the voltmeter would allow the measurements of impedance of either the whole body or of a body segment (left or right leg, left or right arm). The four different body positions were: normal upright position (N), position 1 (P1) with arms stretched horizontally from the trunk, position 2 (P2) with arms in a 90° angle und position 3 (P3) with arms stretched parallel to the trunk and bended knees.

Results

The results of the whole-body impedance showed significant differences between position N and positions 2/3 as well as among positions 1 to 3. However, there was no significant difference between position N and P1. The body segment impedances showed significant differences in the arms and legs depending on body position. Generally speaking, the impedance tended to be overestimated by P1 and underestimated by P2 and P3, compared to position N.

Conclusions

Significantly different values of impedance for different body positions were obtained in the present study, suggesting that it is necessary to standardize the body position in order to get reliable results. The normal position is the standing position with arms stretched alongside the trunk. Changes from that position can, besides other variables such as ingestion of food or exhaustive exercise, lead to over- or underestimated values of impedance.

BIOELECTRICAL IMPEDANCE ANALYSES: RELIABILITY OF THREE DIFFERENT SCALES

Knuth, S., Yue, Z., Mester, J.

Institute of Training Science and Sport Informatics, Germany

Introduction

To measure the body composition is of vital importance in elite sport and for health purposes. The body weight is used particularly e.g. for the determination of the relative performance or the relative maximal oxygen uptake. Even minor changes in body composition may affect performance. Thus the accuracy of a measurement is important. There is a set of methods to determine the body composition (dual-energy x-ray absorptiometry (DEXA), underwater weighting (UWW), skinfold measure). Besides intricate lab techniques bioelectrical impedance analyses (BIA) are used widely although these methods are often criticized with respect to accuracy.

Three different BIA scales are used in the study. The purpose of the study was to investigate the reliability of the three scales.

Methods

Nineteen subjects (age: 28.3 ± 8.9yrs, height: 172.3 ± 5.5cm, body weight: 64.1 ± 6.6kg) participated in this study. They carried out five trials in the morning and in the evening on three different scales (scale 1: BC 418MA, scale 2: BF 576 (both: TANITA Europe GmbH, Germany), scale 3: CS-25, CURAmed GmbH, Germany). The devices using BIA and are equipped with eight (scale 1) respectively four (scale 2/3) electrodes. Four stainless steel foot pad electrodes, two for toe and heel each, and two handles with additional four electrodes for the hands (scale 1 only) are integrated to measure impedance. Measured parameters were body weight and body fat.

Results

The correlations of the five trials showed very high reliability coefficients for all three scales. For body weight the reliability coefficient of the five trials was 1.0 each on all three scales. The mean correlation coefficient of body fat was 0.996 for scale 1, 1.0 for scale 2 and 0.998 for scale 3. On scale 1 the correlation coefficient of impedance reached 0.994. The comparison of the five trials for the body weight, body fat and impedance (scale 1 only) with repeated measures ANOVA showed no significant differences.

Conclusions

The measurements of three scales point out high correlation coefficients for body weight and body fat. Non-significant mean differences between the five trials underline these results. This leads to the assumption that the scales appear to be reliable. The results align with several investigations, where test-retest-reliabilities for body fat between 0.957 and 0.999 were found. Also surveys for validity of BIA with DEXA (r=0.91-0.94) or UWW (r=0.71-0.81) as reference show similarly strong results. Due to the high reliability of BIA these method seems to be suited notably for intra-individual measurements.

VARIATION IN BODY STRUCTURE, AEROBIC/ANAEROBIC FITNESS AND MATURATIONAL STATUS OF FEMALE PORTUGUESE SWIMMERS 12-13 YEARS

Figueiredo, A., Coelho e Silva, M., Ribeiro, L., Rama, L., Peña Reyes, M., Malina, R.M.

University of Coimbra, Portugal

The present study considers the growth and maturity status and performance profile of Portuguese female swimmers 12-13 years of age. The total sample (T) included 25 swimmers classified as local (n=17, L) and elite (n=8, E) level competitors. Somatic characteristics included the dimensions needed to estimate somatotype (Carter & Heath, 1990) and the androgyny index (Tanner et al., 1951). Aerobic and anaerobic performances were assessed with the 30-minute freestyle swim test (Olbrecht et al, 1985) and the 6x50-meter swim test (Cazorla,

1989), respectively. The latter provides the fastest and slowest trials and a mean time. Since the intermittent test was not performed on the same style, time-scores were converted to FINA short course point scores. Hand-wrist radiographs were taken and skeletal age (SA) was assessed with the FELS method (Roche et al., 1988). Chronological age (CA) was subtracted from SA to provide an indication of maturity status (Malina et al., 2004). In addition to descriptive statistics, comparisons between local and elite swimmers were made with the significance level set at 0.05. Mean CA was 13.0±0.5 years and mean SA was 13.5±1.2 years, and there were no differences between the two groups of swimmers. There also was no difference in maturity categories: local, 1 late (delayed), 11 on time, and 5 early (advanced); elite, 1 late, 5 on time, 2 early. There was no difference between groups for weight; the mean (T: 48.6 kg) was between the 50th and 75th percentiles of US reference data. However, elite swimmers were taller (E: 161.7 cm, circa 75th percentile; L: 156.4 cm, just below the 50th percentile). Elite swimmers were leaner with a lower sum of skinfolds (E: 39 mm; L: 58 mm), but there was no difference between the groups in the androgyny index (T: 76.7). Mean somatotypes were 4.7-3.3-3.2 (balanced endomorph) for local competitors and 3.1-3.9-3.4 (central) for elite swimmers. Elite swimmers attained better performances in the aerobic (E: 2092 m; L: 1636 m) and anaerobic (E: 374 points, L: 244 points – best sprint; E: 347 points, L: 210 points – mean of 6 trials) protocols. In conclusion, elite and local level female swimmers do not differ in skeletal maturation and body weight, but the former are taller and leaner, and attain better aerobic and anaerobic performances.

TWO-YEAR STABILITY AND IN-FIELD RELIABILITY OF FUNCTIONAL CAPACITIES AND SOCCER SKILLS AMONG YOUTH SOCCER PLAYERS

Figueiredo, A., Coelho e Silva, M., Malina, R.M.

University of Coimbra, Portugal

The purpose of the study was to examine the stability and reliability of tests of functional capacities and soccer skills among young soccer players over a two year period. The sample consisted of 44 male soccer players who were measured and tested on three occasions at 11.6±0.3 (M1), 12.6±0.3 (M2) and 13.6±0.3 (M3) years, respectively. Tests of functional capacities included the 10x5-meter agility shuttle run, vertical jump (squat and counter-movement protocols using an ergo jump), 7x34-meter sprint shuttle run (anaerobic, Bangsbo, 1994), YO-YO intermittent endurance shuttle run - level 1 (Bangsbo, 1994). Tests of soccer-related manipulative skills were ball control with the body, dribbling speed and shooting accuracy (Portuguese Soccer Federation, 1986) and passing accuracy (Kirkendall et al., 1987). Inter-year correlations (M1-M2; M2-M3, M1-M3, respectively) for the functional indicators were moderate to moderately high for the yo-yo test: (0.75, 0.87, 0.64), mean sprint (0.69, 0.68, 0.74) and squat jump (0.64, 0.59, 0.54); moderate to low for the fastest sprint (0.42, 0.52, 0.58) and counter-movement jump (0.45, 0.32, 0.46), low for the fatigue index based on the 7x34-meter sprint (0.31, 0.14, 0.13, and variable for the agility test (0.37, 0.70, 0.15). Corresponding inter-year correlations for soccer skills were, respectively, moderate to moderately high for ball control with the body (0.81, 0.71, 0.58), dribbling speed (0.81, 0.69, 0.84), and passing accuracy (0.64, 0.63, 0.55); and moderate to low for shooting accuracy (0.58, 0.36, 0.17). Inter-age correlations were generally lowest across the two year interval (M1-M3), although the trend varied among tests. Coefficients of reliability (%) in M1, M2 and M3 were moderately high: yo-yo (83, 88, 86), fastest sprint (83, 81, 83), mean sprint (82, 88, 89), fatigue index (81, 82, 79), squat jump (77, 83, 71), counter-movement jump (85, 87, 82), agility shuttle run (80, 84, 83), ball control with the body (82, 77, 80), dribbling speed (76, 74, 89), passing accuracy (73, 83, 73) and shooting accuracy (70, 71, 71). With few exceptions, the indicators of functional capacity and soccer skill were generally stable and quite reliable over the two year interval.

REGULARITIES OF THE ATTACK DEPENDING ON RECEPTION AND SETTING ZONE:

Mesquita, I., Afonso, J.

Faculty of Sport -University of Porto, Portugal

The purpose of this study was to establish associations between attack patterns and reception and setting zones, and it used a sample of four national volleyball teams integrating an intercontinental pole in the 2001 World League – Portugal, Japan, Cuba, and Yugoslavia. Two matches per team were analyzed, totalizing eight games, 25 sets and 549 game sequences. The variables were the zones of reception, setting and attack. Descriptive and inferential statistics were used, namely the Chi-Square, in order to test the association between variables. For all the variables, the agreements percentage was above 80%.

The present study has shown that the most common reception zones were 1, 5 and 6, being zone 2-3 the most common setting zone for side-out, and out of zone 2-3 the most common in transition. The most solicited zone in attack was zone 4, especially with the setting zone being out of 2-3. The middle attack had reduced expression with sets performed out of zone 2-3. Receptions from zones 1 and 3 make the construction of the attack difficult by zone 3, and the receptions from zone 2 drastically reduce the number of attacks by zones 1 and 2, revealing the attack construction by the central and left zone of the net.

PERFORMANCE PREDICTING FACTORS DURING PROLONGED NON-STEADY STATE CYCLING

Laaksonen, M.S., Björklund, G.B., Pettersson, S., Schagatay, E.

National Winter Sport Center, Mid Sweden University, Sweden

The work intensity during road cycling competitions involves periods of extremely high but also relatively low work intensities (e.g. Fernandez et al. 2000). However, only few studies have evaluated the physiology behind a non-steady state exercise pattern (e.g. Ekelund & Holmgren 1964; Bot & Hollander 2000). Although there are several possible tests that could predict performance in endurance sports, few of these tests takes into account the variability of workload.

Therefore, the purpose of the present study was to examine to prognostic value of blood lactate (La), respiratory exchange ratio (RER) and heart rate (HR) during non-steady state prolonged exercise (NSS). Eight male cyclist (age 26 (4) yrs; VO2max 4.7 (0.5) L min-1; BMI 22.5 (1.8) kg m-2) performed first maximal ramp test to establish the maximal aerobic power (VO2max) and power output (Wmax). After 24-48 hrs the subjects performed NSS-test which consisted of six high intense (HI) workloads at 90% of VO2max for 3-min each, interspersed by five middle intense (MI) workloads at 70% of VO2max for 6-min each. During the NSS test blood lactate (La) concentration, respiratory exchange ratio (RER), oxygen uptake (VO2) and heart rate (HR) were measured.

VO2 during MI and HI workloads were 3.4 (0.4) L min-1 and 4.2 (0.4) L min-1, respectively, and were kept stable with no difference between workloads ($p>0.05$). RER and HR increased when exercise load switched form MI to HI. However, only RER decreased when exercise mode shifted from MI to HI ($p<0.05$). La concentration increased also for each transition from MI to HI ($p<0.05$). During the first HI La was 2.8 (1.3) mmol L-1 and increased by 110%, 140% and 170% during the consecutive three HI workloads. During the first MI La was 3.3 (1.6) mmol L-1 but large individual differences were observed. HR, RER or VO2 responses were not associated with the time to exhaustion during NSS test. However, the changes in La concentration from the first HI to the first MI workload correlated inversely with the time to exhaustion during NSS test ($r = -0.714$; $p = 0.047$).

These results indicate that the magnitude of decrease in La concentration between the first high intensity workload and the consecutive middle intense workload could be a predictor for performance during prolonged non-steady state exercise.

THE EFFICACY OF A GENERAL PHYSICAL CONDITIONING PROGRAMME ON GREEK CADETS' PERFORMANCE CAPACITY

Havenetidis, K., Paxinos, T., Kardaris, D.

Hellenic Army Academy, Greece

Introduction

The Hellenic Army Academy, as other Military academies across the world, comprises a general conditioning programme, aiming the improvement of 1st Grade cadets' physical condition. The purpose of this study was to test the efficiency of this physical training programme by evaluating various physiological parameters pre and post its application on male and female cadets.

Methods

A total number of 60 cadets (43 males and 17 females) recruited from the Hellenic Army Academy, participated in the present study. For male cadets average ± SD values for age, height, body mass and body fat percentage were 19.1±0.7 years, 174.9±6.0 cm, 72.8±9.6 and 13.2±4.9 respectively. For female cadets average ± SD values for age, height, body mass and body fat percentage were 19.5±1.8 years, 163.3±6.5 cm, 64.7±8.9 and 23.5±4.6 respectively. All cadets followed a 16-week physical conditioning programme combining callisthenics, strength (body mass bearing exercises) and endurance (running and swimming) exercises for 90 minutes per day 3 times a week. Prior and post this training period the following evaluations were performed:

- Flexibility: using the sit and reach test (SRT)
- Leg muscle power: using the Standing Jump (SJ), the Counter Movement Jump without (CMJ) and with arm movement (CMJA).
- Cardiovascular Fitness: using the 20m shuttle run test and predicting maximum oxygen uptake (VO2max)
- Pulmonary functions: using a hand held spirometer and measuring Forced Expired volume in one second (FEV1), Forced Vital Capacity (FVC) and FEV1/FVC ratio
- Body composition: using bioelectrical impedance and estimating body fat (BF)
- Upper muscle endurance: using the Bench Press Endurance Test (BPET)
- Hand maximal strength: using hand dynamometry for Dominant (DOM) and Non-Dominant hand (NDOM)

Results

Male cadets (post versus pre training) improved on (FEV1; $p<0.01$) 3.7±0.6 versus 3.5±0.6 litres, (FEV1/FVC ratio; $p<0.05$) 0.8±0.1 versus 0.8±0.1, (SJ; $p<0.01$) 30.3±4.2 versus 28.9±4 (CMJ; $p<0.001$) 31.4±4.5 versus 34.5±4.7 (CMJA; $p<0.001$) 37.2±5.3 versus 34.5±4.7 (VO2max; $P<0.001$) 52.1±3.7 versus 48.0±5.7 ml/kg/min, (BF; $p<0.001$) 10.1±4.6 versus 13.2±4.9%, (SRT; $p<0.05$) 38.9±7.7 versus 25.5±8.9 cm, (BPET; $p<0.001$) 30.7±10.1 versus 24.0±9.3 repetitions, (DOM; $p<0.01$) 42.0±7.2 versus 39.6±9.5kg and (NDOM; $p<0.05$) 40.0±6.1 versus 38.8±7.0kg respectively. In contrast, female cadets presented an improvement only in (BF; $p<0.001$) 20.0±3.8 versus 23.4±4.5%, (BPET; $p<0.05$) 54.4±18.9 versus 47.8±16.0 repetitions, (SJ; $p<0.05$) 23.8±3.7 versus 21.6±3.2 and (VO2max; $P<0.001$) 44.6±6.2 versus 41.8±6.2 ml/kg/min respectively.

Discussion/Conclusion

The present results suggest that the current physical conditioning programme is effective on both performance (cardiovascular fitness and strength) and health related parameters (body composition) which comprise Greek cadets' physical capacity.

ORGANIZATIONAL BASIS OF RATIONAL LONG-TERM PREPARATION SYSTEM

Shynkaruk, O.

National University of Physical Education and Sport of Ukraine, Ukraine

Introduction. Optimization of the Youth sport system in country on the basis of up-to-date science and world practice data is one of the most important reserves of increasing of effectiveness of the Olympic preparation. One of the main problems of the Ukrainian Olympic sports is work with the sport reserve, insufficient intensive supplement of national teams with young perspective athletes, and as a result, big number of athletes, which don't have real future for achieving high results on the Olympic arena, there.

Material and Methods. Analysis of the scientific literature and official documents, questioning, statistic methods were used in the work.

Findings. It is very important not only to optimize organizational structure, but to provide implementation of some positions during formation of the organizational basis of rational long-term preparation system at its different stages – in national teams, future and perspective reserve. First position is to put equal attention to all organizational structures, to all stages of long-term preparation process, concerning staff, scientific-methodological and medical supplement. Concentration attention on the main staff of the national team and neglecting work with future and perspective reserve will negatively result in effectiveness of the Olympic preparation.

Second position concerns the provision of the optimal disposition of the quantity of participant at different stages of the long-term preparation process, which is oriented on the constant outflow of the perspectless athletes during this process and inflow of the perspective youth.

Third item is about methodics of the long-term sport preparation. Rational methodics is mostly defined with the organizational basis, such as positions about different organizations, in which the long-term sports preparation is conducted, their programs and academic plans, criteria of the effectiveness of the coaches' work with the Olympic athletes at various stages of the preparation, and so on.

Conclusions. That's why it is urgently important to connect the organizational aspects of the national teams' preparation, their future and perspective reserve with the regularities of the rational long-term preparation process. Imperfection of the organizational basis of the long-term preparation system, fault criteria of evaluation of effectiveness of the coaches' work, engaged in youth sport, irrational sports calendar at different stages of the long-term preparation might negatively influence at the effectiveness of the sport reserve preparation.

GENERAL THEORY OF ATHLETE PREPARATION IN OLYMPIC SPORTS AND METHODOLOGICAL ASPECTS OF ITS BUILDING-UP

Platonov, V.

National University of Ukraine on Physical Education and Sport, Ukraine

Intensive and versatile activities of several generations of specialists have led to formation of a complicated and integral system of knowledge in the field of athlete preparation theory which at present has got quite a comprehensive and full mounting as an independent teaching and scientific discipline. Applied disciplines (morphology, physiology, biochemistry, psychology, sociology, organization and management etc) and some general science disciplines and theories (cybernetics, operation researches, adaptation theory, functional systems theory, a systematic approach and the like) played a significant role in its formation. Finally this allowed formulating a theory of athlete preparation as an integrative theory of an analytic-synthetic character but not a collective one. The process of integration of biological knowledge into general theory of athlete preparation should be considered as bilateral. It is hard to say whom the priority belongs here. Specialists in an area of general theory preparation, who made an appreciable contribution in its development, build up their activities on understanding of organic interrelation of sportive-pedagogical material with the knowledge from applied disciplines of biological cycle. The representatives of sport-relating medical-biological disciplines conducted their researches proceeding from the tasks of sport practice and development directions in general theory of athlete preparation. Absence of strict formalization of knowledge in a field of athlete preparation theory supported by a wide application of mathematical apparatus in a give case is a reflection not a weak elaboration of the theory as it is sometimes seen but its extraordinary complexity. Theory of athlete preparation can be formalized neither in full, nor in its generalized parts, that however does not exclude a possibility of quite a hard formalization of separate elements of theoretical knowledge including mathematical ones. Important methodological moment of modern knowledge system construction in an area of athlete training is an application of systematic-integral approach where it is not typical to study one-side connections but such interrelations and interconnections between different knowledge elements when there not only integral qualities of the system are defined by the contents of knowledge about separate sub-systems, chains, elements, but in its turn the nature of the latter depends on the qualities of the whole system. That is why when forming the athlete preparation theory there are two aspects of full knowledge vision – systematic and elementary, which are so interconnected that a definite interpretation of one of them leads to a strictly definite interpretation of the other. Finally a system of knowledge acquires new qualitative characteristics, and new necessary prerequisites are created for implementation of theoretical knowledge into practice.

THE CHARACTERISTIC OF RELATIONS BETWEEN TRAINING EFFORT AND THE LEVEL OF AEROBIC CAPACITY IN YOUNG FOOTBALL PLAYERS

Szmatlan-Gabrys, U., Bakalarski, W., Gabrys, T.

Academy of Physical Education in Warsaw, Poland, Poland

Introduction. The main objective of training sessions is to obtain changes in the level of organism adaptation to the effort which is required from a player during a sport contest by applying strains [Reilly, 2005, D'Ottavio, Castagna 2002]. The objective of this research was to determine the impact of training effort on the level of aerobic capacity in 16-17 year-old football players.

Material and methods. 30 16-17 year-old players (body weight 65,23±7,03 kilos body height 173,8±7,36cm) were subjected to tests carried out during a 6-month training period (3-month periods:preparatory and starting one). VO2max, VO2AT, HRmax and HRAT were determined during a progressive test on a treadmill Saturn(HP Cosmos). During traning sessions the level of HR was monitored using a Polar Team monitor (Polar). 4 zones of strain intensity described by HR were determined, defined by %VO2max(Borg 1986): VHI very high (86-100%); HI–high(76-85%); MI–average(51-75%); LI-low(31-50%); AR an active regeneration (15-30%). The rank correlation analysis was applied in order to determine correlations between the level of oxygen function and the magnitude of training strain. The results of research were drawn by Statistica(StatSoft). Financed by MNiI AWF DS.53

Results. The effort increase in the AR zone during preparatory period demonstrated a negative impact on VO2max growth (r =-0,401 p≤0.05), HRmax (r=-0,658 p≤0,001) and HRAT (r=-0.591 p≤0,01). The strain in LI zone is characterized by a similar impact on the parameters of oxygen function as observed in case of AR strain. The values of the parameters: HRmax (r=-0,542 p≤0,01) and HRAT (r=-0,533 p≤0,01) are decreasing with the increase of work volume in this zone. In a starting period a negative correlation between VAT (r=-0.386 p≤0,05) and the level of LI strain was observed. In a preparatory period the HI strain shows relation with VO2max(r=0,561 p≤0.01) and %VO2AT(r=0,440 p≤0,05). VHI strains show an impact in a preparatory period on both VO2max(r=0.688 p≤ 0,001) and HRmax (r=0,675 p≤0,001) as well as on HRAT(r=0,653 p≤0,001). In a starting period it was observed that there is a negative relation of the effect of strain in HI and VHI zones onVO2max (respectively VO2max (r=-0,471 p≤0.05, r=-0,495 p≤0,05)

Conclusion. The increase of VHI means in a preparatory period influences the rise of aerobic capacity. In a starting period tendency is opposite. In a preparatory period the increase of AR and LI means has a negative effect on parameters of aerobic capacity. It was proved that in 16-17 year-old players the drop in the increase of aerobic capacity while applying effort on LT level as well as the lack of a significant effect of increase in MI intensity

FEASIBLE MISTAKES IN THE INCREASE OR MAINTENANCE OF THE BONE MINERAL DENSITY

Glaner, M.F., da Silva, R.A.

Catholic University of Brasília, Brazil

Many researchs have shown a significant (p<.05) increase or maintenance of bone mineral density (BMD) before/after physical activity and diet programs, prostheses implant and supplementary medicaments. However, they lack for information about the quality of this data of BMD measured by dual-energy X-ray absorptiometry (DEXA). Thus, the aim of this study was to compare the paired BMD analysis of the lumbar vertebrae (L1 to L4), maked in different days, derived from a single scanning. The subjects for this study were 26 women and 13 men (age= 45.1 sd14.8 and 32.0 sd11.9 years old; body mass= 63.2 sd13.6 and 75.0 sd16.8 kg; stature= 161.2 sd6.9 and 176.8 sd5.0 cm - women and men, respectively: sd = standard deviation). Each subject was scanned just once (MEASURE 1). This MEASURE 1 of BMD was taken according to the handbook of the manufacturer's Lunar DPX-IQ v.4.x, and the machine was calibrated regurarly using the manufacturer's phantom model. The first analysis was maked in the same day of the MEASURE 1, and the results were printed, but not recorded in computer. The second analysis was maked 30 days after the MEASURE 1. All scanning and analysis were conducted by the same technicist, who has 3 years of experience in this function. The data of the BMD (g/cm2) of the L1 to L4 obtained in the first and second analysis was compared by paired t-test and Pearson's (r) correlation (ap<.05). The results for the first and second analysis were, respectively: L1a= 1.1170 sd.2171 and 1.1258 sd.2217; L2a= 1.2038 sd.2180 and 1.2114 sd.2204; L3= 1.2537 sd.2318 and 1.2565 sd.2318; L4= 1.2268 sd.2374 and 1.2155 sd.2364; L2-L4a= 1.2281 sd.2235 and 1.2364 sd.2249. High correlation was evident between all L1 to L4 (ra= .935 to .998). Although previous studies have revealed increase or maintenance in BMD of the L1 to L4 due to physical activity and diet programs, prostheses implant and supplementary medicaments, in this study were found differences (ap<.05) between BMD of the L1, L2 and L2-L4 obtained by MEASURE 1. This suggests that other factors may also contribute to the increase or maintenance of BMD, e.g. the removal of surrounding soft tissue, incorrect determination of the intervertebral disk space and abdominal fat. It is possible because the analyses are maked using the finger-board of the computer. Thus, there is no security that, in two or more analysis in the same subject, will be removed the same amount of surrounding soft tissue in the lumbar spine. Other studies are required to confirm or not these findings.

SIMPLIFIED DOUBLE BOUTS EXERCISE METHOD FOR NON-EXHAUSTIVE AEROBIC CAPACITY DETERMINATION IN SEDENTARY RUNNING RATS

de Barros Manchado, F., Contarteze, R.V., Gobatto, C.A., Luciano, E., de Mello, M.A.

Sao Paulo State University - UNESP, Brazil

The exercise physiology often uses experimental animal models to observe the physiological responses to exercise, but few studies deal with the exercise intensity. Therefore, it is necessary to develop simple methods for physical evaluation of exercise rats. The aim of this study was to simplify the double bouts exercise method for non-exhaustive aerobic conditioning determination in running rats, based on the protocol originally described by Chassain (1986) for human beings and adapted to rats by Manchado et al. (2006).

Adult Wistar rats (n=10) were used. The running animals were selected and adapted to treadmill running. All rats accomplished 4 tests at different velocities (10, 15, 20 and 25m.min-1) with intervals of 48 hours among them. The Chassain's method is characterized by double bouts exercise at the same intensity separated by a passive recovery. In present study, the rats run two efforts of 5 minutes each at the same intensity, separated by 2 minutes of rest, with blood collection for lactate analysis. For each velocity, it was calculated the value of delta lactate, by subtracting the blood lactate concentration at the end of the first effort (LACE1) from the lactate concentration at the end of the second effort (LACE2). With the delta lactate for each velocity, an individual linear interpolation was plotted, which enabled the determination a "null" delta lactate, equivalent the critical load (CL). For amplified the applicability of test, the CL was also determined using only deltas lactate at two velocities: 10 and 25m.min-1. The rats also were submitted to maximal lactate steady state protocol (MLSS) to verify the stabilization of the blood lactate, composed by 25 minutes of continuous exercise at 15, 20 and 25m.min-1 velocities, with blood collection every 5 minutes.

One-way Anova was used to compare the CL determined using all deltas lactate, CL obtained using only two deltas and MLSS velocity. We also observed the Pearson correlation between CLs (P≤0.05).

The estimated CL using four deltas was 16.9±0.8 m.min-1, with significant linear regressions (R=0.94±0.02). The CL obtained for two points interpolation (10 and 25m.min-1 deltas) was 16.5±0.82 m.min-1. The MLSS was observed at 20 m.min-1 for all animals, in blood lactate concentration at 3.7±0.2 mmol.L-1. There was no significant difference in CL determined by the two different methods and these parameters were highly correlated (r=0.85). In both the determination methods, CL was 20% less than MLSS velocity.

The results suggest that the simplified non-exhaustive simplify protocol using two velocities underestimate the MLSS in 20%, but showed similar results to the standard protocol using four intensities. Due to easier and faster utilization with rats, the simplified protocol seems to be more applicable than the standard protocol.

EFFECTS OF COMPUTER-GUIDED STRENGTH TRAINING WITH ECCENTRIC OVERLOAD IN TRAINED ATHLETES

Klute, K., Bauer, T., Kinscherf, R., Vorwald, S., Bischoff, D., Müller, H., Weber, M.A., Kauczor, H.U., Bärtsch, P., Billeter, R., Friedmann, B.

University Hospital Heidelberg, Germany

It was recently reported that computer-guided strength training with eccentric overload (desmodromic training) leads to distinct adaptations towards a stronger, faster muscle in untrained subjects (Friedmann, B. et al. 2004). The aim of the present study was to find out if in trained athletes desmodromic strength training has greater effects on strength (concentric one repetition maximum, 1RM), performance in jumping tests, muscle cross sectional area (CSA, magnetic resonance imaging), fiber cross sectional area (FCSA) and fiber type distribution (biopsies from vastus lateralis muscle). 26 athletes from a variety of sports who regularly perform quadriceps strength training were

randomly assigned to either desmodromic (DES, 24.1 ± 3.6 yrs, 185 ± 7 cm, 80.0 ± 8.4 kg) or conventional (CON, 24.5 yrs, 184 ± 7 cm, 80.5 ± 7.8 kg) knee extension exercise 3x/weeks for 6 weeks with 5 (DES) or 6 (CON) sets of 8 repetitions to compensate for the (1.86 fold) higher eccentric training load in DES. Afterwards, subjects performed jump training 2x/week for 3 weeks. After strength training, 1RM and CSA were significantly ($p<0.001$) increased in both groups by 16.3 ± 8.4 kg (DES), 16.4 ± 6.7 kg (CON) and by 6.0 ± 6.1 cm2 (DES) and 8.0 ± 5.9 cm2 (CON), respectively. Both groups improved maximal performance in the jumping tests [Countermovement by 2.2 ± 2.9 cm (DES) and 1.2 ± 3.7 cm (CON), Squat by 3.3 ± 2.3 cm (DES) and 1.7 ± 4.2 cm (CON), Drop, reactivity index by 0.26 ± 0.38 (DES) and 0.09 ± 0.49 (CON)], however, the increases were significant ($p < 0.01$) only in DES. There was a tendency towards a higher percentage of type IIA fibres in CON before strength training (38.1 ± 13.0 vs. 28.3 ± 7.1 % in DES, n.s.); after training this difference reached significance [43.1 ± 14.8 % (CON) vs. 30.1 ± 7.5 % (DES), $p = 0.029$]. Accordingly, the increase in percentage type IIA area was significantly greater in CON than in DES (6.8 ± 7.5 % vs. 2.8 ± 10.9 %, $p = 0.018$). There were no significant changes of % type I and type IIX fibres nor of the respective FCSAs or mean FCSA.

The significant performance increases in the jumping tests in DES point to a specific adaptation to desmodromic strength training in trained athletes. However, the greater increase of percentage type IIA area in CON and similar increases in CSA in both groups show that the morphological adaptations to desmodromic strength training seem not to be superior to equivalent conventional strength training in trained athletes.

SPORT-SPANNING TRAINING VARIABILITY AUGMENTS INDIVIDUAL SUCCESS POTENTIAL IN ELITE SPORT

Güllich, A., Emrich, E.

University of the Saarland, Germany

We recently presented results from retrospective reports of German national squad athletes (questionnaire; n=1,558) indicating, that a higher training volume in other sports beyond the individual's current main sport and a higher variability of played sports is mostly associated with deceleration of the juvenile training- and performance-related development in his or her current main sport, but with higher long-term success in elite sport. Each, juvenile success, training volume in the main sport, and volume of support interventions, does not have such success-discriminating effect (Güllich & Emrich, 2006).

In the present study, the according hypotheses are tested in longitudinal design: 244 squad members volunteered for two measurements (t2-t1=33 months), 119 of them aging over sport-specific junior age at t1. A special coding technique enabled the inclusion of success data in regression and manova procedures (Bortz, 2005; Güllich & Emrich, 2006). Explanation of elite sport success at t2 was approached by iterations of independent variables (stepwise inclusion) including complexes of former and current success, training volume and continuity in the main sport and in other sports, and duration of inclusion in support programs, each measured until t1.

Among elite athletes, training volume in the main sport does not contribute significantly to the explanation of success at t2. On the other hand, just two variables, success at t1 and the training volume in other sports, clear considerable success variance at t2: R2adj=0.41; n=106. Further significant contributions were found for the duration of injury-induced training reduction and for the period of training age with inclusion in support programs (R2adj =0.51; n=89). The data signify that more durable and voluminous training in varying sports, longer periods of injury-induced training reduction, and a longer period of development beyond support programs – and their intended steering effects – are associated with higher success in the long run.

The empirical findings indicate considerable inconsistence between a socially constructed ideal-type of long-term careers and empirically displayed conditions for success. Furthermore, the results partially even disaccord the hard core of assumptions underlying traditional long-term training and support concepts, e.g. commonly assumed positive long-term correlations of each, juvenile performance, volume of sport-specifically goal-directed training, and corresponding steering of performance and training, with later success. Possible intervention- and selection-effects and their additive, selective, and/or interactive patterns are suggested and discussed from perspectives of training science, time-economy, and social sciences.

THE STRUCTURE OF EFFORT INTENSITY IN AN ICE HOKEY GAME OF POLISH NATIONAL TEAM

Gabrys, T., Bakalarski, W., Szmatlan-Gabrys, U.

Academy of Physical Education in Warsaw, Poland

Introduction.The method is based on the assumption that HR increases linearly vs.VO2 (Astrand et al. 2003). The objective of the research was to apply HR assignment to VO2 values to the level of effort intensity occurring during an ice hockey match.

Material and methods. The research was carried out on selected 23 ice hockey players of a Polish national team during 4 international matches. VO2 zones and HR values corresponding to them were determined during an ergometric progressive test. The VO2 level capture was carried out with a gas analyzer Kb4 (Cosmed), and the HR readings with a Polar Team monitor (Polar). 5 zones of effort intensity were determined accounting for %VO2max: VHI– very high intensity (86-100%); HI - high intensity (76-85%); MI– an average intensity (51-75%); LI- low intensity(31-50%); AR- active regeneration (15-30%); SR– rest (≤14%). The percentage structure of work in each intensity zone was defined. In order to determine dependencies between the level of oxygen function and the ability for highly intensive work and the speed of restitution a correlation analysis was carried out between the time of work in each zone and the individual level of VO2max. The results of the research were drawn up by Statistica (StatSoft). The work and research were financed by KBN project AWF DS.53

Results. In the first period of the matches the examined group was doing 46-51% of total work in the VHI sphere in next periods the decrease of the parameter to the level of 36-40% was observed. Simultaneously the increase of the work in the MI zone from 17-20% in the first period to 23-28% in the second and third period was observed. In the first period high correlation between the level of VO2max and the time of work in the spheres from LI to SR (r=493 do 561 p≥0.05) was stated. In the second period with work in the spheres LI, MI, VHI (r=.487 do .649 p≥0.05).

In the III period with work in the spheres LI and VHI (respectively r= .497 i r=.723, p≥0.05).

Conclusion. The redeployment of performed work between the I and III period from the intensity VHI in the direction of MI and LI and the gradual disappearance of intensity SR and AR in the II and III period was recorded. With the passage of a game time the effort intensity in the examined group is decreasing. The correlation between VO2max and the game time showed that the level of oxygen function influ-

ences the effort intensity during a game. It conditions the speed of restitution (the transition from an AR and SR sphere) and in the III period it conditions the ability to work in the VHI sphere. The presented method allowed to assess the realization of the team potential during a match basing on the players VO2 individual level.

CORRELATION BETWEEN SHORT DISTANCE VELOCITY AND DRIBBLING IN YOUNG ELITE FOOTBALL PLAYERS

Laudenklos, P., Herdener, L., Lottermann, S., Weber, K.

German Sport University Cologne, Germany

INTRODUCTION: In football the short distance velocity – up to ten meters – is an important performace factor (Verheijen, 1999) just like the dribbling, which is one of the basic skills (Bisanz & Vieth, 2001). The aim of this study was to analyze whether a correlation exists between these two parameters in young football players.

METHODS: The players were members of youth teams from German Bundesliga-Clubs (LZ) (n = 873) in the age-groups (AG) 1987 to 1994. They had to execute a 10 meter linear sprint (LS) and a dribbling test (DT) (Lottermann, Laudenklos & Friedrich, 2003). Every test consisted of two heats by which the better one was evaluated. The test-times were measured by light barriers. The Product Moment Correlation Coefficients (Pearson) were analyzed for every single age-group on a significance-level of 5%.

RESULTS: In LS the means varied from 1,86 ± 0,08 s (n1987 = 34) to 2,13 ± 0,09 s (n1994 = 115). The means of DT ranged from 9,87 ± 0,79 s in AG 1987 to 10,95 ± 0,72 s in AG 1994 (n = 112). The correlation coefficients decreased from AG 1987 ($r = .39$; $p < .05$) to AG 1990 ($r = .09$; $p = 0.30$; n = 151), followed by an increase up to AG 1994 ($r = .49$; $p < .01$; n = 112).

CONCLUSION: The results show a significant correlation between LS and DT in the oldest as well as in the youngest age-group. In the remaining age-groups no significant correlation between these two performance-relevant parameters was detected. The part of the combined variance is 15% in AG 1987 and 24% in AG 1994. Thus, the common factor(s) in these age-groups has/have to be identified and developed in practice. In further studies it is to clear up whether one combined factor is the acyclic fast strength.

PHYSIOLOGICAL PROFILE OF ELITE PORTUGUESE TRIATHLETES

Martins, F., Oliveira, E., Ascensão, A., Magalhães, J., Soares, J.

Faculty of Sport, University of Porto, Portugal

Portugal has a know tradition in sport long distance events, especially in marathon. More recently, triathlon becomes a popular sport with relevant international sport results. The main objective of this study was to evaluate the physiological profile of Portuguese triathletes, participants in international championships. Were evaluated 12 male athletes of Triathlon with high training level and leaders of the national team (30±6.8 yrs; 70.2±6.4 kg; 177.5±5.4 cm; 6.7±1.9% fat and 5.2±0.5 yrs of specific training). The stature and body fat of Portuguese athletes were similar to other international participants. In spite of the bilateralism of this sport, significant differences between right and left side, were found in peak torque (isokinetic evaluation in Cybex System 2) in knee extension at 90°/sec and at 360°/sec (7.3±4.2% and 9.9±6.1%, respectively).

Portuguese athletes showed a lower maximal power, evaluated by the Wingate Test, when compared to triathletes of other countries participating also in international events (10.2±0.9 W/Kg vs 11.2± 1.2 W/kg). The VO2 max, obtained in treadmill, (64.2±7.7 ml/kg/min) is similar to other high level triathletes but slightly lower than the values found in elite Portuguese long distance runners (75.4±4.2 ml/kg/min) observed in our lab. The anaerobic threshold might be considered similar to the values found in other countries (76.2±3.8 % of the VO2 max.). The maximum race velocity was set at 19.6±1.2 Km/h.

The results show that Portuguese triathletes have similar physiological characteristics than the described for other international elite racers. Moreover, the bilateral differences found in knee extension might be carefully observed in order to maximize performance as well as to prevent possible soft tissue injury due to probable muscular unbalance.

EFFECT OF CYCLIST SPECIFICITY ON THE SELECTION OF THE PREFERRED PEDALLING CADENCE IN SEATED AND STANDING POSITION

Duc, S., Bertucci, W., Pernin, J.-N., Grappe, F.

Institut FEMTO ST (UMR CNRS6174) - Laboratoire de Mécanique Appliquée R. Chaléat, Université de Fran, France

Purpose - Competitive cyclists use generally a lower preferred pedalling cadence (PPC) in uphill than in flat race (1). This reduction could be due to i) the decrease of the power output, ii) the increase of the road slope, iii) the limited gear ratio and iiii) the frequent switch of body position (2). The specificity of cyclists can also affect the selection of the PPC. At our knowledge, none study had compared the PPC between flat terrain specialists and climbers.

Methods – Eight trained cyclists classified as flat terrain specialists (n = 4) or climbers (n = 4) performed two pedalling trials of three minutes at 80% of maximal aerobic power on a motorised treadmill with a slope of 4%. Two positions (seated and standing pedalling) were studied in a randomized order. During the first minute of each trial, the subjects had to choose their PPP with adjusting their gear ratio and then kept this rate until the end. Throughout the tests, the pedalling cadence and the power output were measured and controlled with a Powertap hub. The statistical analysis was performed with using the Mann-Withney Rank Sum test.

Results – This preliminary study showed that climbers choose a higher PPC in standing position (78  6 rpm) than the flat terrain specialists (68  3 rpm). The PPC in seated position is not significantly different between the two groups: 81  7 vs 76  5 rpm, respectively.

Conclusion – We suppose that flat terrain specialists choose a lower PPC during standing pedalling in order to generate greater peak pedal force and to decrease the number of vertical elevations of pelvis, which increase energy cost (due to their higher weight). Theses results must to be confirmed with increasing the sample size of the two groups.

KNEE RANGE OF MOTION IN HEALTHY ADULTS: A NON INVASIVE STUDY DURING TREADMILL WALKING

Lovecchio, N., Turci, M., Shirai, J.F., Mantovani, E., Sforza, C.

Università di Milano, Italy

Introduction - Walking is one of the most important weight-bearing activities performed by humans. In a previous study, we developed a method for the quantitative assessment of lower limb movements during treadmill running and walking (1). In this investigation, we assessed the normal knee movements during treadmill walking in a group of healthy sedentary adults.

Methods - Fifty-seven healthy men (mean age 30 y, SD 15, range 19-79; mean standing height 175 cm, SD 7; mean weight 73 kg, SD 12; mean BMI 23.8 kg/m2, SD 3) and 46 healthy women (mean age 33 y, SD 13, range 20-69; mean standing height 166 cm, SD 6; mean weight 59 kg, SD 8; mean BMI 21.5 kg/m2, SD 2.6) walked at 1 m/s on a treadmill set at 0° inclination. Twelve steps were recorded for each subject using a 9-TVC optoelectronic instrument operating at 120 Hz (2, SMART System - B.T.S., Milan, Italy). Twelve passive, retroreflective markers identified the thighs and the legs (two sets of three markers for each limb). Three-dimensional left and right knee joint movements were assessed, and angular motions were divided into the three anatomical planes using original software (2). Bivariate analysis was used for descriptive statistical calculations. Comparisons were performed using Watson-Williams' tests (the analogue of Student's t test for angular data) and correlation analyses, with a level of significance set at 5%.

Results - In men, the mean movements in the sagittal plane (flexion-extension, direction of motion) were 65° (SD 1°) for both sides. In women, the mean movements were 67° (SD 1°) for both sides. The difference was statistically significant (Watson-Williams' test, $p<0.05$). In the frontal plane (rotation), no significant sex-related differences were found ($p>0.05$): men had mean motions of 23° (SD 0.9°, right side) and 20° (SD 0.7°, left side); women had mean motions of 23° (SD 0.7°, right side), and 22° (SD 1°, left side). The movements were symmetric (no side related differences; Watson-Williams' test, $p>0.05$ in both sexes); in both sexes, no significant relationships with age were found ($p>0.05$ in all occasions).

Conclusions - The method was fast and not invasive, and allowed a complete measurement of the dynamic characteristics of the knee during treadmill walking free from projection errors (2). Data can be used as normative values for sedentary healthy persons, and for future comparisons with patients with alterations of the lower limbs, before and after rehabilitation of the knee joint. In particular, considering that a mean range of motion of 67° is currently judged necessary to allow a normal swing phase of gait (3), the quantitative assessment of the actual movements in the single patient could be a useful tool for rehabilitation.

PRELIMINARY STUDY OF CONSTRUCT VALIDITY OF THE DEMOCRITUS-PSYCHOMOTOR ASSESSMENT TOOL FOR PRE-SCHOOL CHILDREN

Kambas, A., Venetsanou, F., Aggeloussis, N.

DEMOCRITUS UNIVERSITY OF THRACE, Greece

Democritus-Psychomotor Assessment Tool for Preschool Children (PAT-PRE) (Kambas, Aggeloussis, Gavrilidou, 2003) is a new assessment battery for children 4-6 years old, based on Motoriktest für vier- bis sechsjährige Kinder (MOT4-6) (Zimmer & Volkamer, 1987), one of the most known and valid testing batteries for this particular age. The most important consideration in evaluating and selecting an assessment tool is its validity (Dunn, 1989). The purpose of the present study was the preliminary examination of the competence of PAT-PRE to differentiate among i) different age-groups and ii) contrast groups. PAT-PRE was administered to: a) 88 non-disabled children which were divided in four age groups [48-59 months (n=19), 60-71 months (n= 24), 73-85 months (n= 24), and 86-96 months (n= 21)], b)16 children aged 75-95 months identified by the local Diagnosis, Assessment and Support Centre as having learning difficulties, and c)14 children aged 75-96 months which attended Elementary School for children with special needs. One–way analysis of variance (ANOVA) that was applied to the total PAT-PRE scores revealed that there were statistically significant differences among the motor performance of the above groups ($F=41,058$, $p<.001$). Post hoc comparisons using Sidak test followed, with alpha set at .05. According to the results, the non-disabled group of 86-96 months had the highest performance, followed by: a) the non-disabled of 73-85 months, b) children with learning difficulties, c) the group of 60-71 months, d) the group of 48-59 months and e) children with special needs. From the above results the construct validity of PAT-PRE battery is supported. As the administrative traits of the battery (short duration for test administration, inexpensive equipment, game like items) support its ecological validity (Zittel, 1994) and render it a very attractive and viable tool for the motor assessment of preschool –aged children, a further examination of the rest validity criteria is needed, so as the technical adequacy of the battery to be established.

EFFECTS OF ISOKINETIC TRAINING USING SUBJECTIVE EFFORT TO REGULATE INTENSITY ON MUSCLE STRENGTH IMPROVEMENT

Onodera, K., Iwaoka, K., Yamaji, K.

University of Toyama, Japan

PURPOSE: The purpose of this study was to examine the effects of isokinetic training using subjective effort to regulate intensity on muscle strength improvement. METHODS: Sixteen healthy male subjects (age:47.9±5.7 yrs, height:168.0±4.5 cm, weight:67.8±8.2 kg) participated in muscle training program (three times a week for 6 weeks). In this study the integer scale from 0 to 10 (maximum) was adopted in evaluation of subjective effort and rating of perceived exertion. Subjects isokinetically trained the right and left quardriceps femoris keep-

ing constant of a given level of subjective effort for 30 repetitions using COMBIT-CB2 at an angular velocity of 60 deg.s-1. Subjects divided into three groups: one group (GI,N=5) trained at 10 level of subjective effort, a second group (GII,N=5) at 8 level and a third group (GIII,N=6) at 6 level. RESULTS: In training, muscle force decreased gradually with repetition in spite of maintaining the same level of subjective effort. However relative value to maximal work intensity kept constant at each point of repetition. Training induced increase in maximal peak torque of knee extension (left leg : GI, 152.0±27.7Nm to 174.5±6.5Nm, GII, 157.6±32.2Nm to 167.6±51.7Nm, GIII, 103.9±28.3Nm to 117.8±20.1Nm). Exponential regression line was indicated between subjective effort and exerted muscle force during the incremental test. Regression line shifted above according to muscle strength improvement after training, but it remained unchanged in case of relative muscle force to maximum (% of maximal force). CONCLUSIONS: Repetition maximum (RM) method for muscle training forced maximal effort to a person at the end of repetition. The results obtained in this study indicate that subjective effort is good index of muscle training intensity and also safe and effective means to muscle training for health.

IS TRAINING ABLE TO INFLUENCE THE HEART RATE CIRCADIAN RHYTHM ?

La Torre, A., Roveda, E., Montaruli, A., Calogiuri, G., Carandente, F.

Institute of Physical Exercise, Health and Sport Activity, Italy

Introduction

Training can represent an important synchronizing factor that influence the circadian system. The physical exercise effect on HR circadian rhythm is of particular interest. We investigated the effect that physical exercise of different intensity and length, done at different time of the day, can have on the synchronization of HR circadian rhythm.

Materials and methods: Study 1 20 male endurance athletes (aged 20-25) carried out 2-hrs-daily training sessions at 75-85% of the HRmax for 5 consecutive days. Four different weekly training timetables (09-11;11-13; 16-18;18-20) were followed; each athlete trained in turn in each time slot for a week. In the fifth day of each week a 24hrs-HR-monitoring was carried out by the HR monitor (Polar S810). For all subjects four 24hrs-HR-monitoring were collected, one for each weekly training timetables.

Study 2 20 male subjects (aged 20-25), practising moderate physical activity, carried out 1-hour-daily training session at 50-60% of the HRmax for 3 consecutive days, in two different weekly training timetables (08-11;18-21). In the third day of both weeks a 24hrs-HR-monitoring was carried out. For every subject we collected three 24hrs-HR-monitorings, two for each training session time and one during a sedentary life day (basal).

Data were analysed by the single and mean cosinor methods; the HR population circadian rhythm was compared using the Hotelling Test. Data were analysed excluding the HR data recorded during training sessions and the 2 hours following the training session.

Results: Study 1 Rhythmometric analysis, carried out on 7 subjects who strictly observed the study protocol, revealed a statistically significant circadian rhythm for all monitorings.The mean cosinor, calculated grouping the HR monitorings with the same training session, demonstrated a statistically significant circadian rhythm in all 4 experimental sessions. The Hotelling Test showed statistically significant difference of HR achrophases between the 09-11 and 18-20 training sessions: the HR achrophase for training done between 18-20 is delayed approximately 3 hours compared to that one of training done between 9-11.

Study 2 Rhythmometric analysis, carried out on 14 subjects, revealed a statistically significant circadian rhythm for all monitorings. The mean cosinor demonstrated a statistically significant circadian rhythm in all 3 experimental sessions. HR achrophase for evening session shows a shift of approximately 1 hour compared to the basal condition nevertheless the Hotelling test showed no statistical differences in the different experimental sessions.

Discussion : An intense training program can modulate the HR temporal structure. Instead a moderate physical activity program seems to be insufficient to change the HR temporal structure.

ANAEROBIC EXERCISE TESTS IN TAEKWON-DO ATHLETES: A COMPARISON OF AN INTERMITTENT ANAEROBIC TEST AND A 60-S BOSCO JUMP TEST

Vodicka, P., Heller, J.

Faculty of Physical Education and Sport, Charles University, Prague , Czech Republic

The most common anaerobic performance tests are of a constant nature (such as the Wingate test); however, many anaerobic activities such as martial arts fighting are of an intermittent nature. Therefore, the purpose of the study was to investigate and compare the results of the two anaerobic performance tests, an intermittent anaerobic cycle ergometer test (IAT) and 60 s Bosco jump test in elite male and female taekwondo (WTF) contestants.

A group of elite male (n= 31, age 17.6 +/- 2.7 (SD) years, body mass 68.5 +/- 6.5 kg) and female (n= 13, age 16.8 +/- 2.1 years, body mass 53.8 +/- 6.3 kg) taekwon-do athletes performed, the IAT and 60 s Bosco jump test in a randomised order, on the same day. The IAT (computerised cycle ergometry) consisted of 10 repetitions of 5 s all-out exercise loads (at a resistance load 6 W.kg-1 and 5 W.kg-1, for the males and females, respectively) separated by 30 s recovery breaks (Heller and Psotta, 2000). The main results of the IAT were: 5-s peak power (PP), mean power (MP) and/or total work (A, kJ), power decrease (W) and/or fatigue index (FI, % of PP). The second test, 60 s Bosco jump test (Vodicka and Heller, 2003) determined total work (AB, kJ), power decrease, and a theoretical peak power (PPB, W, defined as an intercept of linear dependence of work throughout the test on time, at a time equal zero). The values of PPB, 305 +/- 39 W in males PP were significantly related to the absolute values of PP in IAT (1002 +/- 114 W, r= 0.67, p<0.01) but were unrelated to relative values of PP in IAT (14.6 +/- 0.8 W.kg-1, r= 0.06, n.s.). In females, the values of PPB, 206 +/- 26 W were significantly related both to the absolute and relative values of PP in IAT (583 +/- 61 W, r= 0.87, p<0.01, and 10.8 +/- 0.5 W.kg-1, r= 0.63, p<0.01). The total work from the jump test (AB, 17.3 +/- 2.5 kJ in males and 11.3 +/- 1.4 kJ in females) was significantly (p<0.01) related to the A and/or MP values in the IAT (42.2 +/- 4.2 kJ, 844 +/- 85 W, r=0.85, in males, and 26.1 +/-2.8 kJ, 522 +/- 56 W, r= 0.66, in females, respectively). Regardless the relationships found in PP and total work, the power decrease and/or fatigue indices from the two tests were unrelated one another.

The results of the study had demonstrated that both the 60 s Bosco jump test and IAT may be good predictors of explosive strength (peak power) and general anaerobic capability (total work), regardless of different nature of these tests. On the other hand, power decrease and/or fatigue index in jumping and supramaximal cycling seems to be test-specific, and not a valid predictor of fatigability in taekwon-do athletes.

SOFTWARE FOR REGISTER AND EVALUATION OF LOAD IN TRIATHLON

Kovar, K., Suchy, J.

Charles University, Faculty of Physical Education and Sport Prague, Czech Republic

Quality training records are an integral part of managing the training process. They facilitate the routine analysis of training, an evaluation of its effect, and operative changes in planning. The choice of appropriate parameters for the records, and the flawless processing of data on training and its use, have not been entirely resolved and run into a number of problems. The use of information technology to record and analyse a training programme can greatly simplify that.

This abstracts summarises the current level of knowledge on training records in the multi-endurance sports - triathlon. On the basis of research results, we have selected and theoretically justified training indicators suitable for the recording of the training process in the selected disciplines. Training indicators refer to programme intensity and specificity in relation to the competition programme. Work on this theme has required a systematic analysis of data, computer programming and processing, modelling and verification.

We have organised the selected training indicators into a theoretical model, facilitating their computer recording. On the basis of that model, as part of this dissertation we have designed and developed special software to process training records. The programme allows the data entered to be analysed and evaluated for the needs of planning training for triathlon.

RELATIONSHIP BETWEEN A NEW FUTSAL INTERMITTENT ENDURANCE TEST (FIET) AND REPEATED-SPRINT ABILITY IN PROFESSIONAL FUTSAL PLAYERS

Barbero-Álvarez, J.C., Miladi, I., Ahmaidi, S.

Universidad de Granada y Faculté de STAPS, Amiens, Spain

To perform at a high level, the futsal players need a well-developed capacity to perform high intensity activities such as cruising and sprinting, as well as the capacity to recover properly during low-intensity activities such as walking and jogging over different periods. For this reason, the physiological requirements of futsal are reported to be met by both aerobic and anaerobic metabolism.

In futsal performance is related to the athlete's ability to repeatedly perform intense exercise. Therefore, an important fitness component of these sports is what has been termed repeated-sprint ability (RSA). Aerobic fitness (i.e., VO2max) has been often suggested to be an important determinant of RSA, by means of speeding up the recovery processes. A significant correlation was observed between Futsal intermittent endurance test (FIET) performance and aerobic fitness (see another abstract). This study aims to investigate the influence of an individual's FIET performance on RSA in professional futsal players.

All subjects (n=15) were competitive, professional team sport male athletes in futsal (mean ± sd: age 24.2 ± 4.9 y, height 186.0 ± 0.18 cm, mass 86.2 ± 13.8 kg). The RSA test used in the present study comprised 8, 25-m running sprints separated by 25-s of recovery. Total sprint time (TST) and fatigue index (FI) were calculated for the RSA test. The correlation coefficients were determined and tested for significance using Pearson's product–moment test.

The mean results for the FIET and RSA showed a significant inverse correlation between FIET performance and total sprint time in the RSA test ($r = -0.718$, $P = 0.029$) whereas this was not the case for the fatigue index ($r = 0.30$, $P = 0.379$).

The total time is considered as a index of the anaerobic work capacity performance (Dawson et al., 1993), therefore these results reporting a strong correlation between the FIET performance and the repeated sprint ability. However, the FIET score was not related to sprint decrements (i.e., fatigue index). In accordance with previous studies (e.g., Bishop and Spencer. 2004), this suggest that factors in addition to aerobic fitness are likely to be important for the recovery of muscular power output during repeated sprints. In conclusion, the Futsal intermittent endurance test is a field test who provides information not only on fitness aerobic of the player, but also with his ability to carry out a work anaerobic or an intermittent work of maximum intensity in concordance with the physiological requirements of futsal.

HEART RATE MONITORING DURING OFFICIAL SOCCER MATCHES

Stanganelli, L.C., Eliotério, E.C., Bortolossi de Souza, O., Frisselli, A., Dourado, A.C.

State University of Londrina, Parana State, Brazil

Soccer is an open-skill interval activity characterized by high unpredictability inherent to individual and team behavior between matches and individual players (EKBLOM, 1994). Considering this model of sport, it is important to use the heart rate (HR) based methods to monitor intensity since there are few studies regarding their application in soccer official matches. Thus, to assess and to analyze the HR during a match is important because it could evaluate the internal training load induced by this situation and an objective way to prescribe exercise intensity in soccer. The main purpose of this study was to monitor the HR of the under-20 players of a professional team during two official matches of the Parana State championship – Brazil. The sample was composed by 10 athletes from the Londrina Junior Team aging from 17 to 20 years old. A short-range radio telemetry system "team system" (Polar Electro Oy, Finland) for monitoring HR was used voluntarily by the subjects simultaneously during two official matches. Average temperature was 32°C e 31°C for matches 1 and 2, respectively and humidity ranged from 41% to 45%. Both matches started at 3 and 3:30 pm, respectively. The results showed that maximal HR ranged from 190 to 210 bpm (mean: 202 bpm). In general, the average intensity of the two matches was 81% of HRmax. According to the positional roles, the intensities (%HRmax) were: full back, 83%; forwards, 82%; midfielders, 81% and defenders (right and left), 80%. Related to the absolute values and using the classification for the intensity zones presented by GOMES (2002) it was possible to verify that the HR remained above 160 bpm as following: midfielders, 69%; forwards, 64%; full back, 60% and defenders, 58%. In conclusion, it could be seen that intensity during the two matches were above 80% of HRmax for all positional roles but the midfielders spent more time at higher intensities compared to the others positions. These data are according to BANGSBO, 1994 who stated that the average intensity for a soccer player in a 90 min match is close to 80-90% of HRmax. Also, these results could be important for those professionals who are responsible for prescribing the training loads of the soccer teams based on scientific information about the intensity induced by a match.

TRAINING ADAPTATION ON JUMP CAPACITY OF ELITE VOLLEYBALL PLAYERS IN THREE DIFFERENT MACROCYCLES

Stanganelli, L.C., Dourado, A.C., Oncken, P., Mançan, S.

State University of Londrina, Parana State, Brazil

The main objectives of the present study were to verify periodically the training adaptations on jump capacity of the under-19 Brazilian volleyball team during the preparation for the world championships of 2001, 2003 and 2005 and to compare the results among these three different macrocyles aiming to have reference values for training adaptations on volleyball players after a systematic period of training. The athletes were submitted to the squat jump, countermovement jump and height and vertical jump for specific tests for spike and block. A Pre test (1st week) and a Post test at the 18th week (2001), 14th week (2003) and 17th week (2005) was applied for both teams. The adaptations were expressed as percent changes on the performance of four different types of tests and calculated between these two moments. The Post test toke place just before the teams departed from Brazil to the countries where the championships happened. The sample was composed of 36 athletes, divided in 11 for the 2001 (age: 18,0±0,5 years; height: 197,1±3,9 cm; weight: 87,8±6,3 kg); 13 for the 2003 (age: 17,90±0,4 years; height: 197,6±3,9 cm; weight: 86,2±6,1 kg) and 12 for 2005 (age: 17,7±0,7 years; height: 197,4±8,0 cm; weight: 88,9±12,1 kg). Descriptive statistics were computed and the ANOVA was utilized to test differences among all groups of means with the Tukey HSD follow-up test as a pos hoc. The significance level was set at p0.05. The results showed that the mean improvement for the three groups in the squat jump and in the countermovement jump was 2.4±6.8% and 3.1±8.0%, respectively although these adaptations were not statistically significant. On the other hand, the height of spike reach showed significant adaptation among all groups (2001: 2.9±0.9%; 2003: 4.2±1.4%; 2005: 1.6±1.1% at p=0.0000) while the vertical jump during spike demonstrated changes only between the 2003 (19.5±7.6%) and 2005 (9.6±8.2%) groups at p=0.0073. The result of the test for the height of block reach also revealed positive and significant adaptations among the 2001 (3.47±1.4%) and the 2003 groups (3.83±1.8%) when compared to the 2005 group (0.9±1.17%) at p=0.0000. The same happened when analyzing the vertical jump of the block which presented significant improvement of the performance in the groups of 2001 (20.6±7.7%) and 2003 (20.0±4.9%) when compared to the 2005 group (3.1±6.6%) at p=0.0000. All the evaluated variables demonstrated positive adaptations during the macrocycles and the three groups of athletes showed different responses to the training stimulus which could be normal considering the individual characteristics and the training loads applied. Besides, it is still difficult to point out the main reasons for the verified responses to the systematic volleyball training and more data should be collected regularly aiming to determine a profile of these adaptations in such a young group of athletes.

OXYGEN UPTAKE RESPONSE TO 800-M AND 1500-M RUNNING RACES

Hanon , C., Thomas, C., Levêque, J.-M., Vivier, L.

INSEP, France

The present study was designed to determine the profile of VO2 response during an 800-m and a 1500-m races on an outdoor track in well-trained middle-distance runners. We hypothesised that maximal cardio-respiratory stress assessed by maximal oxygen uptake would be reached by the end of the races due to the high running intensity occurring usually at the beginning of races as observed by Gajer at al (2001).

On an outdoor track, 16 trained middle-distance male runners first performed an incremental test to determine VO2max (VO2maxIncr) and then at least two days later, a supra-maximal 800-m (n=5) or 1500-m (n=11) running test, realized on the respect of the competition strategy. VO2 response was measured from the start to the end of the exercise with the use of a miniaturised telemetric gas exchange system (Cosmed K4). Blood samples were taken from the earlobe before, just after and 3, 5, 7 and 10 min after the end of the supra-maximal exercise.

The mean exercise relative intensity of the 800-m and 1500-m was respectively 120,8 + 3,4% (mean ± SD) and 107,6 + 2 %VO2maxIncr. As observed in competition, the velocity at the onset of the races were systematically greater than the mean velocity. At the end of the races, the velocity decreased for all the subjects (800-m) and for a part of the subjects (1500-m).

VO2maxIncr was reached by all the subjects at 45 + 11 s (i.e., 316 ± 75 m), and 78 + 17 s (i.e., 463.63 + 67.4m) after the onset of the 800-m and 1500-m races, respectively. During the 800-m races, VO2max was maintained during 33 ± 6 s (i.e., 219 ± 41 m). An unexpected significant decrease in VO2 (24.1 ± 7.0%; $p<0.05$) was observed in all subjects during the final 38 ± 17 s (i.e., the last 265 ± 104 m).

During 1500-m races after reaching a value of VO2 significantly greater than VO2maxIncr (VO2Peak1500), and although the velocity for all subjects was at any time of the races above v-VO2maxIncr, VO2 remained stable during the following 800-m in a value equal to 93 + 3,5% of VO2peak1500. and to VO2maxIncr and decreased significantly from 1200-m to 1500-m.

On the two distances, the slowing down period of VO2 is significantly related to the velocity decrease ($p<0.05$). Furthermore, the decrease in VO2 was concomitant with a decrease in the tidal volume (VT) for all the athletes ($p<0.05$ and $p<0.0001$ on 800 and 1500-m respectively).

Unlike the results observed on treadmill running at constant velocity (Spencer et Gastin, 2001 ; Heugas et al, Draper et al), all the subjects of these studies reached VO2max.

We can conclude 1) that the race profile used in middle-distance competition (fast start followed by even pacing) is not without any consequence on metabolic parameters as already shown by Bishop et al (2002) with kayak athletes 2) VO2max can be reached during supra-maximal exercises of 2 to 4 min 3) an unexpected significant decrease in VO2 was observed at the end of the two race distances.

REPEATABILITY OF THE STABILOMETRIC ASSESSMENT OF BODY SWAY

Galante, D., Shirai, Y.F., Pallavera, A., Ferrario, V.F., Sforza, C.

Università di Milano, Italy

Introduction - Small amounts of sway can be seen during the standing position in human beings. This position involves both voluntary movements and postural reflexes that compensate for minor oscillations of the body. The eyes, the vestibular receptors, and a combination of cutaneous and kinesthetic mechanoreceptors embedded in the skin surface, muscles, joints and tendons, provide the input to the central nervous system to determine such corrections (1). Some influence is also claimed to be provided by oral proprioceptors (2, 3). Within clinical contexts, body sway is usually measured using stabilometry, and the modification of the position of the centre of foot pressure (COP) on a force plate for a period of time is assessed (1, 2). The COP is the centre of gravity of the vertical forces that act on a support surface. Literature reports on the intra-day and day-to-day repeatability of COP variations are scanty.

Methods - Five men (age 22-29 y, standing height 172-188 cm, body weight 60-78 kg) and five women (age 22-44 y, standing height 160-170 cm, body weight 53-60 kg), were assessed. Body sway was assessed either with open (EO, looking in a mirror) or closed eyes (EC), in

the morning (9:00 AM) and afternoon (2:00 PM) of two week days. A computerized platform (Lizard, Lizarmed, Como, Italy) with two separate left- and right-side sensors was used. Data collection begun approximately 10 s after the correct vision (eyes open or closed) condition had been assumed by the subject, and lasted for 30 s for each test. The variations of COP were analyzed through bivariate analysis, and the area of the 90% standard ellipse was computed. The velocity of COP oscillation was also measured. Data collected in the four repetitions were analyzed by calculating intraclass correlation coefficients (ICC).

Results - When considering all four repetitions, COP velocity was more repeatable than the area of the 90% standard ellipse, and the closed eyes condition was more repeatable than the open eyes condition (ICC area EO 0.342, EC 0.443; velocity EO 0.417, EC 0.626). Intra-day repeatability appeared larger in the first day in most occasions (ICC area EO, day 1: 0.22, day 2: 0.471; EC, day 1: 0.579, day 2: 0.413; velocity EO, day 1: 0.627, day 2: 0.433; EC, day 1: 0.744, day 2: 0.66). Day-to-day repeatability appeared larger in the afternoon than in the morning (ICC area EO, AM: 0.005, PM: 0.431; EC, AM: 0.308, PM: 0.59; velocity EO, AM: 0.069, PM: 0.644; EC, AM: 0.546, PM: 0.573).

Conclusions - Overall, repeatability in the stabilometric assessment of body sway was limited, and further assessments are warranted within each clinical contest: a particular care should be given to the experimental conditions, and the timing of measurements. The better intra-day repeatability of COP velocity vs area is in accord with previous investigations (3).

CONTINUOUS VERSUS INTERVAL AEROBIC TRAINING IN 8-11 YEAR-OLD CHILDREN

Baquet, G., Thevenet, D., Gamelin, F.-X., Nourry, C., Nottin, S., van Praagh, E., Berthoin, S.

Faculté des Sciences du Sport et de l'Education Physique, Université Lille, France

Introduction: Several studies have demonstrated that both well-designed continuous and intermittent training protocols induced significant aerobic fitness improvement in prepubertal children (Baquet et al., 2003). However, to our knowledge, few studies have compared simultaneously both training modalities on a same population. The aim of the present study was, therefore, to compare the effects of a continuous and an intermittent training on children aerobic performances. Methods: 65 children (9.6±1.0 years) were divided into an intermittent training group (ITG, 11 girls and 12 boys), a continuous training group (CTG, 13 girls and 10 boys), and a control group (CG, 9 girls and 10 boys). During 7 weeks, ITG and CTG followed three 30-min running sessions per week. Before and after training, they underwent a maximal graded test in order to determine Maximal Aerobic velocity (MAV), with continuous heart rate monitoring (HR, Polar Accurex+, Finland). Intermittent training consisted in short intermittent runs with exercise/recovery sequences lasting 5/15s, 10/10s, 15/10s, 20s/20s and 30/30s. Intensities were set from 100 to 190% of MAV. For continuous training sessions, exercise/recovery sequences lasted 4*6', 3*8', 2*10', 2*12', 1*15', 1*18', 1*20' with 5' recovery between each set. Intensity was set from 80 to 85% of MAV. Running intensity was gradually increased in proportion of the training sessions. All groups participated in regular physical education classes. Training effects were analysed with a two way ANOVA (group x time). When necessary, Tukey post-hoc test was used to confirm data differences. Statistical significance was set at $p < 0.05$. Results: At baseline, no significant group difference occured between values for MAV and HRmax. Any group by time interaction was found for HRmax values. HRmax values were (pre- vs post-test) 201±9 vs 200±7 bpm for CTG, 202±6 vs 201±6 bpm for ITG, and 203±9 vs 201±7 bpm for CG. Analyzing pre- and post-test MAV values revealed a group by time interaction ($p<0.001$). After training, MAV was significantly ($p<0.001$) improved in CTG (10.7±1.1 vs 11.6±1.1 km.h-1), ITG (11.3 vs 12.1±0.7 km.h-1, $p<0.001$), while no difference occurred for the CG (10.9±1.4 vs 10.9±1.4 km.h-1). Discussion: Our results demonstrated that both continuous and intermittent running sessions induced significant increase of MAV. They were similar to those of McManus et al. (2005) who reported similar improvement in aerobic power in children performing continuous or intermittent cycling exercises. Therefore, when adequate combinations of intensity/duration exercises are offered to children, many modalities of exercises can successfully be used to increase their aerobic fitness.

INFLUENCE OF RECOVERY INTENSITY ON THE TOTAL OXYGEN UPTAKE DURING A SINGLE INTERMITTENT SESSION IN YOUNG ATHLETES

Thevenet, D., Leclair, E., Tardieu-Berger, M., Prioux, J.

UFR STAPS , France

Introduction: It has been established that the efficiency of an exercise for the development of the aerobic system, is greatest when it allows subjects to maintain a long time at maximal oxygen uptake (tVO2max) (Billat et al., 2000). However, tVO2max is not the only significant parameter accounting for the effectiveness of an exercise. In fact, the total oxygen uptake (TotO2) during an exercise will account for the impact of an exercise on the aerobic system of a subject. In other words, the more an exercise will request the aerobic system, the more the total oxygen uptake during the exercise will be significant. The aim of this study was to analyze, during a short supramaximal intermittent exercise model (30s-30s), the effects of the recovery intensity on TotO2 in young athletes. Methods: 8 endurance trained males (15.88 years(0.48)) performed 4 field-tests until exhaustion: an incremental test to determine their VO2max (57.42 ml.min-1.kg-1(2.17)) and MAV (17.88 km.h-1(0.16)), then in a randomized order, 3 intermittent exercises consisting in repeating 30s runs at 105% of MAV alternating with 30s active recovery: 1/ 50% of MAV (IE50), 2/ velocity (vLT) associated with second lactate threshold (LT-IELT) and 3/ velocity (vLT-d) ranging between 50% of MAV and LT (IELT-d). The delta (d) is the velocity associated with LT minus half of the difference between vLT and 50% of MAV (For a LT corresponding to 75% of MAV: vLT-d=62.5% of VMA:[75-[(75-50)/2]]). We calculated the TotO2 in absolute value (ml.kg-1) and in relative value i.e. related to covered distance and mean intensity (ml.kg-1.km-1.km.h-1). After, we determined the TotO2 during the first part of IE50 (IE501) and IELT-d (IELT-d1) i.e. while basing ourselves on IELT total exercise duration (tlim-tlimIEP501 and tlim IELT-d1=tlim IELT). Results: tlim was significantly longer for IE50 than IELT ($p<0.001$) and IELT-d ($p<0.01$) and it was significantly longer for IELT-d than IELT ($p<0.05$). TotO2 in absolute and relative values were significantly lower during IELT compared with IE50 ($p<0.001$) and IELT-d ($p<0.05$), and they were significantly higher during IE50 compared with IELT-d ($p<0.001$).The same results were observed for TotO2 determined as a function of IELT tlim. Discussion: Our results highlight that TotO2 is more significant during IE50 than during IELT or IELT-d. It can be explained by the fact that oxygen uptake could depend on muscle structure. Thus, when more and more

motor units are recruited at higher speeds, the importance of Type II fibers increases together with anaerobic energy metabolism (Kyröläinen et al., 2003), that is why we could think that TotO2 decreases while recovery running speed increases. Thus, it seems that recovery at 50% of MAV could lead to a higher aerobic system solicitation because of a longer exercise duration and a more higher TotO2.

PLASMA GLUCOSE, ENERGY EXPENDITURE, VO2MAX AND POWER MARKERS AFTER A RUNNING-BASED ANAEROBIC SPRINT TEST (RAST) IN FEMALE COLLEGE STUDENTS

Ghanbari-Niaki, A., Fathi, R., Ghorbanalizadeh-Ghazian, F.

Tarbiat Modares Universit (TMU), Iran

Anaerobic power and capacity are two key physical variables in power and sprit sports. It seems that Wingate anaerobic test is more common for assessment of the anaerobic power and capacity. However , there is another less known field anaerobic test for this matter named Running-Based anaerobic test (RAST) which is reliable for anaerobic power and capacity measurement. The purpose of this study was to assess plasma glucose, HRmax, VO2 max , and maximum ,average power and fatigue index, and energy expenditure after two consecutive RAST in female college students. Twenty-six female physical education students (age 22.34±0.3 year, 160.2 ± .84cm,55.65 ± 1.6 kg, 21.62 ± 0.48 in BMI, and VO2 max 36.3 ± 3ml/kg/min-1)(Shomal University Amol , Mazandarn) volunteer to participated in the present study. Subjects were asked two RAST sparated with 1 minute rest. A paired T student was used for analysis Plasma glucose concentration significantly (P<0.01) was higher the end of test. HRmax, VO2max, and energy expenditure were significantly (P,0.01) increased after second test. A significant (P,0.01) reduction in Power max and Power Avawere observed. The present study provide the first data about glucose response and VOmax , and HRmax and energy expenditure to RAST. RAST can be used as a stimulus for some exercise-induce adaptation for power and sprint-base sports.

THE SIGNS OF STRAIN AND DISABILITY CARDIOVASCULAR ADAPTATION TO THE TRAINING LOADS IN ELITE ATHLETES

Yashchenko, A.

State scientific research institute of physical culture and sport, Ukraine

It is general accepted that the most possibilities for realization of functional reserves of the athletes and for increasing their special workability are depending on improving the exercise programmes. In such case stays not enough appreciate the functional fitness of the athletes. Meanwhile the effectiveness of the training process, especially in modern sport conditions, considerably depends namely from the adaptation of active functional systems in the athletes to the training and performance loads.

Complex and regularly control of the athletes' functional fitness provides with double connection between the coach and the athletes, as also can assist to increasing the special workability of last one. Detail knowledge on the character and intensity the signs of functional system adaptation or on the appearance the strain's signs of adaptation are the crucial with regard to the increasing of the special workability of the athlete.

The purpose of this presentation is to review the main signs of cardiovascular system adaptation's strain to training loads with taking into account the direction.

It was shown that initial sings of strain adaptation in some functional systems are reversible [1]. Using the regular control for functional fitness of the athletes, it is possible to correct as the volume and intensity, as also the character of the training loads for control of the effectiveness of these measure. The main signs of adaptive strains or disturbances in systemic blood circulation are increasing the heart rate during rest conditions above 80.0 b•min-1, systolic arterial pressure (APs) above 140 mm Hg; diastolic arterial pressure (APd) above 95 mm Hg; decrease the cardiac index (CI) under 2.0 l•min•m-2; increase the total peripheral resistance of the vessels more than 2500 din•s•sm-5.

As concern the signs of the strain in peripheral circulation adaptation they are for brain blood circulation following: asymmetry of the pair hemodynamic parameters above 25 %; increase the vascular tone of arteriole and venule above 90 %; appearance of the signs of venous outflow disability and diminishing of the blood supply in the studied vascular region. As concern the muscle circulation it is necessary to stress that some of signs, with the strain adaptive shifts are similar to sings of disability for brain blood circulation, only one peculiarity of these shifts is the decreasing the vascular tone of arteriole and venule under 25 - 30 %, it is necessary to add that such decreasing as usual manifests only on the one side of extremity.

WAYS OF SOLUTIONS IN THE FORCE-SPEED RELATION IN THE TRANING OF JUNIORS RUNNERS – THE EVENT: 100 M HURDLES

Mihailescu, L., Mihailescu, N., Mihailescu, L.

University of Pitesti, Romania

In sprint runs, hurdles, the athlete defeats the force of resistance of his own body; he develops the suitable speed for defeating those forces of resistance and tries to maintain the index of the maximum speed during the distance of the contest.

The classic conception concerning the development of the muscular force aims at the rise of the mechanical force by using the weight lifting, which leads to a reduction of the speed according to the Hill relation.

The purpose of this paper is to validate the truth of this hypothesis which laid at the basis of this research: training using the system of simulation of condition II. ERGOSIM can establish the growth of the force at maximum and minimum speed required in events as hurdles sprint.

The main method of research was pedagogical experienced; those who took part in this experiment were 12 juniors II (16-17 years old) hurdles runners.

As a work experience in training of forces at maximum and minimum speed it was used the system of simulation of condition II. ERGOSIM technology worked out by the National Institute of Research, Bucharest.

Those exercises used on the system of simulation were: drives, attack, trailer, the foot extension.

If the speed and the charge can be shaped, than the exercise can be performed with the characteristics selected by the coach.

During the experiment one can establish: mechanic work, the time work, length, active power and speed, the movement of the set upon foot at a speed of 6.5 m/s.

The results of the experiment confirm the hypothesis of work: the sportswomen improved their strength simultaneous with the technical improvement of their own exercises with feed-back reactions offered by the work technology.

- The training method based on the ERGOSIM system of simulation : emphasises the link between speed – strength during the hurdles runner's training
- The perfect synchronization between force and speed leads to best results concerning both the physical training and the competition.

COMPARISON BETWEEN CONTINUOUS AND INTERMITTENT TRAINING IN CHILDREN 8-11 YEARS OLD CHILDREN

Baquet, G., Dupont, G., van Praagh, E., Berthoin, S.

Faculty of Sport Sciences and Physical Education, University of Lille, France

Introduction: The knowledge of time to exhaustion (TTE) is an easy way to indicate which exercise duration is acceptable for an individual. However, it is not possible to measure multiple TTE. An alternative is to calculate general performance models based on the linear relationships between exercise distance to exhaustion (DTE) and TTE (convenient: critical velocity concept). The purpose of this study was to compare running performances obtained either by continuous or short intermittent high-intensity running exercises, and to apply the critical velocity concept on a prepubescent children population. Methods: Eleven 8 to 11-year-old children underwent a maximal graded field test to determine peak oxygen uptake (peakVO2, Cosmed K4b2, Italy) and maximal aerobic velocity (MAV), three continuous runs (90%, 100%, and 110% of MAV) and three intermittent runs (120%, 130%, and 140% of MAV) until exhaustion. Intermittent exercises consisted of repeated 15-s runs separated by a 15-s passive recovery. For continuous and intermittent exercises, linear DTE versus TTE relationships were calculated to determine continuous (CVc) and intermittent (CVi) critical velocities. Result: Values for peakVO2, and MAV were 45.8±5.3 ml.kg-1.min-1 and 10.5±1.0 km.h-1, respectively. Mean continuous TTE were 551±173s, 278±93s, 137±38s at 90%, 100%, and 110% of MAV, respectively. Mean intermittent TTE were 421±121s, 233±56s, 136±34s at 110%, 120%, and 130% of MAV, respectively. A significant relationship was found between mean DTE and TTE for continuous ($r^2=0.99$, $p<0.05$) and intermittent ($r^2=0.99$, $p<0.05$) exercises. Mean values for CVc and CVi were 9.0±1.0 km.h-1 (85.5±3.8 %MAV) and 11.4±1.2 km.h-1 (108.0±6.1 %MAV), respectively. A significant relationship ($r^2=0.86$, $p<0.001$) was noticed between CVc and CVi. Significant relationships were found between peakVO2 and both CVc ($r^2=0.60$, $p<0.01$) and CVi ($r^2=0.47$, $p<0.05$). Discussion: In prepubertal children a linear relationship was observed between DTE and TTE for 15s/15s intermittent exercises. PeakVO2 was significantly correlated to CVc, and to a lower extend with CVi, suggesting that this parameter is an index of aerobic fitness. Continuous aerobic performances are mainly determined by peakVO2, energy cost of running, or velocity at ventilatory/lactate thresholds. Additional factors such as a faster adjustment of energy production to energy requirement at the onset of exercises and a faster recovery may influence intermittent performances, and explain the lower coefficients of determination observed between VO2peak and CVi than between peakVO2 and CVc. In conclusion this study provides original data on children's intermittent performances and shows that the "critical velocity" concept can successfully be applied to children's intermittent performances. Moreover, it is of practical interest that the intermittent exercise duration (repetition of 15-s runs) can be adapted to the abilities of the child.

A STUDY OF AN ELITE BACKSTROKE SWIMMER WHO MADE RAPID PROGRESS

Yoshimura, Y., Tanaka, T., Oishi, K., Yasukawa, M., Matsuo, A.

Chuo University, Japan

A speed meter that measures a subject's moving velocity by pulling a fine wire over a generator (Maglischo, 2003) for a distance of 25 m was developed for use with competitive swimmers. In our previous study, the authors used the speed meter to check for skill differences between competitive breaststroke swimmers of international achievement and collegiate breaststroke swimmers who had not reached national or international levels. The results showed that this method was useful for identifying differences in skill between the two groups of swimmers. In this study, the authors used the speed meter to determine skill changes for a male collegiate backstroke swimmer who made very rapid progress over the course of one year. The subject improved 1.38sec for 200m backstroke swimming (an improvement about 1.16%) within 12 months. A computerized video analysis of his 200m backstroke races both before (120.17 sec) and after improvement (118.79 sec) revealed that the primary reason for his reduced time was an improvement in his underwater dolphin kicking. The speed meter was also used to record his intracyclic velocity changes during a 25m maximum effort backstroke swim which included approximately 12 m of underwater dolphin kicking. Speed meter measurements were made before, and after the swimmer improved his time for the 200m backstroke. The speed meter velocity curves indicated that his mean velocity was significantly greater during underwater dolphin kicking after the time improvement took place (Wilcoxon rank sum test, $p=0.02518$). Before and after improvement velocity curves for both the up-kicking and down-kicking of one complete dolphin kicking cycle were compared. It was concluded that the down-kicking was the most improved portion of the dolphin kicking cycle. The mean velocity of the up-kicking before improvement was similar to that after improvement (Wilcoxon rank sum test, $p=0.05958$). However, the mean velocity of the down-kicking after improvement was significantly higher than before improvement (Wilcoxon rank sum test, $p=0.00025$). These results suggested that improved down-kicking during the underwater dolphin kicking was primarily responsible for this swimmer's improved performance.

CAFFEINE HAS A TRIVIAL EFFECT ON 5 KM RUNNING PERFORMANCE

O'Rourke, M., O'Brien, B., Knez, W., Paton C.

University of Ballarat, Wintec, Australia

Purpose The purpose of this study was to investigate whether caffeine ingestion improved 5 km running time trial performance in endurance and recreational athletes. Methods 15 endurance trained and 15 recreational athletes consumed either 5 mg.kg-1 of caffeine (No Doz) or placebo approximately one hour prior to performing a 5 km time trial on a 400 metre running track in a double blind randomized cross-over study. Results Data is reported as mean ± standard deviation. The endurance trained group completed the 5 km time trial in 1047 ± 69 seconds in the caffeine treatment and in 1058 ± 68 seconds in the placebo treatment. The recreational athlete group com-

pleted the 5 km time trial in 1286 ± 86 seconds the caffeine treatment and in 1298 ± 84 seconds in the placebo treatment The improvement in 5 km time trial performance in the caffeine treatment was statistically significant for both the endurance and recreational athlete groups ($p < 0.05$). Conclusion Our results show that caffeine ingestion will improve 5 km running time trial performance by approximately 12.5 s in endurance trained and recreational athletes. However, the improvement in running performance attributed to caffeine is similar to the re-test error of 1 and 1.4% for the endurance trained and recreational athlete groups. Therefore caffeine only has a trivial effect on 5 km running performance.

A META-ANALYSIS OF SINGLE-SET VS. MULTIPLE-SET-TRAINING

Fröhlich, M., Gießing, J.

University of Saarland, Germany

Introduction: Single-set training (SST) has gained popularity as an alternative training method to multiple-set training (MST). Proponents of SST point out that SST produces similar results as MST but requires less much training time. However, many trainees, especially those who compete on an elite level, still apply MST. Methods: 52 primary studies with a total of 1934 subjects were analysed according to an open a priori coding scheme. The meta-analysis consisted of a descriptive analysis of all 52 studies, looking at several aspects of testing and training methods, specifications concerning methods and evaluation of each primary study as well as an analysis of the conclusions drawn by the authors. 19 of the 52 reviewed studies presented enough data to calculate the effect size (ES) for the factor "increase in 1-RM" which made it possible to compare the effectiveness of SST to that of MST. Results: 75% of the primary studies contained information concerning training parameters. Intensity ranged from 40 to 90 % of 1-RM, however, no study contained explicit information concerning which degree of training intensity was applied. Total training sessions averaged 42.0 +/- 27.8 over a period of 14.9 +/- 9.2 weeks. 2.8 +/- 0.7 training sessions per week were performed. 75% of the primary studies presented information on the testing procedure used. Although MST showed an insignificant advantage of efficiency of 61.4 %, there were no consistent significant differences between SST (ES = 0.70 +/- 0.69) and MST (ES = 1.13 +/- 1.06) ($t(1, 26) = -1.27$; $p = 0.21$). No significant differences (main effect) were found for the factors "number of subjects" (more or fewer than 30 subjects) ($F(1, 24) = 1.38$; $p = 0.25$) and "age" (younger or older than 22 years) ($F(1, 20) = 0.03$; $p = 0.86$). A significant difference (main effect) between SST and MST was found for the criteria "trained/untrained subjects" ($F(1, 24) = 12.88$; $p < 0.01$). When periodization was applied, the following results were found: a) main effect number of sets ($F(1, 24) = 1.63$; $p = 0.21$); b) main effect periodization ($F(1, 24) = 2.03$; $p = 0.17$) and c) interaction ($F(1, 24) = 0.22$; $p = 0.64$). Discussion and conclusion: The majority of the primary studies favour MST (cf. Fröhlich in press). Studies which favour SST show similar but not superior improvements of 1-RM-strength. Although there is a lack of information concerning the factor "training intensity" in the studies reviewed, the results of this meta-analysis imply that SST appears to be an appropriate method for untrained persons, recreational athletes or those whose primary goal is improving their health whereas MST appears to be more appropriate for experienced athletes in general and elite competitive athletes in particular.

THE AEROBIC POWER IN RELATION TO SUSTAINING OF HIGH TRAINING LOADS IN YOUNG GYMNASTICS

Sawczyn, S., Zasada, M.

Academy of Physical Education and Sport, Gdansk, Poland, Poland

Introduction. It is known that maintenance of short-term, intense exercise as it proper for gymnastic exercises relies on high rate of ATP regeneration, an increase glycolytic flux, and production and accumulation of metabolites. But recovery from bouts of such exercise as it takes place in gymnastic training session may be related to aerobic capacities. We supposed that aerobic power of gymnasts may agent of training stability. Study of the level of aerobic power in relation to survivability of training loads in the best young gymnastics was the purpose of the research.

Methods. Twenty male 13-17 years old gymnasts performed test of maximal oxygen uptake (VO2 max) in incremental test protocol and 30 s anaerobic tests. Monitoring of training loads by S. Sawczyn (2000) and sports results stability (CV) has been made for one year before measurements. The comparison was made for the best gymnasts (group 1, n=7) and remaining part of young athletes (group 2, n=13).

Results. Results showed that calculation of VO2 max (kg body mass) has shown presence of the tendency to their decrease with age in-group 2. The analysis has shown a large range of oscillations of personal levels of VO2 max - from 39,5 up to 63,9 ml.min-1·kg-1. The range of oscillations for the «perspective» gymnasts was smaller - 46,3 - 63,9 ml.min-1·kg-1. The mean value of VO2 max in-group 1 was significantly more than in-group 2 ($p<0.05$). The analysis for all gymnasts' shows significant interrelation of VO2 max with a volume of training loads ($r=0,60$; $p < 0.05$) and the tendency interrelation with sport results stability ($r=0.41$; $p<0.1$). The interrelation of aerobic and anaerobic power for the young «perspective» gymnasts only was significant ($r=0,65$; $p<0.05$).

Conclusion. The results confirm the suggestion about a role of aerobic power for successful process of training of young gymnasts. It was connected with the main role of aerobic power in overall physical working capacity and in recovery possibilities. In this connection there is a necessity taking into account of the standards of general working capacity for different stages of long-term preparation of young gymnasts. The data can indirectly testify to the relevant role of interdependent development anaerobic and aerobic power, as a factor of increase of general special training endurance capabilities.

INFLUENCE OF RESPIRATORY TRAINING ON ATHLETES' CARDIORESPIRATORY FAST KINETICS AND SENSITIVITY TO CO2 AT FATIGUE INDUCED BY EXHAUSTIVE TRAINING SESSIONS

Tomiak, T., Mishchenko, V.

Academy of Physical Education and Sport, Gdansk, Poland, Poland

Increased (in relation to volume of lung ventilating) the activity of respiratory muscles in some cases induce increase of cardiorespiratory (CR) reactivity (Mishchenko V et al, 2004). It may be related to CR response to exercises in training session. There is unknown the effects of respiratory training on CR reactivity changes at fatigue induced high training loads. The purpose was to determine the influence of respiratory muscle training (RMT) on CR sensitivity to hypercapnia and fast kinetics in endurance athletes at fatigue induced several exhaustive training sessions.

Sixteen high performance rowers 18-24 yrs (VO2 max=69.7±1.5 ml.kg-1.min-1) executed special designed intermittent type of training exercises, which consist in 5 exhaustive training sessions for week. It was weekly high loading micro cycle of high performance rowers. Part of rowers (n=9) in final part of training sessions were performed RMT (3 x 30 inhalation at about 70% of max power, Powerlung). The other part of rowers (n=7) did not conduct RMT. The lung ventilation response sensitivity to hypercapnia (ΔVE/ΔPACO2, re-breathing) and fast kinetics (T50) of VE, VO2, VCO2 (breath by breath) and HR in monoexponential function (5 min exercise 2 wt.kg-1, "Concept 2") were measured before and 12-14 hours after last training session of the micro cycle. Mean power and blood lactate (1-st min recovery) at sport specific 6 min max rowing test were measured before and after the micro cycle of training.

The results showed that CR sensitivity to hypercapnia of rowers without RMT was significantly decreased (-19.6±4.6%, $p<0.05$) 12-14 hours after the last exhaustive training session of weekly micro cycle. There were no significantly changes of CR sensitivity to hypercapnia in rowers, who applied RMT in final part of training sessions (-4.7±0.9%, $p>0.05$). The decrease of CR sensitivity to hypercapnia was related to increase T50 of VE, VO2, and VCO2 (r= -0.71; -0.67; and –0.70 respectively, $p<0.05$). Mean power of 6 min max rowing test was higher (8.9±1.1%) and blood lactate was lower (6.7 ±0.7%) after the exhaustive training sessions in rowers that applied RMT in comparison to group rowers that did not used RMT ($p<0.05$). The utilization of VO2 max in 6 min max test was significantly higher also in rowers that used RMT (12.9±1.7%). Before the exhaustive training sessions there were no significant differences those indices.

The results showed that fatigue induced by several consecutive exhaustive training session influences were connected with transient decreases of CR sensitivity to CO2 and CR fast kinetics. RMT applying in several exhaustive training sessions resulted in maintenance of CR responsiveness in exhaustive micro cycle of training and thus has the fatigue correction effect.

Mishchenko V, Tomiak T, Kuehne T (2004) Influence of respiratory muscle training on cardiorespiratory response sensitivity and fast kinetics in endurance athletes.9th Congress ECSS:189.

THE COMBINED EFFECT OF TIME OF DAY AND MENSTRUAL CYCLE ON VARIOUS METABOLIC VARIABLES

Forsyth, J., Reilly, T.

North East Wales Institute of Higher Education and Liverpool John Moores University, United Kingdom

The combination of diurnal and circamensal rhythms and their effect on performance has not been investigated extensively. In women, menstrual cycle phase could interact with circadian variations, and by not controlling for time of day, underlying effects may be accentuated or masked. The purpose of this study was to examine the isolated and combined effects of time of day and menstrual cycle phase on various metabolic variables in response to incremental exercise. Eleven female, endurance-trained athletes (mean±SD age, 32.4±6.9 years) completed a continuous, multi-stage, 3-min incremental protocol to exhaustion on the Concept II rowing ergometer at 06:00 h and 18:00 h and at two phases of the menstrual cycle, the mid-follicular and the mid-luteal phase. Rectal temperature (Trec) was measured at rest; power output, oxygen consumption (VO2), pulmonary ventilation (VE), heart rate (HR), respiratory exchange ratio (RER) and blood lactate concentration were recorded at rest, throughout the exercise test, and post-exercise. There was a significant ($F1,10,=12.00$, $p=0.006$) menstrual cycle phase effect for Trec, with mean values being higher in the mid-luteal phase compared to the mid-follicular phase. There were no significant circamensal differences in resting or maximal values of VO2 and RER. Mean maximum values for VE reached significance ($F1,10,=4.96$, $p=0.05$), being higher in the mid-luteal phase than in the mid-follicular phase (77.3±15.6 and 74.7±15.7 l.min-1, respectively). Although no differences existed for HR at rest, at maximum exercise, values were significantly higher ($F1,10,=5.47$, $p=0.041$) in the mid-luteal phase. Mean resting VO2, VE and HR were significantly higher at 18:00 h than at 06:00 h in both phases of the menstrual cycle, coinciding with the peak in Trec. There were no significant differences due to time of day for maximum values of HR, VO2, VE and RER. Interaction effects for values of maximum blood lactate concentration approached significance ($p=0.06$), being higher at 18:00 h than at 06:00 h, and higher in the mid-follicular phase compared to the mid-luteal phase. In this instance, the elevated levels of blood lactate concentration observed in the mid-follicular phase were more apparent when tests were carried out in the evening compared to the morning. Although interaction effects were not apparent for the majority of variables measured, the findings suggest that, when using metabolic variables in physiological assessment, independent consideration should be given to the menstrual cycle phase and time of day in which the test is carried out.

STRUCTURE OF TECHNICAL PREPARATION OF ACROBATS

Niznikowski, T., Sadowski, J., Booban, W., Mastalerz, A., Niznikowska, E.

Józef Pisudski Academy of Physical Education in Warsaw, Poland

The increasing of complexity and difficulties of programs' range for gymnastic competition introduced by International Federation of Gymnastic (FIG), is manifested by the new, more effective means, forms and methods of teaching. Therefore complexity of motion structure causes unknown difficulties in teaching process.

Diagnostic questionnaire, pedagogical experiment, literature analysis and poll questionnaire were applied to the group of acrobatics coaches (n = 25, length of work – 20-45 y.). Cinematographic analysis systems were also used to analyze acrobatic jump (n = 30, age 11 – 25 y., 60 Hz - JVC GR – DVL9800 NTSC camera and APAS 2000 - Ariel Dynamics Inc).

Structure analysis of acrobats technical preparation (PT) allows to formulate their three components. It was established, that described components are suited to long-term sport improvement: "motion school" – versatile period, special technical preparation – direct period and sport technique of competition exercises – expert period. Such components are functionally connected to each other, and they support training process.

Results received from pedagogical experiment allow to affirm that special technical preparation with biomechanical indices of junction elements performance in acrobatic evolution is more effective ($p<0,05$) then traditional manner of training.

MODIFICATION OF CYCLING BIOMECHANICS DURING A SWIM-TO-CYCLE TRIAL

Delextrat, A., Tricot, V., Bernard, T., Vercruyssen, F., Hausswirth, C., Brisswalter, J.

London Metropolitan University, United Kingdom

The recent apparition of multi-sport activities, such as triathlon (swimming, cycling, running) raises many questions relative to the influence of locomotion mode transitions on kinematic adaptation during each discipline. The aim of this study was to investigate the influence of a prior 750-m swim on cycling kinematics, and to relate these alterations to the metabolic demand of cycling. Eight well-trained male triathletes underwent three sub maximal sessions in a counterbalanced order. These sessions comprised a 10-min ride on a cycle ergometer at 75% of maximal aerobic power (MAP) and at a freely-chosen cadence. This exercise was preceded either by a 750-m swim

performed alone at competition pace (SCA trial), a 750-m swim in a drafting position (i.e., swimming directly behind a competitor) at the same pace as during SCA (SCD trial) or a cycling warm-up at 30% of MAP for the same duration as the SCA trial (CTRL trial). A number of biomechanical and physiological parameters were measured during cycling. Differences between SCD, SCA and CTRL trials were analysed using a Wilcoxon test. The level of confidence was set at 0.05. No significant difference between SCD and CTRL trials was observed for all the parameters measured. When compared to SCA trial, the swimming bout of SCD trial was performed with significantly lower heart rate values (-6.4%, P<0.05) and blood lactate values (-28.8%, P<0.05). This decrease in swimming metabolic cost was associated with a significantly lower pedal rate (85.0±6.2 vs. 90.2±8.8 rev.min-1, P<0.05) and significantly higher mean torque exerted during the downstroke of the dominant leg (31.3±3.2 vs. 30.2±3.5 Nm, P<0.05), mean torque exerted during the downstroke of the non dominant leg (29.8±3.4 vs. 28.6±3.5 Nm, P<0.05), peak torque exerted during the downstroke of the non dominant leg (44.8±6.6 vs. 43.6±6.9 Nm, P<0.05) and gross efficiency (19.5±1.6 vs. 18.5±0.6%, P<0.05) in SCD trial vs. SCA trial. It could be suggested that following the high intensity swim (SCA trial), involving a possible decrease in leg muscular capacity, the subjects intrinsically adopted a pedal rate close to the theoretical mechanical optimal cadence (90 rev.min-1, Neptune et al., 1999) in order to minimize neuromuscular fatigue. Conversely, following the swim at lower relative intensity (SDC trial), the subjects were less fatigued and therefore spontaneously chose a lower pedal rate associated with higher torques, but a lowest energy expenditure (Brisswalter et al. 2000). VALIDITY OF UNIAXIAL ACCELEROMETRY ESTIMATING THE ENERGY EXPENDITURE OF WALKING AND RUNNING IN EARLY CHILDHOOD

Sunami, Y., Shiomi, Y., Okishima, K., Nishimuta, M., Yoshitake, Y., Adachi, M.

Fukuoka Jo Gakuin University, Japan

It is known that low levels of physical activity and physical fitness during childhood increase the risk of obesity leading to life-style-related diseases later in life. There are a number of different techniques that have been used to assess energy expenditure and physical activity. According to these assessments, accelerometry was thus found to be a useful method for measuring the intensity, duration, energy expenditure, and the step rate of daily physical activities for youth, adults and elderly. The purpose of the present study was to evaluate the validity of a uniaxial accelerometer which estimated energy expenditure of walking and running for early childhood in comparison to oxygen consumption and metabolic equivalents (METs).

The subjects considered of eleven male healthy children who were all 6 years old. After the experiment was explained, informed consent was obtained from the parents of all children. Each subjects underwent a submaximal exercise test at two walking speeds (3.0, 5.0 km/h) and one running speed (7.0 km/h) on a treadmill at a 0% grade. The duration of each stage was set at 3 minutes. During the walking and running, each subjects wore a uniaxial accelerometer (Lifecorder, Suzuken Co. Ltd, Japan) on their waist belt. Each grade of exercise was separated by a two-minute rest periods. Expired air was collected in a Douglas bag using the standard open circuit spirometric techniques during the last one minute of each work load. The volume of expired air was quantified with a respirometer. The VO2 and VCO2 were calculated by measuring the oxygen and carbon dioxide concentrations using mass spectrometry (ARCO-1000, ARCO System Co. Ltd, Japan). Furthermore, after overnight fasting for 12-14 hours, the subjects were walked calmly to kindergarten from their home. Thereafter, all subjects rested on a chair for over ten minutes before the resting metabolic rate was measured. In this study, MET values was directly measured for each subject by dividing the measured energy expenditure by their resting oxygen consumption. Energy expenditure was calculated using a simplified version of Weir's formula.

The activity level of walking and running estimated by means of an accelerometer showed a significant increase from 3km/h to 5km/h, and also from 5km/h to 7km/h. The activity levels measured by the Lifecorder correlated positively with the VO2 ($r=0.88$, $p<0.001$), METs values ($r=0.83$, $p<0.001$) , and the energy expenditure as calculated by Weir's formula ($r=0.90$, $p<0.001$). Based on our obtained data, we consider the threshold of walking to running intensity in early childhood to be about 3 to 4 METs, and 6 to 7 activity levels detected by Lifecorder.

The findings of the present study suggest uniaxial accelerometry to be a valid and reliable device for quantifying walking and running in early childhood. Moreover, this device is also useful for assessing the physical activity corresponding to the MET categories for the children.

OCCURRENCE, CLUSTERING AND ASSOCIATION OF CARDIOVASCULAR RISK FACTORS IN ADOLESCENTS FROM PORTO (1998 – 2003)

Martins, C., Gaya, A.R., Silva, F., Ribeiro, J.C., Santos, P., Mota, J.

Faculty of Sports Porto University Catholic University of Brasilia - Brazil , Portugal

INTRODUCTION: Epidemiological studies have identified several risk factors for coronary heart disease, many of which are present in youngsters (McMenemy, 1999) and tend to cluster (Boreham et al.,1993). OBJECTIVE: The aim of the present study was to examine the occurrence of single cardiovascular risk factors as well as its clustering among two cohorts (1998 and 2003) of adolescents. METHODS: The sample comprised 248 adolescents (58 boys and 80 girls in 1998 and 44 boys and 66 girls in 2003), aged 14-15 years-old. Risk factors were the follows: BMI, calculated from the ratio of weight / height2; Systolic and Diastolic Blood Pressure were assessed according to procedures described by Gillman et al. (1995); Total cholesterol was analysed by Reflotron Analyser – Boheringer Mannheim Diagnostics, Indianapolis); Cardiorespiratory fitness was assessed by shuttle-run test from Fitnessgram (Prudential Fitnessgram, 1994). The cardiovascular risk factors (risks of obesity, hypertension, hypercholesterolemia and \low cardiovascular fitness) were determined by international cut-off points. Statistical analysis was performed using SPSS (Windows version 12.5). A two-tailed t-test and a qui-square test were used for comparison between cohorts. Pearson correlation and Multivariate linear regression analysis was used to determine correlation coefficients between various cardiovascular risk factors. Level of significance was set up at p≤0.05. RESULTS: Cardio-

respiratory fitness decreased significantly (p=.05) in boys and girls in the second cohort. In 2003, there were an increased percentage of adolescents with two or more CVD risk factors. The percentage of adolescents below the healthy zone of cardiorespiratory fitness increased for both sexes in 2003. Cardiorespiratory fitness was associated with BMI (p=.01) and its decrease was associated with increasing values of BMI for girls in 2003 (P=.04) as well as with clustering of CVD risk factors in boys in 1998 (p= .01). CONCLUSION: Upon five years, the percentage of adolescents in cardiorespiratory healthy zone decreased significantly in both sexes. CVD risk factors clustering tend to increase in second cohort. Decrease in cardiorespiratory fitness healthy zone was significantly associated with changes in BMI in girls.

DETECTION OF HEALTH AND FITNESS RELATED LEVELS OF TURKISH CYPRIOT CHILDREN THROUGH GRADING OF THEIR EUROFIT TEST RESULTS

Tnazc, C., Emiroglu, O., Burgul, N., Atamtürk, H.

Near East University, North Cyprus, Cyprus

To reveal the level of health and fitness in prepubescent children of Turkish Cypriot population 7425 EUROFIT test results of 9-11 years old junior school children from all 90 schools of North Cyprus were graded on percentile table. Height and weight measurements, test for skinfold thickness, flamingo balance test, plate tapping, sit-and-reach test, standing broad jump, handgrip strength, sit-up test, bend arm hang test, 10m*5 sprint and shuttle run tests were comprising 12 EUROFIT tests.

For this purpose each parameter of the EUROFIT test has been classified from 5% to 100% on the percentile scale. Consequtive grading of percentile table has given us ranges between 5 and 100 points for health and between 1 and 90 points for fitness related tests (some tests assessed both health and sports related fitness).

Analysis of obtained points has shown that children with 90th percentile of their test results and above were fit enough to be successfully engaged in sports activities, which vary with age and gender, whereas those children with data below 23rd percentile had risk of facing with health problems in the future.

Assessment of age differences of test results also indicated on different impact of this factor on health and fitness levels of children. We revealed that percentile level for fitness decreased with age progression, whereas increase of health related percentile threshold pointed out on increase of risk for health with children's age.

LEISURE PHYSICAL ACTIVITY OF UNIVERSITY REQUIRED PHYSICAL EDUCATION COURSE STUDENTS IN HONG KONG

Cheng, Y.C.

The Chinese University of Hong Kong, Hong Kong

Introduction:

The promotion of health is one of the essential issues of the University's physical education curriculum. It is hoped that through this emphasis, students will develop their own lifelong exercise habit before they graduate and are more conscious of the fact that a sedentary lifestyle and obesity are positive risk factors to coronary artery disease (ACSM, 2006). Students are made aware that developing a healthy lifestyle from as early as the teenage years would reduce their acquiring the above mentioned risk factors.

Method: 208 male and 234 female students, who enrolled the required physical education course in the Chinese University of Hong Kong, were invited to participate in this study. A self-report activity questionnaire (Godin, 1997) was modified to assess leisure time physical activity patterns of the students. The content of the questionnaire included measurement frequency of their weekly different intensity physical activities.

Results: Results of the overall findings:

1 The mean and standard deviation of body mass index of the male and female students were 20.8 ± 4.5 and 19.1± 4.5 respectively.

2. There was significant difference between the male and female students in their average weekly leisure time physical activity pattern scores. (Scores were 43.1 ± 28.3 and 33.3± 21.5 respectively. ($p<0.05$)

3. No significant difference was recorded in the comparison between the individual and team sports courses students in their average weekly leisure time physical activity pattern scores.

4. There was significant difference in percentage between the male and female students in their response to their engaging of weekly regular activity long enough to work up a sweat. The percentage of male and female students answered to "often, sometimes and never/rarely" were 23%, 64%, 13% and 8%, 59%, 33% respectively. ($p<0.05$)

Discussion: The findings showed that male students exercise more in their leisure time than female students. More male students responded that they would often engage in regular activity long enough to work up a sweat than female students. The different kind of sports in the physical education course had no effect on students' daily leisure time physical activities. The male students' weekly leisure time physical activity average score was less than 50, which was light to moderate intensity, relative to healthy adults. There is room for improvement in their exercise intensity as improvement would bring about a strengthening of their cardiovascular fitness. The content of the physical education curriculum could include inspiring and motivating students to exercise on a regular basis. The limitation in this study is the difficulty encountered in the measurement of actual energy expenditure in their daily physical activities. Future studies could focus on the reasons affecting students' preference for leisure activities and the comparison of leisure physical activity patterns among different university students in Hong Kong.

ECRES, A SOFTWARE TO PREVENT THE EXERCISE INDUCED HYPOGLYCAEMIA IN TYPE 1 DIABETIC PATIENTS: PRELIMINARY RESULTS

Francescato, M.P., Geat, M., Tosoratti, E., Noacco, C.

University of Udine, Italy

Empirical reductions of the insulin dose are often suggested to type 1 (insulin dependent) diabetic patients in order to face the increased glucose turnover during exercise (ADA, 1997). However, the occurrence of exercise is often unforeseen, hence changes of the insulin dose cannot be easily made, giving importance to additional glucose ingestion to prevent hypoglycaemia. We report here preliminary data obtained by means of a newly developed software (ECRES, Exercise Carbohydrate Requirement Estimating Software), which allowed us to estimate the additional carbohydrates (CHO) required to maintain glycaemic balance.

The software is based on previous results showing that the amount of glucose oxidized during exercise can be estimated from heart rate also in type 1 diabetic patients (Francescato, 2005) and that the amount of CHO required to prevent exercise-induced hypoglycaemia is linearly related to insulin concentration (Francescato, 2004). The software runs as follows. After a setting procedure, handling the patient's personal data and his/her specific therapy and training habits, the software processes actual exercise parameters, thus yielding the amount of CHO to be consumed before/during the effort.

Eight type 1 diabetic patients (6M, 2F; HbA1c 6.7±1.4%, duration of diabetes 20±7 years) aged 18-50 years, gave their voluntary consent to participate, after being informed on the possible risks. Average body mass and height were 68±11 kg and 175±11 cm. Patients were asked to perform up to eight 1-hour outdoor runs, scheduled at different daytimes and at two different intensities (as set by predetermined heart rates; HR). Half an hour before the start and/or during the runs, the amount of CHO calculated by ECRES was given to the patients (mainly in the form of sugar-drops). During the trials, patients wore a HR monitor (Polar, Finland) and maintained HR as constant as possible. Glycaemia was tested at regular intervals by means of commonly used reactive strips (Glucotrend glucose, Roche Diagnostics, Switzerland).

Overall, thirty-one runs were performed. HR amounted on average to 109±10 beats/min; glycaemia at the start of exercise was 9.1±2.5 mmol/L and decreased to 6.6±2.3 mmol/L at the very end of the trials. In spite of the spreading of the trials over the whole day and of the different exercise intensities, only in 8 trials (25.8%) the glucose level fell below 3.9 mmol/L during the run, requiring the administration of further amounts of CHO.

In conclusion, the preliminary results obtained applying ECRES are promising. The percentage trials for which ECRES provides a satisfactory estimate of the CHO requirement is high, suggesting that the software can be a useful tool for type 1 diabetic patients to prevent the exercise-induced hypoglycaemia.

HEALTH RELATED HABITS AMONG HIGH SCHOOL STUDENTS IN SLOVENIA

Jurak, G., Kova, M., Strel, J., Starc, G.

University of Ljubljana, Faculty of Sport, Slovenia, Slovenia

Heterogeneous individually determined lifestyles are characterised by the main characteristics of modern information time: the imbalance between passive and active relaxation, and the related sedentary life style (Armstrong & Welsman, 1997; Hardman & Marshall, 2000; Dietz, 2001; Jurak et al., 2003; Strel et al., 2004; Brettschneider et al., 2004); improper nutrition (Hurson & Corish, 1997; Cruz, 2000; Samuelson, 2000; Gabrijelčič Blenkuš, 2001, 2005; Brettschneider et al., 2004) and abuse of intoxicating substances (Currie et al., 2004).

On the sample of 664 high school students of both sexes, averagely aged 18,05 years (±1,41 years), we studied the extent of some unhealthy habits and estimated the differences in this habits between the general population of the high school students and athlete students.

The analysis was carried out with a questionnaire while the data was analysed with discriminant analysis, t-test for independent samples, the calculation of Pearson χ2 coefficient and the calculation of appropriate correlation coefficients.

In general there are differences in life styles between athlete students and other students. Athlete students show less unhealthy habits. In general, this confirms the hypothesis that there exists correlation between involvement in sport and healthy life styles.

Both groups of students were most clearly determined by smoking. This factor shows the highest correlation with other health-risk factors. The analysis of individual factors shows that athlete students eat more regularly than other students but that they eat less than recommended. Athlete students in general use less intoxicating substances but there are no differences in the use of some substances. Athlete students smoke less, use less soft drugs and drink less coffee, while there are no differences between the use of vine and energy drinks between them and the general student population. Athlete students attend weekend parties in the same extent as other students but in a healthier manner.

According to a poorly developed system of nutrition for athlete students it is recommendable that schools with sport classes implement a system of nutrition for these students that are individually planned and adapted to their individual needs.

PHYSICAL ACTIVITY AND PERCEIVED ENVIRONMENTAL CHARACTERISTICS IN A PORTUGUESE SAMPLE OF MEN

Santos, R., Ribeiro, J.C., Santos, P., Mota, J.

Faculty of Sports University of Porto., Portugal

Background: There is a reason to believe that physical environments variables play an especially important role in the level of Physical Activity (PA). Few studies have examined the association between environmental variables and level of PA in Portuguese adults.

Objectives: This study aims were: (1) - to evaluate differences in perceived neighbourhood environment according to PA level, and (2) to determine which, if any, perceived neighbourhood environmental variables were associated with reported PA levels in an adult population.

Methods: The sample comprised 3 226 men, aged 39.42± 9.57. A questionnaire using the Environmental Module of the International Physical Activity Prevalence Study assessed Perceived Neighbourhood Environments. PA was also assessed by questionnaire (International Physical Activity Questionnaire – short version) and used as the dependent variable. Subjects were classified in two categories according to their level of PA: inactive (participants that reported less than 150 min/week of at least moderate-intensity PA) and active (participants that reported 150 min/week or more of at least moderate-intensity PA).

Results:

The active men were more likely to agree ($p<0.05$) that Access to Destinations (i.e. accessibility of shops and transit stops), Infrastructure for Walking and Cycling, Social Environment (i.e. see others being physically active in the neighbourhood) and Aesthetics of the neighbourhood are important environmental features. Logistic regression analysis showed that Infrastructure for walking and cycling (OR= 1.309; p= 0.001), were related to being physically active.

Conclusions: Some perceived neighbourhood environmental attributes were found to be associated with level of physical activity in men.

AN ACCELEROMETRY METHOD TO TRACK THE EFFECTIVENESS OF A WALKING PROGRAM

Schutz, Y., Hills, A.P., Lecoultre, V., Terrier, P.

University of Lausanne, Switzerland / Queensland University of Technology, Australia, Switzerland

It is commonly suggested that daily moderate-intensity physical activity (PA) is an important factor in the prevention, treatment and management of obesity. Although a theoretical 0.3kg weight loss per week would be possible with 1h walking/day, many studies conclude that this value is rarely reached. Hypotheses used include 1) the added exercise induces higher food intake; 2) poor adherence to activity programs may occur; 3) compensation for extra-exercise by an increased placidity may be observed.

The objective of the present study was to assess the effectiveness of 3 different walking programs. We used a motion sensor (bi-axial accelerometer) able to record daily PA profile over several weeks. The device can measure: 1) number of steps per day; 2) estimated total energy expenditure; 3) duration of walking activities per day from an analysis of activity profile.

Seventeen young women participated in the study (body mass 60±11kg, height 165±7cm, Body Mass Index (BMI) 22.3±4.6kg/m2). Participants wore the accelerometer during 8 consecutive weeks, from which 2x2 weeks (i.e. before and after the 4-week prescription) were the baseline activity, without exercise prescription. Three different PA programs were randomly assigned to the participants: 1) 30min walking; 2) 60min walking; 3) 90min walking. The prescription involved the completion of additional walking periods to one's habitual activity in "blocks" of a minimum of 30min walking, 5 days per week during 4 weeks. Adherence to the program was evaluated by comparing the duration of walking objectively assessed by the accelerometer with the prescribed duration. We tested whether the extra-walking imposed was partly offset by a lower spontaneous PA in pre/post exercise periods by comparing the average baseline activity level with the level during the program weeks.

The PA programs increased the average number of steps per day as compared to baseline level by 21% (30min, N=6), 36% (60min, N=5) and 60% (90min, N=6), respectively. In terms of total daily energy expenditure, increases were 3.6%, 5.8% and 10.2 %, respectively. The adherence to exercise averaged 93±32% (N=17, range 22-141%), with no significant differences among groups. All participants compensated for the imposed extra exercise by diminishing their spontaneous walking activities, except one. On average, the basal activity level (i.e. excluding the exercise periods) decreased by 25±16%, with a higher effect seen with 90min exercise prescription (37±19%, $p<0.05$ vs 30min) than for 60min (19±12%) and 30min (18±8%).

Despite good adherence to the activity program, we found that a substantial part of the effect of exercise on total daily activity was lost due to a decrease in spontaneous activity in pre- and post- exercise periods. This may in part explain the mitigated effect of prescribed exercise encountered in the literature. However, the large inter-individual variability we observed requires the conduct of further investigations to better describe the compensation effect.

ANTHROPOMETRIC MEASURES AS RISK PREDICTORS OF CARDIOVASCULAR DISEASES

Glaner, M.F., Lima, W.A.

Catholic University of Brasília, Brazil

Cardiovascular disease (CVD) is the number one of the causes of death in Brazil, and the obesity has increased. The major risk factors for CVD are elevated serum total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), triglycerides (TG), guclose (GL) and low serum high-density lipoprotein cholesterol (HDL-C) associated to %fat (%F) and topography fat distribution. The %F and topography fat distribution can be measured by anthropometric technique. The aim of this study was to verify how much those risk factors can be influenced by the %F and by different anthropometric measures. Were measured 76 men, with age = 34,4 +/- 9,4 years; stature = 168,6 +/- 7,3 cm; body mass = 73,2 +/- 10,6 kg; %F = 21,3 +/- 8,4 (dual-energy X-ray absorptiometry). The Blood to estimate TC, LDL-C, HDL-C, TG and GL was taken from the antecubital vein, after 12-hour overnight fast. These variables were analyzed using the enzimatic spectrophotometric technique (reagent: doles; Bioplus, BIO-2000). Stepwise regression analysis was used to determine the influence of the %F and anthropometrics measures in the risk factors. The independent variables were used: %F; body mass index (BMI); waist-to-hip ratio (WHR) (WHR1: abdominal perimeter 2.5 cm (ABp2.5) above to the umbilicus; WHR2: abdominal perimeter above to the umbilicus), neck perimeter (above to the laryngeal prominence), familiar history of CVD; diastolic and systolic blood pressure; body image perceive by researcher (BIPR) and by volunteer (silhouette: Stunkard et al., 1983). The mains results were: TC = 130,532 + 2,072 (%F), (R= 0,450, R2= 0,202, p= 0,0005); HDL-C = 51,627 – 2,472 (SPA), (R= 0,349, R2= 0,122, p= 0,002); LDL-C = 63,540 + 1,860 (%F), (R= 0,408, R2= 0,166, p= 0,0005); TG = 183,126 + 4,007 (ABp2,5), (R= 0,396, R2= 0,157, p= 0,0005); GL = 66,675 + 0,308 (ABp2,5), (R= 0,249, R2= 0,062, p= 0,030). The results shown that %F influences in 20,22% the TC and 16,6% of the LDL-C. The BIPR explained 12,2% the HDL-C. Whereas, the TG and GL are most influenced (TG 15,7%; GL 6,2%) by the ABp2.5. The remainder independent variables did not influence significantly the risk factors. By and large the ABp2.5 is the anthropometric measure that more influences the TG and GL. The %F is the variable that more influences the TC and LDL-C. In this manner, the ABp2,5 and %F are the better signs to CVD than the usual BMI and WHR. Therefore, it is important to avoid fat accumulation, essentially in the trunk, to prevent the precocious development of CVD.

PREDICTABILITY OF CARDIOVASCULAR FITNESS AT AGE 35 YEARS FROM BMI IN EARLY VERSUS LATE MATURING CHILDREN: A LONGITUDINAL STUDY

Taeymans, J., Hebbelinck, M., Borms, J., Abidi, H., Duquet, W.

Internationale Akademie Physiotherapie , Switzerland

Introduction

In adulthood, high VO2max is correlated with a decrease of cardiovascular disease and is important for sucess in many sports (1). It was the aim of this study to investigate the possible relationships between childhood BMI and some cardiovascular fitness (CVF) variables at age 35 yrs in former early and late maturers.

Methods

For this study, data of the Belgian longitudinal "LEGS", were used (2). Of the original 515 subjects who had been followed from 6 to 18 yrs of age, 119 (M=59; F=60) participated in this follow-up study at age 35 yrs. Informed consent was obtained. CVF can be expressed in terms of systolic (SBP) and diastolic (DBP) blood pressure and heart rate at rest (HR) and in terms of VO2max during exercise. At rest SBP and DBP, HR, height and weight were measured. VO2max was directly assessed during an incremental bike ergometer protocol until exhaustion. Age at peak height velocity (PHV) was calculated using the JPA method and software (3). Early (EM), moderate and late maturity (LM) groups were established using tertiles. For statistical analysis the SPSS 12.0 was used. Pearson correlations (r) were calculated. Significance was set at 5%.

Results

In EM girls BMI of all ages show moderate to very strong negative r (-0.4<r<-1.0) with VO2max at age 35 yrs (p<0.05).There are moderate and positive r (r>0.4; p<0.05) with HR, except at ages 13 and 14 yrs when r are weak (p<0.05). Correlations with SBP and DBP are positive low to moderate (0.2<r<0.5) until age 15 yrs but moderate to very high from age 16 yrs on (p>0.05). In former LM women, the r between childhood BMI and VO2max at age 35 yrs are very weak to moderate but negative (p>0.05), while r between childhood BMI and adult HR, SBP and DBP are very weak (until age 13 yrs) to moderate (from age 14 yrs on) but positive (p>0.05).In former EM men the r between childhood BMI and HR at age 35 yrs are positive weak to strong (r>0.6) and significant at the ages 7 and 11 to 18 yrs except at age 15 yrs. None of the other r are significant.This is also the case for all r between childhood BMI and CVF variables at age 35 yrs in former LM men.

Discussion

Our data suggest that former LM men and women have the more healthy cardiovascular outcome at age 35 yrs. In former EM women the predictability of adult CVF from childhood BMI values is very good. This is not the case in female LM. For each of the CVF variables prediction is not possible from BMI during childhood and adolescence in LM girls and in EM and LM boys. Our findings suggest that in the female subjects the childhood maturation status is discriminative for the predictability of selected adult variables of CVF (HR, SBP, DBP and VO2max) from childhood BMI.

Conclusion

Assessment of BMI in young EM girls may be a useful tool when screening them for adult CVF. In LM girls and in EM and LM boys, determinants other than BMI, will be needed to predict adult CVF.

A PILOT STUDY OF THE COMPARISON OF ATTITUDES TOWARDS PHYSICAL ACTIVITY AND EXERCISE HABITS OF ALUMNI FROM UNIVERSITIES WITH DIFFERENT PHYSICAL EDUCATION PROGRAMS IN HONG KONG

Leung, F.L., Wong, H.S.

The Chinese University of Hong Kong, Hong Kong

The purpose of this study is to compare the attitudes and exercise habits of alumni from universities in Hong Kong with different PE programs. The findings are useful in formulating a curriculum and developing strategies in promoting PA.

Method

Participants were selected from the alumni of two research universities in Hong Kong. These two universities were chosen because they are similar in their campus environments, facilities, and student population characteristics. University A has a PE course requirement, and two credit hours of PE courses are required for full-time undergraduate graduation. On the other hand, University B does not have a PE course requirement, as their PE courses are provided as part of a noncredit recreation program. One hundred alumni (University A: 50; University B: 50) who graduated between 2001 and 2005 were invited to take part in this pilot study. A self-administered questionnaire was sent to them through e-mail, and they were requested to complete and return it likewise by e-mail. The questionnaire collected demographic data from the alumni, as well as their attitudes and exercise habits.

Results

The overall findings were as follows:

1. A significant difference was found between the two universities with regards to their alumni's perceived value of their respective universities' PE programs in terms of its contributions to their knowledge on fitness. The alumni from University A significantly (p< .05) valued perceived knowledge more than the alumni from University B.

2. No significant difference was found between the two universities with regards to the alumni's perceived value of their respective universities' PE programs in terms of its contributions to their attitude toward fitness.

3. No significant difference was found on the alumni's exercise habits in terms of the number of minutes per exercise workout and the number of workouts per week.

Discussion/Conclusion

The required PE course appeared to have had a positive effect on the perceived knowledge on fitness of the alumni (University A) who completed it as compared to the alumni (University B) who were not exposed to such a course. However, this positive effect did not lead to any significant influence on the attitudes and exercise habits of the alumni. However, there are some limitations in our study. First, the findings were from two research universities of Hong Kong, which means that the majority of the survey participants came from upper-middle class backgrounds. The ability to generalize the findings in other universities with more diverse academic requirements and students from different socioeconomic backgrounds was limited. Second, this study examined PE activity program, implications for conceptually based PE programs may be limited. Future studies could focus on the comparison of the long-term effects of PE activity programmes and conceptually based PE programmes.

GESUND BEWEGT - MOVE FOR HEALTH AND THE ENVIRONMENT: PHYSICAL ACTIVITY PROMOTION IN GENERAL PRACTICES IN SWITZERLAND

Handschin, M., Joss, M.K., Nüscheler, M., Braun-Fahrländer, C.

Swiss Doctors for the Environment, ecos ag, Institute for Social and Preventive Medicine, Basel, Switzerland

Background

Physical inactivity is increasing in the Swiss population. A Swiss pilot project in 5 private practises in Zurich showed that systematic screening of patients by the doctor and subsequent counselling increased physical activity in patients.

Aim

The project Gesund bewegt aimed at developing and testing a model for a systematic screening and counselling of patients in primary health care institutions suitable for a large number of general practitioners. A minimum of 25 general practitioners from the Northwestern region of Switzerland was planned to be recruited.

Method

Primary care physicians were invited to participate in the project through mailing, journal articles, presentations at meetings and personal contacting by physicians of the project team. Participating practices carried out a systematic screening about physical activity of patients aged 16-65 years by means of a short questionnaire distributed to the patients when they visited the practise. Distribution of questionnaires occurred during several two-week periods from January 2004 to July 2005. People identified as inactive were offered a brochure or a voucher for individual counselling with a trained physical activity adviser.

Results

44 primary care physicians participated in the project. 13 physiotherapists and 5 doctors were trained and certified as physical activity advisers. Recruitment of general practitioners for participation in the project was most successful when effected through personal contacts of a colleague of the project group. Physiotherapists were mostly recruited through information in their professional journal and after a presentation at a meeting of their professional association. Introduction of participating physicians into the practical and theoretical details of the project was mostly (68%) carried out face to face in the practise of the respective colleague because attendance of an introductory workshops was poor due to lack of time. Once recruited into the project effort was devoted to keep the general practitioners in the project and to adapt the screening schedule most flexibly to the needs of the individual practices. Eight screening cycles were run, most practices took part in 4 or less cycles because more time than scheduled was needed for their recruitment. During the eight screening cycles 7'455 patients were eligible for recruitment to the project and 4'987 (67%) filled in the questionnaire. Out of 4'621 analysed questionnaires 1'049 patients (22.7%) were identified as being physically inactive receiving further intervention.

Conclusion

Our experience shows that it is important to develop a concept that takes the reality of general practitioners into account, being flexible and minimizing the work load of doctors and assistants added by the project. It is essential that the project is supported by doctors to increase credibility and acceptance within the medical community.

EFFECTS OF WEIGHT EXCESS AND GENDER ON BLOOD PRESSURE VALUES IN A SCHOOL-AGED POPULATION SCREENING

Zaccaria, D. 1, Bottinelli, R. 1, Giussani, M. 3, Tono, V. 2, Sironi, A. 2, Galbiati, S. 2, Pieruzzi, F. 2, Genovesi, S. 2

1 University of Pavia, 2 University of Milano-Bicocca, 3 FIMP Milan, Italy

The raising in the prevalence of overweight and obesity in the paediatric population underlines the necessity to develop a programme of physical activity since youth. Weight excess is frequently associated to hyperlipidaemia, hyperinsulinaemia and hypertension also in children. The aim of our study was to evaluate the prevalence of hypertension in relation to the gender and the level of weight excess in a paediatric population.

Methods: in 5070 children (2473 females, 2597 males) from 6 to 11 years of age, we measured body weight, height and blood pressure. In children with systolic (SBP) and/or diastolic (DBP) blood pressure values obtained from a single measurement above the 95th percentile (corrected for the child sex, height and age,) three consecutive blood pressure measurements were performed in a different occasion. Elevated blood pressure in children was defined if the mean of the 3 blood pressure measurements was above the 95th percentile. Overweight (OW) and obese (OB) children were defined if BMI values were above the value corresponding to 25 kg/m2 or 30 kg/m2 of the adult, respectively, according to the International Obesity Task Force.

Results: OW children were 19.9% (521 females vs. 490 males, $p = 0.11$), while OB children were 5.7% (148 females vs. 141 males, $p = 0.42$). In 3.7% (187) of the children, SBP and/or DBP values were above the 95th percentile (110 females vs. 77 males, $p = 0.005$). In normal weight children, the percentage of females with elevated blood pressure was significantly higher as compared to the percentage of males with hypertension: 52/1804 (2.9%) vs. 22/1966 (1.1%), $p< 0.0001$, respectively. OW or OB subjects with elevated blood pressure values were equally distributed according to gender. The number of hypertensive children increased as the weight class increased: 74/3770 normal weights (2.0%), 49/1011 (4.8%) OW and 64/289 (22.2%) OB, $p <0.0001$. This phenomenon occurred equally in both genders.

Conclusions: these data show that in our population i) there is a high prevalence of overweight and obesity without differences between males and females, ii) the prevalence of hypertension is greater in females as compared to males given the higher prevalence of normal weight females with elevated blood pressure values, iii) weight excess is strongly associated with elevated blood pressure values and the percentage of hypertensive children is higher in subjects with greater weight excess.

Our screening suggests to use regular physical activity and alimentary education to control body weight and blood pressure starting from schools.

BASELINE CHARACTERISTICS OF EXERCISE ON PRESCRIPTION COMPLETERS AND NON-COMPLETERS

Sørensen, J.B., Jakobsen, R.B., Kragstrup, J., Puggaard, L.

University of Southern Denmark, Denmark

Introduction

Epidemiological studies have demonstrated that physical activity level and/or aerobic fitness are independent and strong risk factors of lifestyle diseases (e.g. 1). Exercise on Prescription (EoP) is used in many countries in an attempt to initiate physical activity among sedentary patients at risk of lifestyle diseases (e.g. 2). Adherence is vital for the success of EoP, and identifying characteristics of non-completers may be valuable. A Danish version of EoP is used in several counties. Sedentary patients with increased risk of lifestyle diseases are referred to an EoP clinic by their GP. The intervention involves physical activity counselling (baseline, and after 2, 4, and 7 months), and 4 months of supervised group training (twice a week for 2 months, and once a week for 2 months). The aim of this study is to describe completers and non-completers at baseline of Danish EoP. Non-completers are, in this study, defined as patients who drop out within the 7 months follow up. The hypothesis is that non-completers rate their health and physical activity lower than completers.

Methods

Subjects were 121 EoP participants in the County of Ribe (83 women and 38 men, age 53±12 years, height 169±9 cm, weight 91.4±17.2 kg, BMI 31.8±5.1, and VO2max 20.5±6.3 ml O2/(kg*min)). VO2max was measured using an indirect maximal cycle ergometer test. Self-reported measures were assessed by means of a structured interview. All tests were carried out by the EoP exercise specialist. Mean values were compared using an independent-samples t-test. Frequencies were compared using a Mann-Whitney test. Data are presented as mean±SD.

Results

Minor differences were observed in diagnoses between completers and non-completers. It seems that hypertension and Chronic Obstructive Pulmonary Disease associates with better adherence, whereas depression associates with poorer adherence.

There is a tendency to completers being older than non-completers (54±12 vs. 50±13, p=0.071). No difference was found in VO2max (21.1±6.4 vs. 19.8±6.1, p=0.260, completers and non-completers, respectively), and BMI (31.5±4.8 vs. 32.1±5.4, p=0.566). Furthermore, no difference was observed in self reported health (p=0.662), physical activity (p=0.490), and current smoking status (p=0.132). However, men dropped out more frequently than women (p=0.048).

Conclusion

The Danish EoP schemes target patients in need of a physical active lifestyle, and the majority of participants are women. The only variable assessed in this study, which is useful for identifying potential non-completers is gender. EoP exercise specialists should try to counter the increased drop out among men. Psychological and socioeconomic variables might prove more useful for identifying non-completers.

PHYSICAL ACTIVITY PRESCRIPTION IN THE COMMUNITY

Bellver, M., Banquells, M., Guerrero, A., Dinares, M., Rueda, J., López-Dóriga, A.

Consorci Hospitalari de Terrassa-Centre d'Alt Rendiment, Sant Cugat del Valles, Barcelona, Spain., Spain

Introduction: Physical activity has a role in disease prevention and is recommended to achieve good health1,2. Family physician departments are the ideal places to recommend healthy lifestyles3, but a few group of them recommend physical activity. Coordination between family physicians, sports physicians, physical educators is also essential to promote physical activity in the population and to lobby for changes in public policy and resources.

Objective: To compare physical parametres and health autoperception in a sedentary group "middle aged" with chronical pathologies , after the practise of supervised exercise during one year. To create a multidisciplinary team with sports professionals and primary care professionals. To apply techniques that we use in top athletes to the community.

Methods: We studied a group between 45 and 65 years old with medical history in the familiar health department (n=22) of hypertension, dyslipidaemia, obesity, diabetes, arthritis. We did a medical evaluation before participation and after the completion of the exercise program6. This evaluation includes a blood profile (blood glucose, total cholesterol, HDL-c, LDL-c and tryglicerides), an electrocardiogram, monitoritzed graded exercise test, kine-anthropometry, pulmonary function tests, Nottingham health profile, flexibility and dinamometry test. For ethical and legal reasons, all programs required an informed consent, which notified the participant of all procedures and potential riscs of participation.

This group practise supervised physical exercise twice per week , one hour per session. They play a circuit weight training, resistence training, walking, coordination and flexibility exercises.

Results: Blood profile, kine-anthrpometric parameters, Nottingham test, exercise test and pulmonary function tests improve with significant differences in glucose levels, weight and fat percetage, emocional reactions, systolic rest blood pressure and duration exercise test, FEF 25-75. Medication and number of medical controls have decreased.

Conclusions: 1) Physical activity improves quality of life: physical health, mental health and it also has social benefits,. in a group between 45 and 65 years old.

2) Advice from a family physician is one of the most influential factors in conviccting an individual to practise physical exercise. 3) We can use techniques that we apply in top athletes to the community.

MOUNTAIN BIKING THROUGHOUT THE LIFE SPAN: PHYSIOLOGICAL DATA IN RECREATIONAL ATHLETES AGED 20 TO 60 YEARS

Heller, J., Vodicka, P.

Faculty of Physical Education and Sport, Charles University, Prague , Czech Republic

Off-road cycling or mountain biking has become increasingly popular for all ages – from youth to the elderly. The purpose of the investigation was to compare body composition, pulmonary function and aerobic capacity in recreational bikers (n= 144) aged 20 to 60 years in a cross-sectional study. The results of the bikers were arranged into 7 age groups, 20 to 25, 26 to 30, 31 to 35, 36 to 40, 41 to 45, 46 to 50, and 51 to 60 years of age, respectively, and compared with the Czech national population norms (Seliger and Bartunek, 1976).

Body fat and body mass index in bikers increased from the youngest to the oldest group, i.e. from 6.76 +/- 3.2 (SD) to 13.3 +/- 3.4 %, and from 21.8 +/- 1.4 to 25.3 +/- 1.9 kg.m-2 (correlation with age r= 0.46 and 0.46, p<0.01, respectively), being lower than national population norms (13.3 to 15.6 % of body fat and BMI 23.8 to 26.7 kg.m-2). Pulmonary function indices (FVC, FEV1 and PEF) expressed as percent of predicted values were unrelated to age, however, absolute values of FVC and FEV1 decreased significantly (p<0.01) with age (r= 0.418 and r= 0.455, respectively). As it could be expected, VO2max and maximum power output decreased with age, from 66.5 +/- 5.4 ml.kg-1.min-1 in the youngest group to 50.9 +/- 5.3 ml.kg-1.min-1 in the oldest group and/or from 5.8 +/- 0.5 to 4.2 +/- 0.5 W.kg-1, respectively. Correlation coefficients of VO2max and maximum power output dependence on age were r= 0.654 and 0.685, both p<0.01. These values corresponded to 150 % and 156 % of the VO2max values in normal population (44.1 ml.kg-1.min-1 at 22.5 years and 32.6 ml.kg-1.min-1 at 55 years of age). Similarly to this, the values of the maximum power output in bikers corresponded to 149 % to 157 % of the population norms (3.9 W.kg 1 and 2.7 W.kg 1 at the age of 22.5 and 55 years of age, respectively). As regards the VO2, power output and heart rate at the anaerobic threshold, the percentages of the parameters were constant across the age groups, corresponding to 77 % of VO2 max, 78 % of maximum power output, and 89 % of the maximum heart rate, respectively.

The results of the cross sectional study in recreational bikers demonstrate the positive effects of physical activity on body composition, maximum power output and aerobic capacity across the age from 20 to 60 years. The decline of physiological indices of physical fitness

during ageing was much more slower in recreational bikers than in the normal population. The results confirmed and quantified the positive effect of biking on physical fitness during ageing.

CIRCUIT TRAINING IMPROVES DAILY FUNCTION IN THE ELDERLY

Cummins, R.A., Hastie, R., Burden, S.

Waikato Institute of Technology, New Zealand

The process of ageing can be associated with declines in physiological variables such as strength and agility. These, in turn, may translate to declines in aspects of daily function, such as the ability to rise from a seated position in a chair. The purpose of this study was to examine the efficacy of a low cost circuit-training programme for improving aspects of daily function in the elderly.

Twenty-four residents from three local rest-homes participated. The intervention group (n=14: 5 females and 9 males; mean age 84 y) performed a circuit-training programme (Sutherland et al. 2005) whereas the control group (n=10 females; mean age 84 y) continued with their normal exercise programme. Both groups exercised twice a week for 30 min per session for eight weeks. Three tests (sit-stand, one-minute walk and grip strength) were used pre and post the intervention period to ascertain aspects of daily function. Confidence limits for comparison between groups of pre to post changes were derived via the t-statistic for samples of unequal size (Hopkins 2004). Two sets of comparisons were made: all intervention members versus all control members; female intervention members versus female control members.

The improvements demonstrated post-intervention by the circuit-training group relative to the control group with respect to all participants were as follows: sit-stand, 23% (90% confidence intervals, 13-35%); one-minute-walk, 15% (7-23%); grip-strength, 6% (0-12%). For the equivalent comparisons for females, the improvements were: sit-stand, 44% (17-76%); one-minute-walk, 33% (19-48%); grip-strength, 14% (0-29%).

We suggest that in rest-homes, long-term implementation of circuit-training programmes of this nature may be of benefit to residents by retarding the decline in daily function that accompanies ageing. In future studies we intend to: increase the duration of the study: increase the number of rest-homes involved; design extra circuit–training programmes to enable their rotation; and incorporate additional exercises specific to improving grip-strength (Hastie 2002).

Acknowledgements: We thank Trust Waikato and Wintec for funding and the staff and residents from participating rest-homes for their involvement.

EFFECT OF EXERCISE TRAINING AND DIETARY RESTRICTION ON HEALTH-RELATED VARIABLES IN OBESE MIDDLE-AGED WOMEN - A 16-MONTH FOLLOW-UP STUDY –

Nakagaichi, M.

Research and Development Center for Higher Education, Japan

The purpose of this study was to investigate the influence of dietary restriction with exercise training on health-related variables in obese women. Subjects for this investigation were 17 obese middle-aged women (52.0±8.3 yr, 153.6±4.6 cm, 65.0±7.9 kg). These subjects participated in exercise and dietary restriction programs for 120 min, 2 days per week, consecutively for 3 months. Significant reductions were demonstrated in body weight (-4.8 kg), body mass index (-2.1), body fat percentage (-2.8 %) for 3 months. In addition, body weight had maintained 16 months after the program (-1.1 kg). In conclusion, the exercise training together with a proper dietary regimen is considered optimal with respect to favourable changes in various health-related variables.

ITALIAN TRENDS IN PERFORMANCE: RESULTS FROM THE EUROFIT JUMP TEST

Paleari, C., Lovecchio, N., Eid, L., Mantovani, B.

Università di Milano, Italy

Introduction - Physical activity and movement represent the basic elements for health and are important conditions to get well-being and quality in life. The Eurofit test battery provides a rapid and low-cost way to quantify physical well-being.

Materials and methods – After a national research in the Italian High Schools, and with the collaboration of the National Physical Education Teachers Association (CAPDI), data on 1020 boys and 870 girls aged 12-18 years were collected. From the Eurofit test battery (1), the Standing broad jump (SBJ) was selected: this test is determined both conditional factors and coordination.. The choice was influenced by the simplicity and low-cost of the required equipments, that are similar to Italian School standards. Current data were compared to those collected four years ago during a similar investigation on 3900 people of the same age.

Results - The present data showed trends similar to those found in the past survey. In boys, a generally constant trend of performances was observed in the 12-to-14 year old age group. The mean result in this age group was 160 cm (SD 25 cm), with a maximum jump of 262 cm. When the current 15-to-18 year old boys were compared to their peers assessed four years ago, an increase of the mean results was observed, with about 23 cm of increment in every age class. The central results varied from 189 cm (15 years) to 239 cm (18 years), showing a general increase of 45 cm (18 years) in comparison to the past. Despite the general increment in the mean values, a trend toward a diminution of the maximum values was found; in contrast, the minimum results increased. This trend justifies the smaller SD values obtained in the current group in comparison to the previous ones.

The youngest girls maintained a constant trend in comparison to the past (145 cm), with an improvement only in the minimum values. In contrast, the mean performance of the oldest girls raised from 143 cm (a value very similar to those found in the youngest performers) to 163 cm. Besides, the minimum performances in all age groups improved when compared to those obtained in the past.

Conclusions - The validity of the Eurofit test and the opportunity of longitudinal surveys could allow to elaborate activity programs that should help in the mantainement of well-being. In boys, the present results point to a general improvement in all ages, with a homogeneous trend. Instead, girls showed an improvement in the oldest age groups only. Despite that the number of people who practise sport at a competitive level is decreasing, the general physical state of Italian young people seems to be improved with a homogeneous course. Therefore, it will be important to promote life habits which can maintain optimal conditions of health and psychophysical well-being.

THE RUNNING SPEED. AN INVESTIGATION TO SHOW THE PERFORMING LEVEL OF ITALIAN YOUNG PEOPLE

Paleari, C., Lovecchio, N., Eid, L., Cucco, F.

Università di Milano, Italy

Introduction - The relationship between performance and fitness is very close. Since 1976, the Council of Europe "Committee for Development of Sport" has been provided incentives for the use of tests to evaluate the physical efficiency in young people. A series of tests was completely arranged in 1986 to verify physical performance as an index of health and correct growth (Eurofit test battery). This method provides a rapid and low-cost way to quantify physical well-being.

Materials and methods - During the last school year, 1120 boys and 900 girls aged 12-19 years were recruited. They all were Italians, all performing non-agonistic sport activities. They were in good general health, free from present or past injuries to the lower limbs. During physical education lessons, the Shuttle Run Test (SHR, 10 x 5 m) was administered as indicated in Eurofit test protocol. Nobody knew the test in advance. The results of this test depend on conditional factors and coordinative skills.

Results – Overall, a good level of performance was found. The best individual results were obtained by two 18-year-old students: a girl (12.7 sec), and a boy (10 sec). On average, girls performed the 50 m of the test in 20.46 sec; the best result was obtained by 17-year-old girls (17.9 sec), while the worst was obtained by 12-year-old girls (22.44 sec). Students aged 17 and 18 were, on average, faster than the other students, but they showed the largest intra-group variability (SD = 3.5 and SD = 3.6 sec). Performance worsened in the oldest girls (19 years of age), with a mean time of 21 sec. In general, boys performed the test in 19 sec. The best times were found in the oldest age groups (17, 18 and 19 years) who performed the test in approximately 17 sec. Nineteen-year-old boys kept speed performance obtaining 17.7 sec on average. Intra-group variability was the largest for the faster age groups (SD = 3 sec).

Conclusions – The analyzed students showed good physical conditions: on average, each 5 m drive was run in 1.9 (boys) and 2 (girls) sec. These results, with a mean speed of more than 2.4 m/sec, are very positive considering the sample of non-agonistic sport subjects. The test proved to be a practical and low-cost method; it provided valuable information about the physical well-being of non-agonistic individuals. Considering the test characteristics, frequent follow-ups can be made.

EXERCISE-RELATED HEADACHE

Fontes Ribeiro, G., Cardoso, A.F., Félix, L., Fontes Ribeiro, C.A.

University of Coimbra, Portugal

Exercise-related headaches are commonly seen but not often associated with significant underlying pathology. The International Headache Society classification (IHS, 2004) describes some forms well, but overall reflects our lack of understanding of how exercise and headache pain are related.

Migraine headache is common and can be triggered by many factors, including exercise, which is one of the criteria for diagnosis. In addition, migraine may be worsened by many components of an active lifestyle or specific training, such as resistance exercise, endurance training, or valsalva maneuvers while training. Other factors are environmental exposure (heat and cold), dehydration, inadequate warm-up, altitude, fatigue, and dyspnea, which can occur during exercise. Exercise has not been related with tension-type headache, which is the most prevalent form of headache.

Another form of headache is primary exertional headache, which is a pulsating headache lasting from 5 minutes to 48 hours, specifically brought on by and occurring only during or after physical exertion, and unassociated with any systemic or intracranial disorder. It is normally found in 1% of the general population. IHS classification describes other forms of exertional headache (eg, cough, sexual). Primary exertional headaches have been described in swimmers, runners, and weightlifters, but presumably exist in athletes of all sports that require physical effort.

This study aimed to compare the prevalence of headaches in two populations of a hospital (nursing and medicine students), characterizing the headaches induced or aggravated by exercise. A specific questionnaire was developed and validated.

Headaches occur in 68.6% of the population studied. Migraine with and without aura affects 17.9 and 6.2 %, respectively, of the subjects, principally the nursing population, and is seen more often in women. Infrequent and frequent episodic tension-type headaches exist in 17.2 and 23.7 %, respectively, whereas primary stabbing or primary thunderclap headaches occur in 2.6 % and primary exertional headache in 0.7% of the population studied. Only one student refers chronic tension-type headache. Slight or routine physical activity is a trigger for migraine without or with aura in 18.4 and 17.6 %, respectively, of our population, and in only 6.4 and 4.6 % of the subjects exercise induces tension-type headaches. Migraine without aura and with aura, infrequent and frequent episodic tension-type headaches are aggravated by exercise in 51.0, 35.3, 12.8 and 20.0 %, respectively, of the subjects. Therefore, exercise significantly induces or aggravates migraine in comparison with tension-type headache.

In conclusion, the majority of migraineurs do not have exercise as a trigger factor and so they can exercise without the fear of headache. To lessen the risk of exercise-induced migraine, a plan should be developed with each individual to avoid exacerbating activities.

PHYSICAL FITNESS OF CHILDREN AGED 6 AND 7 AS A MEASURE OF HEALTH

Rokita, A., Surynt, A.

University School of Physical Education Wrocaw, Poland, Poland

Introduction

The level of physical fitness to a large extent influences the biological value of a human being, his/her frame of mind and the quality of living. It is mainly for these reasons that the physical fitness is commonly considered as a positive measure of health. The aim of our research was the assessment of the level of physical fitness of children aged 6 and 7 against the background of the standards of the

International Physical Fitness Test. The question that we tried to address was the following: what is the level of physical fitness of the examined 6 and 7 year-old children against the background of the Polish national standards?

Material and methods

The assessment of the level of physical fitness of children aged 6 and 7 was performed by means of the International Physical Fitness Test (Pilicz, 2002). The examinations were conducted in September 2004 in the Primary School in Czarny Bôr. The material constituting the subject of the present elaboration was collected in cross-sectional examinations which included a group of 78 children aged 6 (17 girls and 20 boys) and aged 7 (21 girls and 20 boys).

Results

Comparing the arithmetical means of the results (points) achieved by 6 and 7 year-old girls we came to the conclusion that they are below the level of 50 points assumed in the test as the average level of physical fitness of children in Poland. 6 year-old girls achieved a lower assessment of the general physical fitness than the standards elaborated in 2002 by 20,6 points whereas 7 year-old girls by 7,4 points. On this basis we can conclude that both younger and older girls are characterized by a low level of the general physical fitness in comparison to the standards presented in the test. Comparing the boys' (aged 7 and 7) results with the standards of 2002 we noticed, similarly to girls, a lower level of the general physical fitness than the average level of physical fitness of children in Poland. The 6 year-old boys achieved a lower assessment of the general physical fitness than the test standards by 19,2 points whereas the older boys got the result at 8,6 points.

Conclusion

The achieved level of the physical fitness by the examined children aged 6 and 7 is low and unsatisfactory. It is worth pointing out that children aged 7, both girls and boys, do not achieve the level of the general physical fitness and the level of the particular motor features, i.e. strength, speed, agility and power, that was presented by the 6 year-old children 20 years ago (Surynt 2003).

INDICES OF WAIST CIRCUMFERENCE AND THEIR RELATIONSHIP WITH TOTAL BODY FAT AND SUBCUTANEOUS ABDOMINAL FAT IN MIDDLE-AGED MEN AT RISK OF METABOLIC SYNDROME

Scott, A.T., Woolf-May, K., Swaine, I.L.

Canterbury Christ Church University, Canterbury, Kent, CT1 1QU, UK, United Kingdom

Introduction: Waist circumference, waist:hip ratio and waist:height ratio are used as simple anthropometric measures of body fat, in relation to health risk. The purpose of this study was to explore the relationship between waist circumference (WC), waist:hip ratio (W:HP) and waist:height ratio (W:HT), and body fat percentage and abdominal subcutaneous fat in middle aged men at risk of metabolic syndrome.

Methods: Twenty four men with a mean age 53.33 ± 7.72 yrs, height 1.79 ± 0.05 m, body mass 94.78 ± 14.59 kg and WC 105.89 ± 12.14 cm participated. WC was measured at the level of the umbilicus and hip circumference was measured at the largest circumference of the hips above the gluteal fold. Height was measured using a stadiometer (Seca) and W:HT and W:HP were calculated. Body fat percentage was estimated using 7 site sum of skinfold thicknesses (SF-fat) and air displacement plethysmography (Bod Pod; BP-fat) an abdominal subcutaneous adiposity was estimated using abdominal (AB) and suprailiac (SI) skinfolds. The relationships between waist circumference indices, body fatness and abdominal adiposity were explored using Pearson's product moment bivariate correlation.

Results: Each of the 3 waist circumference measures correlated with both SF-fat and BP-fat (r≥0.529; P≤0.011), and with AB and AB+SI (r≥0.534; P≤0.010). The relationships between SF-fat and WC (r=0.673; P<0.001), and between SF-fat and W:HT (r=0.645; P=0.001) were stronger than the relationship between SF-fat and W:HP (r=0.343; P=0.11). However, the relationships between BP-fat and WC (r=0.711; P=0.006), BP-fat and W:HP (r=0.687; P=0.010) and BP-fat and W:HT (r=0.690; P=0.009) were all strong but showed a similar pattern to the SF-fat measures. The relationships between abdominal skinfold thicknesses and the waist indices was strongest when abdominal fat was expressed as AB+SI rather than AB alone. The relationship between AB+SI and WC (r=0.668; P>0.001) was the strongest, followed by AB+SI and W:HT (r=0.609; P=0.002) and AB+SI and W:HP (r=0.433; P=0.035).

Conclusion: Despite the smaller numbers in this study, these relationships between waist indices and subcutaneous abdominal fat in middle-aged men at risk of metabolic syndrome are similar to the findings of Han et al. (1996), who argued that a simple measure of waist circumference was most reflective of abdominal fat, measured by computed tomography. In the present study, waist circumference was also most closely associated with total body fat percentage in these men, which has not been previously reported specifically in men at risk of the metabolic syndrome.

THE IMPACT OF SWIMMING AND ROCK CLIMBING ON BLOOD LIPIDS AND BODY COMPOSITION IN MIDDLE-AGED MEN

Soultanakis, H., Vartelatos, G., Platanou, T.

Faculty of Physical Education and Sport Sciences, University of Athens, Greece, Greece

Comparative studies evaluating the health impact of various activities and sports at the recreational level are limited. The purpose of this study was to evaluate the lipid and body composition profile of middle aged men who engage in swimming, rock climbing or sedentary lifestyles. Twenty eight men, between 40 and 60 years old were distributed in three different groups. The sedentary group (Sed) led very sedentary lives with office type jobs (N=11). The second group (N=9) of recreational swimmers (Swm) and the third group (N=8) of climbers (Clmb) trained for at least 3 times per week for two consecutive years in their respective activity. Measurements of body weight, height and skinfolds were used to determine body mass index (BMI) and percent fat. Blood cholesterol and triglycerides were measured via the automated portable analyzer, by Roche. Statistical analysis was performed by multiple analyses of variance (MANOVA). Significantly lower values of both BMI and cholesterol levels were evidenced in both groups of recreational athletes when compared to sedentary controls (p<0.01). However, sedentary men and swimmers had significantly higher percent fat values than rock climbers (p<0.05). Specifi-

cally mean values of BMI , cholesterol and percent fat for all three groups were respectively: (24.6±2.35 kg/m2; 186.25±21.53 mg/dl; 19.13±3,22%) for the Clmb group, (24.88±2.58 kg/m2; 212.22±40.98 mg/dl; 22.70±5.60%) for the Swm group and (30.66±2.92 kg/m2; 256.81±25.76 mg/dl; 24.86±3.74%) for the Sed group. Triglycerides didn't differ in any of the groups. As it appears, all values of both groups of recreational athletes ranged within normal levels, while the Sed group values were above normal ranges. Both swimming and climbing appear to play a protective role as far as the development of hypercholesterolemia and obesity. However, climbers appeared to have a better overall profile by demonstrating signifant lower percent fat and lower mean values of the other measurements. This could possibly be attributed to the type of training and the level of intensity of the two different sports. Swimmers, trained continuously and at low intensities, while climbers trained in interval bouts of high intensity. Lipid profiles and body composition analyses as well as evaluation of physical fitness, training type and sport performed, may offer good prognosis and serve as the basis for exercise prescription to people of all ages (Giada F et al., 1995; Hafa Y et al, 2000).

EFFECTS OF VIGOROUS AND MODERATE AEROBIC EXERCISES ON THE GENERAL HEALTH OF NON-ACTIVE MEN

Afzalpour, M.E. 1, Gharakhanlou, R. 2, Gaeini, A.A. 3, Seghatol Eslami, A. 1

1 Birjand University, 2 Tarbiat Modares University, 3 Tehran University, Iran

In order to study of the effects of vigorous and moderate aerobic exercises on the general health of non-active men in physical, anexiety and sleeping disorder, social output disorder and depression aspects, 43 individuals volunteered in this research. They were randomly divided into two experimental groups and a control group. Duration of training was 8 weeks and subjects 3 sessions per week and each session 30-45 minutes performed assigned aerobic exercises. Experimental group I (n=15) carried out vigorous aerobic exercise at 80 - 85, and experimental group II (n=16) carried out moderate aerobic exercise at 60-65% of maximal reserve heart rate. Control group (n=12) didn't perform any physical activity through research. General health of participants were evaluated by general health questionnaire (GHQ-28) of Goldber & Hillier in the initial and after 8 weeks of exercise. We applied one-way analysis of variance and LSD test for revelation results of study. Results showed significant improvement in physical signs($P<0.04$), and anexiety and sleeping disorder($P<0.03$) in the vigorous exercised subjects after 8 weeks. In addition, we observed an inclination for improvement (23/35 % reduction) in the general health score of moderate aerobic exercise group. Based on the results, performing of vigorous aerobic exercise at 80-85% of maximal reserve heart rate improved physical signs and decreased anexiety and sleeping disorder, and thereby caused better general health in the participants. Furthermore, change patterns of moderate aerobic exercise group suggest that the general health of these subjects improved and it may reach to the significant levels by increasing duration or frequency of weekly exercises.

RELIABILITY AND VALIDITY OF A NEW TEST TO ASSESS PHYSICAL PARAMETERS RELATED TO FALLS IN THE ELDERLY

Giné-Garriga, M., Guerra-Balic, M.

Facultat de Psicologia, Ciències de l'Educació i l'Esport BLANQUERNA. Universitat Ramon Llull, Spain

Introduction. The impact of physical decadence caused by the aging on the life style of the elderly includes several aspects such as the appearance of pain, decrease in autonomy and independence, a worsening of the postural attitude and the corporal image, as well as a decrease in strength, coordination, speed, balance, flexibility and security, among others.

Due to their frequency and its personal, social and economic consequences, falls in the elderly represent a high sanitary cost, but more importantly, a limitation of their everyday activities and the consequent welfare decrease.

The assessment and treatment of the physical parameters associated to falls (intrinsic factors) is a complex task. Many of the available instruments have been developed for research purposes and are not suitable for use with older adults because of their length, complexity, safety concerns, and/or equipment requirements. Despite of the fact that several tests have been successfully used with older adult populations, each test is designed to assess a specific physical parameter. However, fall risk is indeed multifactorial and hence, difficult to capture with such specific tests.

Purpose. Design and implement a new test that encompasses the four principal physical parameters associated to the risk of falls in people older than 65 years: lower extremity strength, coordination, balance and gait.

Methodology. The new test will measure balance and gait with a modification of the Extended Timed-Get-Up-and-Go Test, coordination will be measured with a manual and cognitive task, while lower extremity strength will be measured with weight lifting in specific conditions.

A sample of 10 subjects and the interjudge reliability method will be used. Each subject will do the test once in front of four judges who will assess each subject individually. The factor K of Cohen is then calculated. The validation will be done with 30 subjects and we'll calculate the index of relation between the new test and the already existing ones.

Foreseeable results and Conclusions. The application of a single test that considers the main different physical parameters associated with the risk of falling will be more efficient than the application of several and independent tests. Its simplicity will allow control programs of prevention and intervention of physical activity in future studies.

GENDER AND OUTDOOR PHYSICAL ACTIVITY RELATIONS: CONSIDERATIONS FOR ACTIVE TRAVEL INITIATIVES AND ENVIRONMENTAL SUSTAINABILITY

Kilgour, L.

University of Gloucestershire, United Kingdom

High levels of physical inactivity are a cause for concern in the UK at present and, to add to this problem, women consistently report lower levels of physical activity than men. In terms of physical activity and health policy, the Government are looking to increase physical activity levels in the population to 70% by the year 2020. However, with many exercise scientists and health professionals identifying physical activity performed as part of daily life the only way for people to begin to reach recommended weekly levels of physical activity, some physical activity and health promotion specialists are looking to the outdoor environment to provide the solution to the problem.

It has been reported that certain environments engender physical activity participation, while other environments can prevent physical activity, with psychological, social and cultural explanations for this. Similarly, we have evidence from neighbouring European countries

that both urban and rural landscapes can be developed to increase outdoor physical activity opportunities that are seen to be both safe and inclusive. Research that has focused on active travel initiatives often produces findings that lean towards the need for improved provision of existing facilities, particularly where accommodating women's needs are concerned. Further, research that has focused solely on women's participation in physical activity has outlined the changes required to outdoor environments that will provide more safer and pleasant opportunities.

This poster presents findings from a recent large scale study that focused on women's experiences of outdoor physical activity, with specific reference to feelings of fear and perceptions of risk. These findings link in with broader issues relating to environmental sustainability, presently a key issue for many western leaders. The main argument here is that by making outdoor environments safer for outdoor physical activity to be performed by 'at risk' groups such as women, and linking this with improved public transport, while at the same time lowering car use, we can move some way to increasing physical activity levels in the population, through lifestyle physical activity such as active travel, while simultaneously protecting the environment.

THE RELATIONSHIP BETWEEN THIGH SKINFOLD MEASURE, HAND GRIP STRENGTH AND TRUNK MUSCLES ENDURANCE: GENDER DIFFERENCES

Doymaz, F., Cavlak, U., Kuçuk, M.

Pamukkale Univ.,School of Physical Therapy & Turkish Red Crescent Society, Denizli Medical Center, Turkey

Aim: The aim of this study was to analyze the relationship between thigh skinfold measure, hand grip strength and trunk muscles endurance in terms of gender.Methods: In the current work 111 females and 89 males, totally 200 healthy subjects with mean age of 31.58±13.78 years without any acute disease were evaluated. Trunk muscles endurance was examined using curl up, static back endurance and horizontal side bridge tests (1, 2, 3). The results were analyzed by Kruskal Wallis test, Mann-Whitney U test with Bonferroni correction and Spearman's correlation coefficient.Results: Significant differences between females and males were found regarding curl up and horizontal side bridge tests (p≤0.05). However there was no difference concerning static back endurance test scores between both sexes (p>0.05).We found a negative relation between thigh skinfold measure and all trunk endurance tests among females (range; r=-0.454/-0.501). Rather a negative poor relation was also found among males (range; r=-0.182/-0.348).We found no correlation between hand grip strength and trunk endurance test scores among females. However, there were a significant positive correlation between hand grip strength and endurance tests except for static back endurance test among the males.Conclusion: We conclude that physical characteristics like skinfold measure and hand grip strength are also important factors which may affect the trunk muscles endurance in healthy subjects. Therefore, gender differences related to skinfold measure, hand grip strength and trunk muscles endurance should also be taken into account. Thus physical therapists should evaluate properly the physical characteristics of the healthy subjects while planning muscle endurance programs to improve their quality of life.

ANALYSING THE EFFECTS OF PHYSICAL CHARACTERISTICS ON TRUNK MUSCLES ENDURANCE IN HEALTY SUBJECTS

Doymaz, F., Cavlak, U., Kuçuk, M.

Pamukkale Univ.,School of Physical Therapy & Turkish Red Crescent Society, Denizli Medical Center, Turkey

Aim: The purpose of this study was to investigate the effects of physical characteristics such as; age, gender, mass, height, body mass index (BMI) and waist-hip ratio on trunk muscles endurance. Methods: In the current work 111 females and 89 males, totally 200 healthy subjects with mean age of 31.58±13.78 years old without any acute disease participated. Trunk muscles endurance was examined using curl up, static back endurance and horizontal side bridge tests (1, 2, 3, 4).Subjects were classified into four different groups in terms of age: first group subjects were younger than 20 years old, second group subjects were between 20–30 years old, third group subjects were between 30–40 years old and fourth group subjects were 40 years old and more. Each group was consisted of 50 subjects. The results were analyzed using by Kruskal Wallis test, Mann-Whitney U test with Bonferroni correction and Spearman's correlation coefficient. Results: The first group had the best scores concerning endurance tests. On the other hand the fourth group had the lowest scores. There was a significant negative correlation between all trunk muscle endurance tests and age (p≤ 0.05). When all subjects were analyzed in terms of gender; males had better scores comparison to the females regarding the curl up and horizontal side bridge tests (p< 0.05). However, there was no correlation between gender and static back endurance test (p>0.05). There was a significant negative correlation between mass, BMI and endurance tests scores (p<0.05). We also found a significant positive correlation between height and the endurance tests scores (p<0.05). And also there was a significant negative correlation between waist- hip ratio and curl up, static back endurance test (p<0.05). However no correlation was found between waist- hip ratio and horizontal side bridge test (p>0.05).We conclude that increasing age, mass, BMI and waist- hip ratio are important factors which cause a decrease in endurance tests scores in healthy subjects (5). We suggest that the effects of physical characteristics on trunk muscles endurance should be taken into account while planning endurance programs for healthy subjects. BMI, %FAT AND VO2MAX IN COLLEGE FEMALES

Nakhosin Roohi, B., Talebi, E.

Islamic Azad University-Ardebil branch, Iran

Aims:
The purpose of this study was to examine obesity and fitness of the female staff of Ardebil Azad University.
Material and method:
37 staffs of Ardebil Azad University participated in this study voluntarily. Primary measurements of interest in the present study were height, body mass Index, subcutaneous skin folds, and cardio respiratory fitness determined by1 mile walk test.
Results:
The achieved measurements were considerable, especially in %Fat and BMI and it's relation to VO2max, according to the other researcher's achievements. According to finding, women in Ardebil Azad University are more obese and less active.
Conclusions:
Social/lifestyle factors such as the level of education, marital status, exercise habits, dietary habits and smoking habits may be related to overweight/obesity in females of Ardebil. It was concluded that there isn't sufficient sport facilities and equipments for females in Ardebil Azad University and there are some cultural problems lead to females be low active.

THE RELATIONSHIP BETWEEN PHYSICAL FITNESS WITH ANXIETY AND DEPRESSION OF DORMITORY FEMALE STUDENTS OF KURDISTAN UNIVERSITY

Sadeghi Boroujerdi, S.

Kurdestan University, Iran

Graduates who are in dormitory are more exposed to stresses such as anxiety and depression due to special problems for their health (especially girl students).
Educational experts and researchers have always tried to find the ways to prevent and reduce psychological disorders among this large social stratum. However, the effect of physical fitness on anxiety and depression has not attracted due attention.
The purpose of this study was investigating the between the physical fitness and anxiety and depression on the female students in dormitory of Kurdistan University in Iran.
Statistical population of this research includes all the female students in dormitory of Kurdistan University (874 students) and 240 of them participated in this study.
Statistical way of this research for the descriptive statistical, t- tests and Pearson Correlation were used.
The descriptive results showed that the level of physical fitness of dormitory female students was nearly the same and were in level of average.
The level of anxiety of dormitory female students was very high from mean.
The level of depression of dormitory female students was very high from mean.
The Hypothesis conclusions showed that: There was not a meaningful correlation between physical fitness with depression and anxiety among dormitory female students.
A significant correlation exists between anxiety and depression of dormitory female students.
A meaningful difference between physical fitness, anxiety and depression of dormitory female students was not observed.

THE EFFECT OF CREATINE SUPPLEMENT ON STRENGTH, ENDOURENSE AND COMBINATION ATHLETICS PERFORMANCES

Senobar Tahaei, S.N., Sadeghi Boroujerdi, S.

Kurdestan University, Iran

In recent years, using creatine supplements, especially in different courses of body building have been had most popularity, so it emphasized on necessity of researching in this case, to do that whether answers and information that are in this case should be increased or if peoples believes about help of acrogenic with abuse creatine is correct or not.
In this way present study that is a semi experimental study with pre-test plane and post-test in two groups of experimental group (using creatine) and control group (using something like drug) is considered that influence of using creatine mono hydrate (using 20gr daily in 6 alter native days and using 2gr in 28 days later) with resistance exercises 8 weekly on actions of powerfully, resistance and body combination (fat weigh and lean body mass of body) body builders are investigated.
In order to do that, among 43 athletes in Kurdistan University that statistic society was doing this study, 20 individuals that are choose and in same situation divided to two groups of experimental and control. Then all of sequences studies are performed regularly.
Powerful resistance and body combinations tests are performed among both of pre-test group and post-test group.
So finally with statistic analyzing, the results of pre-test and post-test of influence of using creatine complement will recognized and finally these follow results are found.
1- Signification increasing of power in scat movements front arm and bench pressing group of using creatine.
2- Signification increasing resistance in scat movements front arm and bench pressing group of using creatine.
3- Increasing weight-increasing weight lean body mass without change in weight of body fat in group of using creatine.

COACHES AND THEIR FIGHT AGAINST DOPING

Peters, C., Selg, P.J., Ohanian, J., Habermann, K., Schulz, T., Pabst, H., Michna, H.

Technical University of Munich, Germany

Coaches are very important attachment figures in athletes surroundings. Frequently, they were addressed by their athletes concerning several sport specific aspects. With regard to doping there are just a few academic examinations about the coaches´ knowledge and

their point of view (Laure et al. 2001). Therefore, we conducted a project (VF 0407/03/41/2003-2004, financially supported by the Federal Institute of Sport Science/Bonn) to examine doping related state of knowledge of athletes and coaches from diverse sports associations as well as flow of information.

By means of a written survey, we asked 620 coaches of different levels (reflux 40.7%) and 1757 high-level athletes (handicapped and non-handicapped; reflux 45.6%) about several doping related aspects.

Coaches claim to be frequently reflected in the doping problem. Besides health aspects, it seems to us, that doping controls and fair play are the most commanding spots. Most disturbing is, that the coaches are poorly informed and just 50% of them owned the current forbidden list. However, most coaches are not proactive and want to be informed by their sports association.

Additionally, a lots of athletes claim to frequently think about doping related topics and in many cases, the coach is their main contact person. Athletes are not proactive at all but were informed by colleagues or other parties. Often national anti-doping associations, diverse booklets or internet information are unknown by athletes.

We conclude, that there are urgent needs to change the information policy of sports associations, Olympic training centres, coaches and physicians which was critically evaluated by athletes. The majority of athletes know the severe side-effects of doping. One third of the athletes could observe physical and psychological side-effects of doping substances used by their colleagues.

The number of coaches, who rate their relation to the athlete as "good" is not to be sneezed at. Therefore, we think that this could be a chance for doping prevention and one efficient way to go. But this requires, first of all, to enhance the state of knowledge of the coaches. They need to use the current knowledge on doping to convince their athletes of the perilous side-effects of doping and starting to lecture them at an age of at least 10 to 15 years. This requires, that not only coaches of high elite athletes but also of lower degrees and levels, who mainly work with younger athletes, need to be informed about doping in particular.

Laure P., Thouvenin F. & Lecerf T. (2001). Attitudes of coaches toward doping. Journal of Sports Medicine and Physical Fitness, 41, S. 132-136.

EFFECTS OF MODERATE OUTDOOR-CYCLING VS WALKING ON AEROBIC ENDURANCE, ANTHROPOMETRIC VALUES & BODY COMPOSITION DURING 5 MONTHS MONOTHERAPEUTICAL THERAPY

Sperlich, B., Wilke, C., Wehner, S., Wienke, C., Knigge, H., Latsch, J., Montiel, G., Falkowski, G., Predel, H.-G., Froböse, I.

German Sport University, Cologne, Germany

Introduction: Obesity is one of the most serious health problems in future. Aerobic training (AT) appears to play a critical role in the loss & maintenance of body weight (BW). A key link to BW loss with AT seems to be an increase in aerobic capacity (AC) & in muscle mass (MM). The specific differences of the most common endurance modalities outdoor-cycling & walking are yet to be investigated. The aim of the study was to investigate the effects of moderate cycling, walking & jogging during a 5 month monotherapeuthic intervention in obese men as the differences may pertain to AC, anthropometric values & body composition.

Method: 60 elderly physically inactive overweight men (54.3 ± 4.9 yrs; 98.1 ± 8.4 kg; BMI 30.5 ± 2.0 kg/ m2) participated in two training groups (TG): bicycling group (BG, n=16); walking group (WG, n=24) & one control group (CG=20). The subjects were randomly selected into TG or CG or chose their preferred exercise modality. All subjects were examined before & after 5 months training. Workload (WattLa2) & heart rate (HRLa2) at 2mmol/l blood lactate (La2) were analysed in an incremental WHO-ergometer test (ET) & a field test (FT). BW, body fat (BF), MM & waist-to-hip-ratio (WHR) were noted. BW, BF & MM were measured using standardized bio-impedance. Both TGs exercised 3 times per wk at an intensity of La2. At first, training sessions (TS) covered 60 min, after 6 wks 90 min. Every TS was supervised by three coaches. CG was briefed not to perform any exercise during the complete study.

Results: ET: WattLa2 increases in all groups in ET ($p<0.01$) whereas HRLa2 remained unchanged ($p<0.05$). FT: Walking speed at LA 2 only increased ($p<0.01$) in WG. HR La 2 did not change in all groups ($p>0.05$). BW reduced in BG ($p<0.01$). There were no difference in WG & CG ($p>0.05$). No changes were found in MM in all groups ($p>0.05$). BF [kg] decreased in BG ($p<0.05$) & WG ($p>0.01$). There were no changes in CG ($p>0.05$). WHR decreased ($p<0.01$) in BG but not in CG & WG ($p>0.05$).

Discussion: Both TG show a visibly increase in AC (16-18%) after AT in ET. HR remains unaltered at higher workrate after AT which most possibly results from a greater peripheral oxygen utilisation & economical cardiac workrate. Cycling seems to have no effect on FT. Decrease of BW in BG most possibly results from an initial higher BW compared to the other groups. BW decrease seems to result from loss of BF. Chronic AT (3 times 60-90 min per week) additionally to daily activity without specific strength training does not affect MM increase, which seems to be one of the key links to BW loss.

Conclusion: Cycling & walking with comparable training stimulus but different muscle impact as monotherapeuthic intervention improved AC significantly. Moderate Cycling does not effect walking performance but vice versa. BW loss results from loss in BF. Chronic ET as practiced in this study does not increase MM.

ANALYSIS OF ANTHROPOMETRIC CHARACTERISTICS OF CADETS AND STUDENTS

Plavina, L.

National Defence Academy of Latvia, Latvia

Introduction

Physical activities and health-related behaviour is important for everyone to keep physical and mental health (1,2).specially for person who decides to connect his life to Army or to Sport(3).

The last research of public health indicated that individual spend for physical activities less time than in previous period. The rate of some diseases that connected to physical inactivity such as heart attack, heart failure stroke, obesity diabetes bone diseases increase.

The target of our work is to analyse and compare anthropometric characteristics of cadets, next officers and students –next Sport and biology teachers

Material and methods

We examined two groups: cadets- next officers and students- next Sport and biology teachers. We fixed main anthropometric parameters (height, body mass), determine anthropometric indices and fix physical fitness level (according Harvard step-test results).

Results

Analysis of the height parameter shows that average data of body height were close in the examined groups of cadets and students. The average body height parameters in the cadets` group in 2002-2004 were from 179.8 ±1.11cm to185.2±1.2 cm. Student's height parameters in the same period were close to cadets' data from 175.9±12.6 cm to 180.5±9.7 cm. The body mass is the most yielding characteristic.

The body mass parameters in cadets' group were from 78.9±1.8kg to 81.2±4.3 kg. In the students' group average data of body mass were lower 70.3±5.34 kg to 79.2±11.6kg Absolute characteristics need evaluation by index-coefficient system using. The weight-height index characterised the load of body mass upon one height cm .The weight-height index for cadets in 2002 –2004 exceeded top standards over 5-7 %, from433.7±45.6 g per cm to 441.7±10.7 g/cm. In students group weight-height index data were closed to standards, from 394.8±18.3 g/cm to 437.6±62.2 g/cm. We used physical load test – Harvard step tests for evaluation the physical fitness. The HSTI data in cadets group support the good level of physical fitness in2002-2004 from72.7±10.8 to 79.5±8.2. Students' physical fitness level according data of Harvard step-test were in the same level – good level of physical fitness, from 65.7 to 81.5±13.8.

Conclusion

1. Students next Sport teacher and cadets – next military officer have good level of physical fitness;

2. Height parameters of cadets and students are closed;

Body mass parameters of cadets are over standards per 5-7 %and over the average data of students;

THE DIFFERENT TYPES OF ISOKINETIC STRENGTH TRAINING IN REHABILITATION PROGRAMS OF OVERWEIGHT WOMEN

Sawczyn, S., Kuehne, T.

Academy of Physical Education and Sport, Gdansk, Poland, Poland

Strength exercises represent of great importance form of physical loads in rehabilitation programs of overweight women. Few studies have focused on the impact of resistance exercise training on fat metabolism. However, the effect of different types o strength exercises for treatment of obesity is not clear. The aim of the study was to compare the effect of low- and high resistance isokinetic strength training in rehabilitation training program middle age women without a concomitant diet on body mass and resting metabolic rate.

19 untrained overweight female (38-49 yrs, BMI 33,07±2,71 kg/m2) were matched for age, body mass index, training history and randomly assigned to high-resistance (group 1, n=10) and low-resistance (group 2, n=9) training groups. The subjects of group 1 were used supervised slow-speed resistance isokinetic strength training (Concept device) the lower and upper body at 75-85% and 60-70% of the individual 1RM (8-10/12-15 repetitions per set, 3 sets) 2 day per week for 16 weeks (duration of one session 80 min). The subjects of group 2 were used high-speed resistance isokinetic strength training. Baseline 1 RM testing was completed every week. The determining of fat folds and oxygen uptake in supine rest (indirect calorimetry – Cosmed) was performed before (week 0), on week 8 and 16.

The results showed that significant variation in resting oxygen uptake was observed between baseline measure (week 0) and 16 weak in both groups. Mean lower and upper body maximal strength significantly increases in-group 1 and 2 (10 and 16%, respectively). BMI in (1) and (2) groups was decreased (-6,7 and -7,1%). From 8 to 16 weeks training resting oxygen uptake significantly increase in low-resistance training group only from 108,9± 4,9 on week 8 to 126,5± 6,2 ml/min/m2 on week 16 ($p<0,05$). Post-trained decrease of percent of fat in group 2 was significantly more (-8,7±1,3%) than in group 1 (-5,2±1,1%). Resting oxygen uptake related to fat-free body mass showed a significant increase in low-resistance training group only (from 4,17± 0,06 to 4,98± 0,07 ml.kg-1.min-1).

We concluded that high intensity isokinetic low- and high-resistance strength training for 8 and 16 weeks significantly improve resting metabolic rate. The results support the supposition that strength training represents an adequate alternative to aerobic endurance training in women rehabilitation training programs. These data indicate that consideration of the role of physical exercises, as a mere factor of caloric expenditures is insufficient for explanation of its full effects, including the case of excessive weight rehabilitation. Available data demonstrate that low-resistance (high-velocity) strength isokinetic exercises are a more effective factor for enhancement in rehabilitation training the efficiency of metabolism self-regulation in obese women by increasing of energy expenditures in post-exercise rest in comparison to high-resistance exercises.

MUSCULAR ACTIVITY, AREA PRESSURE AND COMFORT RATING IN COMBINATION WITH ERGONOMICAL BICYCLE HANDLE BAR AHS FROM HUMPERT©

Sperlich, B., Niedermeyer, C., Guettge, C., Froböse, I.

German Sport University, Cologne, Germany

Introduction: Own findings show cyclist complaining about discomfort in hand (H) and wrist (W). Stretching of the ulnar nerve in W due to radial or ulnar abduction and chronic pressure (P) on H leads to numbness and pain in H and fingers. Common straight handle bars (HB) are not adjustable to the user´s anatomy and seem to increase chronic pain in H during cycling. The aim of the study was to investigate whether an adjustable HB system (AHS) may decrease P and electro-myographic activity (EMG) and increase comfort in everyday cycling.

Method: Study 1: 10 students (174,2±6,1cm; 78,2±8,7kg) participated to evaluate EMG in right arm of m. flex. and ext. carpi rad., m. brachioradialis, m. triceps med. brachii, m. deltoideus post., m. trapezius ascend in 16 different HB crank angles (HBCA) and bar end angles (BEA). The subjects cycled at 70 rpm at 1,0 Watt/kg for 60 seconds. HBCA were positioned randomly with a goniometer. Feeling of comfort (CR) was rated after every HBCA with an own developed scale (0 comfortabel-10 uncomf.). Study 2: 6 students (173,5±7,0cm; 65,8±8,6kg) participated to investigate P (Tekscan) on HB. Pmax was measured in 10 different HBCA and BEA. Test procedure and apparatus were equal to study 1.

Results: EMG differences were only visible in m. ext. carpi uln.: All BEA (0°, 20°,40°, 60°) and HBCA of 37,5° showed the lowest EMG in all subjects (2,4; -4,7mV). Highest EMG was found at HBCA of 7° and 0° (8,7 and 10,1 mV). CR: All BEA tests (0°, 20°; 40°; 60°) were rated most comfortable (0°=4,9; 20°=5,5; 40°=6,5; 60°=5,5). In most cases, the straighter HB was mounted the least comfortable W position was rated (0° HBCA= 7,5; 7,5° HBCA=7;2). P: We measured 3,4 times higher mean P on med. vs lat. H (220,6 vs 754,6 g/cm²). 10° and 30° BEA position showed lowest Pmax (2599,7 and 2176,3 g/cm²). Highest Pmax were found at vertical (10°-30°) and horizontal HBCA of 30° (3681,7 and 2933,7 g/cm²).

Discussion: Only m. ext. carpi uln. shows a obvious difference in EMG. For further investigation M located closer to HB seem to show clearer results. Numbness and pain in upper arm M from these findings should not necessarily resolve from a difference in HBCA. CR values underline the EMG data. In tendency, the straighter HB becomes the more uncomfortable the position is rated. Best values in EMG and CR are found in all BEA positions. HBCA of 30° increases P on W compared to HBCA of 0°-15° most likely because the trunk is held

completely by upper arm M. Therefore the straighter HBCA becomes the back M become more activated and hold the vertical trunk actively.

Conclusion: Common HB with fixed angles can not necessarily be adjusted to the individual anatomy. HBCA between 22,5° and 37,5° and BEA of 0°-60° show the least EMG activation and highest CR in everyday cycling. For comfortable and painless cycling in H and arms we suggest to mount an AHS with a multi positioning function to ensure a natural individual W angle.

EFFECTS OF SMOKING AND FATIGUE ON HEALTH CONCITION OF DAY AND NIGHT COURSE STUDENTS USING CORNELLMEDICAL INDEX

Sakamoto, N., Sakamoto, K.

Hyogo College of Medicine, Japan

The reduction school taught the Judo as essential training in one hour pre week. In this study, the physical and mental complaints of students were examined after the lecture using Cornell Medical Index(CMI).

Subjects were 196 healthy male students aged 18-23 years old, 107 subjects of the night course and 89 subjects of the day course students. Survey was down on day of judo practice using self-entry method on CMI.

The mode of distribution of complaint numbers of items of physical and mental categories and the rate of complaint of each category were examined between night and day course students. On the eye and ear category, the mode and the rate were (mode : one item, rate : 17.9%) in night course, and (no complaint, 15.2%) in day course. On the respiratory system, these were (six items, 18.5%) in night and (two items, 17.5%) in day. On the digestion system, these were (four items, 14.3%) in night and (three items,12.4%) in day. On the habit, these were (no complaint, 33.8%) in night and (two items, 33.6%) in day. Thus the night course student was more complaints of respiratory and digestion system to compare to that of the day course students. The effect of smoking on health condition was analyzed to 47 smokers and 147 nonsmokers by odds ratio. The odds values were significantly high as 1.68 for respiratory system, 1.32 for digestion system of physical category and 0.77 for maladjustment in mental category. On correlation analyses, smoking was correlated significantly with the respiratory system as r=0.26 and the digestion system as r=0.14. Thus, in these young students, the smoking made increase the complaints of respiratory and digestion system. But smoking effected to decrease the complaints of maladjustment, anxiety and tension as mental function, but did not effect to the depression and anger function. The effects of fatigue on the complaint of categories were examined using odds ratio. The subjects who was complaint of fatigue were 90 subjects of 196 students. The odds rate of fatigue was significant for all categories except the eye and ear category. Especially the muscle, nerves and maladjustment categories shown high the relative risk as 2.72, 2,51 and 2.59 respectively. On the correlation analysis, the fatigue was correlated positively significantly with the respiratory system as r=0.31, with muscle system as r=0.39, with nerves system as r=0.38 and with maladjustment as r=0.34. As a results, for the privation of the adult disease nonsmoking must practice in young persons. It seemed that the fatigue felling was related to the complaints of category of muscle, nerves and maladjustment.

Keywords: judo, fatigue. smoking Cornell Medical Index.

THE EFFECTS OF VITAMIN E , VITAMIN C OR COMBINATION OF VITAMIN E AND C SUPPLEMENTATION ON BIOENERGETICS INDEX

Tarverdizadeh, B., Azarbaijani, M.A., Jourkesh, M.

Islamic Azad University,Branch of Bushehr, Iran

Introduction , Materials and methods

In order to studying the effects of vitamin E , vitamin C or combination of vitamin E and vitamin C supplementation on bioenergetics index (aerobic and anaerobic power)36 physical education college (male) ,were selected non-randomly and they were set in 4 groups randomly .

Average of age ,weight , height and fat percentage of them was (22.48-+1.84)years , (64.93-+7.84)kilograms ,(175.4-+5.66)centimeters and (10.94-+5.29)millimeters , respectively. The period considered for consumption of vitamins by experimental groups was a three week period that in this period the first group consumed dose of (400 mg) vitamin E and second group(1000 mg) vitamin C and third group(400 mg VE plus 1000 mg VC) daily and fourth group (control group) consumed placebo. The test which have been exerted in this research consist of :

1) Assessment of anaerobic power by "RAST" test.

2) Assessment of aerobic power by cooper test. Finally data in four group was analyzed by one and two-way ANOVA statistically method

Results

Result indicated that there was not a significant (p<0/05) different between four group in anaerobic power whereas ,there was a significant (p<0/05) different between four group in aerobic power.

Discussion and conclosions

There fore we concluded that daily consumption of 400 mg vitamin E, 1000 mg ,vitamin C and 400 mg vitamin E plus 1000 mg vitamin C for period of three week dose not have any effect on the basis of improvement of anaerobic power ,whereas have effect on aerobic power.

THE EFFECTS OF SAUNA ON PAIN RELIEF AND RANGE OF MOTION IN RHEUMATOID ARTHRITIS PATIENTS

Tabatabaee, A.

Islamic Azad University - Quchan branch, Iran

Introduction:

Pain and pain relief have always been of great importance to man .The most important symptoms of rheumatoid arthritis is the pain.Sauna bathing may also alleviate pain and improve joint mobility in patients with rheumatic disease.(Hannuksela, 2001).

The physiologic effect of the sauna in human beings has been studied extensively, but only recently have there been studies to suggest sauna can be an effective therapeutic modality for patients .

The purpose of this study was to evaluate the effects of sauna on pain relief and effects on range of motion (ROM) of joints affected in rheumatoid arthritis (RA) patients.

Methods

45 male (RA) patients referring to medical center of mashhad were randomly selected.To extract demographic variables from the questionnaires to measure pain in people who go to rheumatology clinics of medical schools in mashhad According to criteria like being male,some patients were selected.

The patients were then randomly assigned to 3 groups,one group served as the control group while the other two groups use one session or two session of sauna weekly for 28 days.

The severity of pain was measured by visual analog scale (V.A.S.) in day 1,15, and 28 for all groups and day 16 and 29 for the experimental groups.

Results

Analysis of variance showed that the pain before research was the same in all groups.The pain in each group a day before and after sauna was significantly different .

There was a significant difference in reduction of pain between the first and the last day of using sauna among groups .

Next day just after sauna with use of cool water in experimental groups no increasing of pain meantion.

According to result , different groups median on the first day and the last day of the research are significantly different .($t = 7.21$, $df = 44$, $p < 0.05$) .

There was no significant difference in pain reduction in the two experimental groups.

Discussion/Conclusion

The results showed that using sauna causes a remarkable reduction in pain and increase ROM of joint affected specially in joints of the wrists, knees and ankle.

These effects may result from stimulation of sympathic system and in turn relieve pain as reported by sori and stimulate nervous system which causes the comfort and pleasure after sauna .

The result of this research a bout pain relief were similar to Nurmikko and Isomaki and Hannuksela.

According this result, and repeat of research again with more samples, it seems that, sauna maybe reduce pain of rheumatoid arthritis association of other non invasive treatment.

EFFECTS OF PHYSICAL ACTIVITY VERSUS CARDIORESPIRATORY FITNESS ON SELECTED CAD RISK FACTORS IN YOUTH

Al-Hazzaa, H.M.

King Saud University, Saudi Arabia

The aim of this study was to examine the effects of physical activity versus cardiorespiratory fitness on selected coronary artery disease (CAD) risk factors in Saudi youth. Participants were 41 young Saudi males (mean age (SD) = 20.5 (1.6)), came from predominantly middle-class family with good nutritional status. They were divided in separate analyses into two groups, based on levels either above or below the 50th percentiles of physical activity and cardiorespiratory fitness. Physical activity was classified according to the daily time spent above 50% of heart rate reserve (active (n=15) averaged 57.1 +/- 26.2 min/day, and inactive (n=25) averaged 10.9 +/- 7.9 min/day). Cardiorespiratory fitness was classified according to VO2 max levels (fit (n=21) averaged 53.8 +/- 3.7 ml.kg/min, and unfit (n=20) averaged 40.4 +/- 4.3 ml.kg/min. The findings of the present study showed that active young males did not differ significantly ($p < 0.05$) from inactive group in BMI, fat%, abdomen circumference, VO2 max relative to body mass, total cholesterol (TC), triglycerides (TG), LDL-C, systolic (SBP) or diastolic blood pressure (DBP). However, active males had significantly ($p < 0.05$) higher levels of HDL-C (40.5 +/- 5.2 vs 34.3 +/- 6.9 mmol/l) and HDL-C/TC ratio (28.6 +/- 5.9 vs 22.8 +/- 6.8). Fit young males, on the other hands, showed higher values than unfit males in BMI, fat%, abdomen circumference, TC, TG, LDL-C, HDL-C/TC ratio, SBP, DBP and daily time spent in moderate level physical activity. But, when data were reanalyzed while controlling for the effect of body fat%, the differences between fit and unfit males disappeared, except for TG and time spent in moderate level physical activity. It was concluded that cardiorespiratory fitness in youth appeared more important than moderate level physical activity in promoting favorable changes in CAD risk factors. The seemingly positive effects that cardiorespiratory had on CAD risk factors may operate through a lower body fat content.

WALKING LIKE A TOOL OF BODY COMPOSITION AND AEROBIC FITNESS INFLUENCE IN SENIOR WOMEN

Bunc, V., Stilec, M.

Faculty of P.E. and Sports Charles University, Prague, Czech Republic

Age related changes in body composition (BC) have implications for physical function and health. The redistribution and increase of fat and the loss of muscle mass result in substantial decrease in functional capacity. Fat mass (FM) plus fat-free mass (FFM) that contains of protein, water, and mineral, are equal total body mass.

Beginning in middle adulthood, FFM begins to decline gradually both in men and women, primarily due to the wasting of muscle tissue. Similarly like FFM decreases with age the body cell mass (BCM) in subjects without of systematically physical training. The BCM is the sum of oxygen-using, calcium rich, glucose-oxidising cells. This variable may indirectly characterize the ability of human to sustain a mechanical work, and indirectly in seniors as a criterion of independency.

One of the basic themes in exercise science research has focused on the relation of exercise on improvement of aerobic fitness (AF), usually measured as maximal oxygen uptake (VO2max).

When evaluating the influence of physical activity on the human it is important to know its energy requirement. A positive influence is exerted only by those physical activities, when during their application a certain minimal threshold is exceeded. The level depends on the purpose for which these activities are performed. An important physiological concept of exercise in rehabilitation and/or conditioning is the type of work that the body is performing. Dynamic work of endurance character like running, walking, swimming and cycling requires the movement of large muscle masses and requires a high blood flow and increased cardiac output. From these activities the walking is probably the most easily accessible, and often underestimated as a way to increase a subject's overall level of fitness in non-trained subjects or in selected groups of patients.

The aim of this study was to verify the moving programme based on walking for influence of BC and AF in women seniors. The walking at a level of 50 to 70% VO2max (HR ranged from 65 to 90% of HRmax) was used in a group of senior women (n=28, age=68.7±5.0 yrs, mass=69.9±7.9 kg, height=161.0±4.9 cm, body fat=37.5±5.1 %, VO2max.kg-1=25.9.1±4.0 ml.kg-1.min-1). The duration of one exercise session ranged from 30 to 70 min, and was performed 3-5 times a week. The total time of walking exercise ranged from 90 to 250 min. The energy output of walking ranged from 640 kcal (2675 kJ) to 1780 kcal (7740 kJ) [mean 950± 230 kcal - 3970±960 kJ] per week. After

12 months of training, the mass was not altered, body fat was practically constant, and BCM was significantly increased (10±2.7 % - p<0.01). Maximal oxygen uptake increased by 8±3.3% (p<0.01). Similarly as in VO2max was increase the performance in 1600 m walking test by 7.8±2.5 % (p<0.01). We may conclude that exercise with total energy content of 900 kcal (3760 kJ) per week may be enough for reduction of age dependent changes in BC, and AF in senior women.

EFFECTS OF AEROBIC EXERCISES ON THE SERUM OXIDIZED LDL AND TOTAL ANTIOXIDANT CAPACITY IN NON-ACTIVE HEALTHY MEN

Afzalpour, M.E., Gharakhanlou, R., Gaeini, A.A., Mohebi, H., Hedayati, M.

1- Birjand university, 2-Tarbiat Modares Uni., 3-Tehran Uni., 4-Gilan Uni.,5-Shahid Beheshti Uni. , Iran

BACKGROUND : It is suggested that physical exercise causes oxidative stress, which is potentially enhanced damage to muscles and other tissues due to production of free radicals. It seems that regular physical exercise enhances the antioxidant defense system and protects against exercise induced free radical damage. The question that arises is, what is interaction between intensity of aerobic exercises and production of oxidative stress resulting from that exercise?

METHODS : In order to study the effects of vigorous(80-85% 0f maximal reserve heart rate) and moderate(60-65% maximal reserve heart rate) aerobic exercises on the oxidized low density lipoprotein(ox-LDL) and total antioxidant capacity(TAC) , 44 non-active men volunteered for this research. These subjects were divided into three groups randomly, including vigorous aerobic exercise(WAE)(n=15), moderate aerobic exercise(MAE)(n=17), and control(n=12) group. Duration of training was 8 weeks, 3 sessions per week and each session lasted 30-45 minutes. Blood samples were taken 24 hours before the start of protocol(pre-test) and 24 hours after the last session of exercise in both middle (mid-test) and end (post-test) of protocol. Dietary intake of subjects during the 2 months of our study was recorded through a 24-hr dietary recall questionnaire. We measured TAC and ox-LDL by Randox kit of UK and DRG kit of USA, respectively. In order to extraction of results , we applied analysis of variance (ANOVA) test for repeated measures. Least significant difference (LSD) test was also used for coupled comparisons between times , groups and time-group interaction .

RESULTS : We observed that both aerobic exercises did not affect significantly serum TAC and ox-LDL. However, we observed significantly increase in high density lipoprotein (HDL) and HDL/total cholestrol ratio of WAE group(P<0.05) after 8 weeks. There was significantly increase(P<0.05) in maximal oxygen uptake(Vo2max) of both exercised groups after 4 weeks as well. There were no significant relationships among TAC ,ox-LDL and HDL , but we observed that TAC changes have significant negative correlation with total cholestrol(r=-0.65 , P=0.000), triglyceride(r=-0.40 , P<0.02) or LDL(r=-0.44, P<0.01) changes after exercise in all subjects. Besides, there were significant positive correlation among Vo2max and TAC(r=0.36, P<0.01) or HDL concentration(r=0.30, P<0.04). CONCLUSION : Although some of studies shown increases in TAC and decreases in ox-LDL due to exercise trainings, we observed that performed aerobic exercises could not produce oxidative stress, and thereby they did not affect TAC or ox-LDL. Moreover, correlation results suggest that improved physical fitness will be associated with higher antioxidant defense system and lower atherogenic risk factors.

OBESITY AND FITNESS IN COLLEGE MALES AND FEMALES

Nakhostin, B., Rahmani Nia, F.

University of Guilan, Iran

The purpose of this study is to investigate obesity and fitness of the staff of Ardebil Azad University. 69 staffs (32males and 37females) of Ardebil Azad University participated in this study voluntarily. Primary measurements of interest in the present study were height, body mass Index, subcutaneous skin folds, and cardio respiratory fitness determined by1 mile walk test. There weren't any significant differences in BMI between males and females. Fat percent were significantly higher (P<0.05) in women than men. Adversely, VO2max was significantly higher (P<0.05) in men than women. Social/lifestyle factors such as the level of education, marital status, exercise habits, dietary habits and smoking habits may be related to overweight/obesity in both genders in Ardebil. It was concluded that there isn't sufficient sport facilities and equipments for females in Ardebil Azad University and there are some cultural problems lead to females be less active than males.

Poster presentation (PP)

PULMONARY FUNCTION AND BRONCHIAL RESPONSIVENESS TO METHACHOLINE IN RECREATIONAL SWIMMERS: A CROSS SECTIONAL STUDY

Ferrari, M., Corradini, G., Cantoni, B., Giordani, G., Tonellotto, L., Buscemi, L., Masiero, M., De Vita, F., Papadopoulou, C., Lo Cascio, V.

University of Verona, Italy

The aim of the study was to evaluate lung volumes and bronchial responsiveness to metacholine in a cross sectional sample of recreational swimmers.

Seven hundred and eighteen swimmers (age 12-55 years, 419 females) performed force expiratory manoeuvres in to portable spirometer. Measurements included forced vital capacity (FVC) and forced expiratory volume in one second (FEV1). A randomly selected subgroup of 330 subjects, underwent methacholine challenge, expressing the results as the slope of the dose-response curve (the last dose divided by the percent decrease in FEV1 registered at the same time). Data on age, sex, smoking habits, respiratory symptoms, diseases were collected by mean of a standardized questionnaire. The swimmers were divided into three groups on the basis of time spent in swimming pool yearly (group1 <72 hours/yr, 268 subjects; group2 72-95 hours/yr, 216 subjects; group3 >95 hours/yr, 234 subjects). Asthmatics were defined the subjects responding positively to the question "have you ever had asthma?" and reporting respiratory symptoms and/or taking medicine for asthma.

In non asthmatic subjects (n.633) FVC%predicted (group1 101.9± 12.6%, group2 102.3± 13.1%, group3 106.6±15.2%), but no FEV1%predicted (group1 101.6±11.8%, group2 101.1±13.4%, group3 102.4±11.8%) resulted positively related to the hours spent in swimming pool (p< 0.01). In asthmatic subjects (n.75) no significant relationship between FVC and FEV1 on one hand, and swimming pool atten-

dance on the other, was seen (p> 0.05). No association between bronchial responsiveness to methacholine and swimming pool attendance was seen both in asthmatic and non asthmatic subjects.

Our results suggest that 1) recreational swimming is associated with a significant increase of pulmonary volumes in normal subjects, but not in asthmatics; 2) airway calibre and bronchial responsiveness seem not to be influenced by swimming pool attendance.

EXERCISE EFFECTS ON A MODEL OF EXPERIMENTAL ARTHRITIS: HORMONAL CHANGES

Vaisberg, M.W., Bacurau, F., Pontes, F., Costa Rosa, L., Navarro, F.

Federal University of São Paulo, Brazil

INTRODUCTION - Rheumatoid Arthritis is an autoimmune disease characterized by chronic inflammation of the joints. It is well established that exercise improves its evolution in patients and animal models, although the mechanisms responsible for this improvement have yet to be elucidated. Clinical and experimental observation has established the influence hormones have on the evolution of arthritis, which can be explained by the close relationship between the immune and neuroendocrine systems. OBJECTIVE - The aim of these experiments was to study the influence of exercise on the hormonal production in a model of experimental arthritis and the consequences for the course of the disease. MATERIAL AND METHODS - Female Wistar rats, weighing between 150-200 g were kept in ideal laboratory conditions and divided into three experimental groups: control (C), arthritis (A) and swimming/arthritis (SA). Experimental arthritis was induced by inoculation of type II collagen in complete Freund adjuvant into the right hindlimb. The training consisted of 5 weekly sessions of swimming for six weeks. Each session lasted one hour, during which a load, equivalent to 5% of the rat body weight, was attached to the tail. After the training protocol, the animals were decapitated. We proceeded with the dosage of the plasmatic hormones estrogen, progesterone, cortisol and prolactine using the "IRMA DPC" kit. RESULTS - We were able to demonstrate a decrease in the plasmatic concentration of progesterone in the arthritis group; these values normalize with training (C- 15,6 +_ 2,9, A- 8,4 +_ 1,3, SA- 13,5+_2,5, ng/ml). Prolactine values showed an increase in the arthritis group, and lowered with exercise (C- 189+_ 1,7, A- 196+_2,1 SA- 186+_2,4, ng/ml). Cortisol showed an increase in the arthritis group and a more significant increase in the swimming/arthritis group (C- 0,6+_0,06, A- 0,7+_0,06, SA- 0,8+_0,06, μg/ml). Estrogen did not show any statistical differences between the groups. Conclusion – Swimming training induced hormonal changes in this model of experimental arthritis, associated with a better course of the disease. The increased concentration of cortisol can be associated with a block of the inflammatory process. Diminution of prolactine can decrease the autoimmune process activation. The increase of progesterone, as described in medical literature, shows a beneficial effect on the course of the disease.

GASTROESOPHAGEAL REFLUX DOES NOT AFFECT THE SEVERITY OF EXERCISE-INDUCED BRONCHOCONSTRICTION

Ferrari, M., Corradini, G., Papadopoulou, C., Giordani, G., Tonellotto, L., Buscemi, L., Masiero, M., Lo Cascio, V.

University of Verona, Italy

Aim of the study was to evaluate whether the presence of acid in oesophagus has any role in eliciting exercise-induced bronchospasm (EIB). Thirty asthmatic patients not regularly treated with inhaled steroids (age 38.2±14.5 years; FEV1 90.0±12.7 %predicted) were studied in basal conditions and after a two week treatment course with omeprazole, 20 mg bid orally. Baseline investigations included 24-hour oesophageal dual-probe pH-monitoring, spirometry, and exercise challenge. The challenge was performed on a bicycle ergometer and was repeated, at the same hour of the day, at the end of treatment. The results of exercise test were expressed as the maximum percentage fall in FEV1 in respect to basal values (DFEV1). At baseline, exercise was performed at the same time of oesophageal pH monitoring.

Fourteen patients demonstrated a significant decrease in FEV1 (>15%) following exercise (DFEV1 25.5±11.4%), while the others were considered negative to the test (DFEV1 4.2±4.9%). In basal condition, there was no difference in FEV1, acid exposure time, number of refluxes measured during the 24h pH monitoring in the proximal and in the distal oesophagus, between patients with or without EIB. Moreover, there was no relationship between spirometry results and DFEV1 after exercise on one hand, and parameters of gastrooesophageal reflux (GER) on the other, both when the whole population studied was considered and when the analysis was performed separately on the patients with or without EIB. Four out of asthmatics with EIB (28.7%) and 7 out of patients without EIB (43.7%) had one or more episodes of GER during exercise challenge, without significant differences between the two groups. After gastric acid inhibition by omeprazole, DFEV1 did not change significantly in respect to basal values, both in asthmatic with or without GER.

Our results indicate that the presence of acid in the oesophagus or its inhibition by proton pump inhibitors has no influence on exercise-induced bronchoconstriction in asthma.

BONE MINERAL DENSITY IN MALE AND FEMALE APPRENTICE IRISH JOCKEYS

O'Brien, M., Byrne, A.M., Beades, M., Donne, B.

Trinity College Dublin, Ireland

Optimal skeletal development is a complex process requiring adequate nutrition and weight bearing exercise modulated by hormonal and genetic factors. Bone mass accrual increases with age, height and body mass throughout childhood and increases significantly during puberty (Bailey et al., 2000). Selection criteria for some sports include small stature and low body mass, factors which could potentially effect skeletal development and diagnosis of osteoporosis (Gafni and Baron, 2004). We examined whether bone mineral density (BMD) data was affected by small bone size and body mass.

Subjects participating in this study comprised 6 female (mean±SD; age 16.3±0.5 yr, mass 48.5±3.5 kg, height 157±9 cm) and 19 male (age 15.5±0.6 yr, mass 46.7±5.1 kg, height 160±5 cm) apprentice jockeys. Anthropometric data, dietary, exercise and fracture history were recorded, lumbar spine (L1-L4) BMD by DEXA (Hologic Ltd., USA), bone age by plain X-ray of the left hand and wrist using the Greulich-Pyle atlas, and fasting hormonal profiles were assessed. The menstrual history of female subjects (age at menarche and menstrual frequency) was also recorded. Using determined bone age the date of birth in the DEXA bibliography was adjusted to equate to bone age and the lumbar spine Z-score data re-calculated based on bone rather than chronological age for each individual. Data were analysed using non-parametric (Mann-Whitney, Wilcoxon) tests, values of P<0.05 inferred statistical significance.

Significant differences (P<0.05) between chronological and bone age were recorded in both male (192±6 vs. 171±11month) and female (202±9 vs. 181±9month) subjects. Mean BMD data for male (0.77±0.09 g.cm-2) and female (0.90±0.07 g.cm-2) subjects were significantly less than age matched norms, mean±SD Z score data were -2.2±0.8 (male) and -1.0±0.7 (female). Bone age adjusted Z-score calcula-

tions were compared with age- and gender-matched controls. This revealed significantly higher lumbar spine Z-score data for both male (-1.2±1.0) and female (-0.4±0.8) subjects, (P=0.02 and P=0.03, respectively).

Apprentice jockeys have low body mass and bone size, leaving their bone mineral density data open to misinterpretation by traditional methods of analysis and overestimating the incidence of low bone density. Using bone age rather than chronological age for calculations of Z-scores addresses the dilemma of small-for-age subjects and avoids erroneous diagnosis which potentially could lead to inappropriate treatment.

CHILDREN PARTICIPATING IN COMPEITITIVE SPORT DO NOT GET INJURED MORE THAN THE AVERAGE CHILD

Mahler, P.B., Guinand, S., Schopfer, C., Duperrex, O.

Service de Santé de la Jeunesse, Switzerland

Sports Injuries is a preoccupation for young sportsmen, their families, coaches and for health professionals. Injuries are often brought up as a danger linked to sports participation, and little is known as to what extent participation in competitive sport leads to more injuries than the average. Furthermore some studies seem to show that parents avoid inscribing their children in sports because of the potential danger of injury.

We used a prospective successive cohort (3 year follow-up) injury database, drawn from 180 children (approximately half boys, half girls) per year, aged 12-16, participating in competitive sports (average 9.93 h of training/wk SD 1.05) and that followed an adapted school curriculum. The data was collected systematically, using an individually reported injury slip and verified during an annual medical evaluation. This has been done since 1990 which permits to establish a baseline injury rate .

The injury prevalence is expressed as injuries/child/year allowing comparison with two other studies carried out in the same geographical area and during the same time period. The injury rate among the competitive sports children was found to be 0.27 (SD 0.07) injuries/child/year and was relatively constant from 1990-2003. It was compared to two other studies; one hospital based study from 1990 that showed an injury rate of 0.22 injuries/child/year (RR:1.24, p=.16) the other was a school based survey from 2001 that showed an injury rate of 0.24 injuries/child/year (RR: 1.17, P= .15).

Conclusion: Taking the limitations of the different study designs in to consideration, it can be suggested that children practising competitive sports in this particular school setting do not get more injured than the average child. This could be due to the setting, but the relative stability of injuries prevalence over the 15 yr period among sportsmen and the similarity in injury prevalence in the two comparative studies leads to believe that independently of study design, there seems to be little difference between the groups.

PLASTICITY OF TRABECULAR BONE ARCHITECTURE FOLLOWING DENERVATION AND SUBSEQUENT REINNERVATION IN RAT PROXIMAL TIBIAE

Tamaki, H., Yotani, K., Ogita, F., Takekura, H.

National Institute of Fitness and Sports, Japan

Purpose: Disused rat hindlimb caused by sciatic denervation is characterized by skeletal muscle atrophy and bone loss accompanying alterations in trabecular bone architecture. We studied the effects of short term denervation followed by reinnervation on the two-dimensional architecture of trabecular bone using a unilateral sciatic nerve freezing model rat of temporary disuse.

Methods: Fischer-344 male rats (n=48) aged 10 weeks were anaesthetized by an intraperitoneal injection of sodium pentobarbitone. The left sciatic nerve was elevated using forceps and frozen by contact with a stainless steel rod cooled (<-180°C) by liquid nitrogen for 3-5 sec. The right and left tibiae of denervated and control rats were removed at 0, 1, 2, 3, 4 and 5 weeks after surgery. After fixation with a mixture of 1% glutaraldehyde, 1% formaldehyde and 0.05% CaCl2 in 0.1M sodium cacodylate buffer (pH. 7.3), the tibiae were demineralized in 0.1M disodium ethylenediaminetetraacetic acid (pH 7.3) for 6 weeks at 4oC, dehydrated through a graded ethanol series, and then embedded in paraffin. Longitudinal sections of 5µm thickness were cut using a microtome. Specimens were stained with the media of Azan or HE (haematoxylin-eosin). Quantitative analysis of microscopic observations was performed using a digital microscope (Coolscope, Nikon), which comprised a video monitor and a personal computer with image analysis software (Image-Pro Plus ver. 5.0).

Results: The sciatic denervation (by nerve freezing) resulted in a marked loss of trabecular bone mostly within first two weeks after denervation. Trabecular bone area gradually decreased ($p<0.01$) and recovered after 4 weeks, and returned to approximately 80% of the control levels (at 0 w) at 5 weeks after denervation. Both the thickness and length of trabecular bone were significantly ($p<0.01$) decreased after denervation. Trabecular thickness, number, and bone area at 4 and 5 weeks were significantly ($p<0.01$) greater than that at 3 weeks, but did not return to the control levels.

Discussion/Conclusion: These findings suggested that 1) the sciatic nerve freezing resulted in a marked loss of trabecular bone mostly within first two weeks after surgery; 2) the temporary denervation and subsequent reinnervation reversibly affects the trabecular bone architecture, especially trabecular thickness and trabecular number.

INFLUENCE OF LOWER LEG ROTATION TO MTC EFFECT OF PATELLAR CARTILAGE DURING ISOMETRIC KNEE EXTENSION

Kudo, H., Mukai, N., Kuno, S., Miyanaga, Y., Miyakawa, S.

University of Tsukuba, Japan

Introduction

Magnetization transfer contrast (MTC) is an imaging method which creates tissue contrast in a different manner as T1 and T2 relaxation time by the exchange of magnetization between macromolecular protons and bulk water, via cross relaxation or chemical exchange. Therefore, it may be beneficial to evaluate articular cartilage using MTC because it has abundant macromolecules, and it's function

should be specified by macromolecular protons. The aim of this study was to evaluate the influence of knee rotation to the quantitative effect of MTC during isometric knee extension in patellar cartilage.

Methods

This study comprised five healthy volunteers and 10 knees. MR imaging was performed with a 0.2T MR imaging system with a knee coil. Gradient recalled echo (GRE) and GRE-MTC sequences to obtain transverse axial images of patellar cartilage were performed to all subjects for 18sec. GRE sequence was TR=100msec, TE=34msec, FA=30deg. The off-resonance sinc pulse was set at a frequency offset of 1.2KHz from the free proton resonance with a duration of 10msec and an amplitude of 12.7x10-6T as preparation for MTC images. GRE and GRE-MTC images were obtained before and during the courses of isometric knee extension. The volunteers performed 1kg loaded isometric knee extension under neutral and external rotation of lower leg for 2.5min. in the MR machine. The quantitative analysis of patellar cartilage was performed with Ms/Mo between neutral and external rotation of lower leg during knee extension. Ms/Mo was calculated as follows: Ms/Mo = SNR with MTC / SNR without MTC, where SNR is signal-to-noise ratio.

Results

Lateral facet of patellar cartilage with neutral and external lower leg rotation had mean Ms/Mo of 0.72+/-0.03 and 0.75+/-0.05, respectively, before knee extension. The Ms/Mo of lateral facet during knee extension with neutral rotation (0&2min) and rest after knee extension (0,4&6min) changed by 0.73+/-0.06, 0.78+/-0.10, 0.77+/-0.01, 0.73+/-0.05, 0.71+/-0.07. On lateral facet in knee extension with rotation, the Ms/Mo also changed by 0.76+/-0.07, 0.80+/-0.01, 0.81+/-0.08, 0.77+/-0.07, 0.74+/-0.04. On medial facet, there was no apparent difference between knee extension with and without lower leg rotation. However, these changes were not significant ($p>0.05$).

Discussion/Conclusion

We investigated the quantitative effect of MTC in patellar cartilage to evaluate the influence of lower leg rotation during isometric knee extension. On external rotation of lower leg, the Ms/Mo in lateral facet fluctuated more greatly than neutral lower leg position. This result suggests that lateral facet has suffered much large mechanical stress than medial facet by external rotation of lower leg during knee extension. The MTC technique would be a promising method to elucidate the effect of exercise on articular cartilage.

COMPARISON OF METHODS TO IDENTIFY LACTATE THRESHOLD DURING LEG PRESS EXERCISE

Puga, G.M., Barros, C.L., De Agostini, G.G., Simões, H.G., Garcia, E.S., Baltissera, V.

Catholic University of Brasilia, Brazil

Lactate threshold (LT) identification during activities such as running, cycling, rowing, and swimming has been the subject of a number of studies for the past several decades. However, little is known about the LT during resistance exercises (RE). PURPOSE: The purpose of this study was to compare five different methods to identify LT in RE during leg-press (LP) exercise for both trained (TR) and untrained (UN) individuals subjects. METHODS: 20 male subjects were divided in 2 groups of 10 subjects: LP-TR (23.3 ± 4.7 yrs, 84.65 ± 12.52 kg) and LP-UN (24.6 ± 3.8 yrs, 72.24 ± 5.92 kg). The subject 1RM load was determined prior to the LT tests. The initial load for the incremental RE tests was 10% of 1RM and it was increased by 10% for each consecutive 1-min trial. Blood collection was performed during the 2-min interval between the exercise trials. The cadence was established at 20 repetitions per minute. The methods used were: 1) the breakpoint of blood lactate (BL); 2) the lactate quotient (LQ) which was found by the blood lactate and workload ratio ([lac] • workload-1) at each stage; 3) LQ modeled through a second grade polynomial function by using all the stages (AS) of maximal incremental test; 4) five fixed stages (5S); 5) three stages, one below, one at and one above the LQ (3S). The one way ANOVA test for repeated measures with Scheffe post hoc was used to compare the different methods in each group. The level of significance was $p < 0.05$. RESULTS: The results of all subjects are shown as percent of their 1-RM test. In LP-TR were 35.5 ± 4.6, 40.9 ± 6.5, 35.9 ± 6.9, 38.0 ± 13.9, and 28.0 ± 6.3 % of 1RM for 5S, AS, 3S, BL and LQ methods respectively and in LP-UN were 37.0 ± 3.1, 40.2 ± 3.8, 34.9 ± 8.1, 40.0 ± 6.7, and 34.0 ± 6.9 % of 1RM for 5S, AS, 3S, BL and LQ methods respectively. The statistical analysis showed no differences ($p<0.05$) between the five different methods to identify LT in LP-TR group, but there was a difference ($p<0.05$) between AS and QL in LP-UN. CONCLUSION: The results suggest that it's possible to access the LT for RE in TR and UN subjects in LP exercise. Modeling of the LQ through a second grade polynomial function using 3S appears to be better than the others methods using more series to precisely identify the LT load for LP exercise. The physiological meaning of LT determination on RE need to be better investigated.

COMPARISON OF METHODS TO IDENTIFY LACTATE THRESHOLD ON RESISTANCE EXERCISE DURING ELBOW FLEXION

Puga, G.M., Barros, C.L., De Agostini, G.G., Simões, H.G., Garcia, E.S., Baltissera, V.

Catholic University of Brasilia, Brazil

Lactate threshold (LT) determination during activities such as running, cycling, rowing, and swimming has been the subject of a number of studies for the past several decades. However, little is known about the LT during resistance exercises (RE). PURPOSE: The purpose of this study was to compare five different methods to identify LT in RE during elbow flexion (EF) exercise for both trained (TR) and untrained (UN) individual subjects. METHODS: 20 male subjects were divided in 2 groups of 10 subjects: EF-TR (25.1 ± 5.7 yrs, 81.40 ± 9.22 kg) and EF-UN (23.8 ± 4.0 yrs, 72.55 ± 6.37 kg). The subject 1RM load was determined prior to the LT tests. The initial load for the incremental RE tests was 10% of 1RM and it was increased by 10% for each consecutive 1-min trial. Blood collection was performed during the 2-min interval between the exercise trials. The cadence was established at 20 repetitions per minute. The methods used were: 1) the breakpoint of blood lactate (BL); 2) the lactate quotient (LQ) which was found by the blood lactate and workload ratio ([lac] • workload-1) at each stage; 3) LQ modeled through a second grade polynomial function by using all the stages (AS) of maximal incremental test; 4) five fixed stages (5S); 5) three stages, one below, one at and one above the LQ (3S). The one way ANOVA test for repeated measures with Scheffe post hoc was used to compare the different methods in each group. The level of significance was $p < 0.05$. RESULTS: The results of all subjects are shown as percent of their 1-RM test. In EF-TR were 38.4 ± 2.0, 39.8 ± 3.9, 36.9 ± 8.2, 33.0 ± 8.2, and 34.0 ± 8.4 % of 1RM for 5S, AS, 3S, BL and LQ methods respectively, and in EF-UN were 37.4 ± 2.4, 39.0 ± 3.4, 34.6 ± 7.0, 26.0 ± 7.0 and 31.0 ± 7.4 % of 1RM for 5S, AS, 3S, BL and LQ methods respectively. The statistical analysis showed no differences ($p<0.05$) between the five different methods to identify LT in EF-TR group, however there were differences between 5S and BL; AS and BL; and AS and QL in EF-UN. CONCLUSION: The results suggest that it's possible to access the LT for RE in TR and UN subjects in EF exercise. Modeling of the LQ through a second grade polynomial function using 3S appears to be better than the others methods using more series to precisely identify the LT load in RE during elbow flexion especially in UN subjects. However, the physiological meaning of LT determination on RE need to be better investigated.

PREVALENCE OF CARDIOVASCULAR DISEASES AMONG MOUNTAINEERS

Faulhaber, M., Flatz, M., Burtscher, M.

University Innsbruck, Austria

In recent years mountain sports have become very popular. In the Alps, the number of tourists visiting altitudes above 2000 m is estimated at about 40 million people per year [1]. Although the percentage of elderly, often suffering from cardiovascular diseases (CVDs), seems to be high [2,3], little information is available about the real frequency of CVDs among mountaineers. Therefore the goal of this study was to provide data - collected in a representative population - about the prevalence of CVDs among mountaineers at moderate altitudes.

We interviewed a representative population of 937 ski mountaineers, 1525 hikers and 1062 alpine skiers / snowboarders (skiers) using a standardised questionnaire. We recorded personal data (age, sex etc) and if the persons had known CVDs such as a prior myocardial infarction (MI), coronary artery disease without infarction (CAD), hypertension, arrhythmias, and other CVDs. Data were statistically analysed by SPSS (version 13.0). Comparison of variables were performed by students' t-test, by chi-square-test or fisher's exact test as adequate. P-Values less than 0.05 were considered to indicate statistical significance. Values are presented as means±SD or frequencies (95% CI).

Data of 934 ski mountaineers, 1431 hikers and 1043 skiers were included into the analyses. The skiers (36.0±18.1 years) were younger than the hikers (41.8±16.1 years) and the ski mountaineers (42.4±12.7 years, $p<0.01$). Gender distribution was different in all the three sports. The prevalence of the cardiovascular diseases is clearly age dependent. The frequency of persons with one ore more cardiovascular disease is increased in hikers (12.7 (11.0-14.4) %) and skiers (11.2 (9.3-13.1) %) when compared to ski mountaineers (5.8 (4.3-7.3) %, $p<0.01$). A prior MI was reported by 0.7 (0.2-1.2) % of the ski mountaineers, 1.1 (0.6-1.6) % of the hikers and 1.0 (0.4-1.6) % of the skiers. Hypertension was the most frequent cardiovascular disease.

Because our data are based on the information given by the interviewed persons, cases of CVDs that are not reported or unknown are not included in our calculations. Although our data can not be uncritically generalized to other regions and altitudes, we assume a high number of mountaineers with CVDs in the Alps. Scientific research should focus on cardiovascular and metabolic responses during mountaineering to provide the data for scientifically based recommendations to persons with CVDs.

STRUGGLE AGAINST DOPING IN OLYMPIC SPORTS:WAYS OUT OF CRISIS

Platonov, V.

National University of Ukraine on Physical Education and Sport, Ukraine

The whole history of the Olympic movement, its reputation and attraction for the world commonwealth are related to the moral-ethic values accumulated in the Olympism ideals including fair play, unity of human spirit, body and mentality etc. Thus such values can develop only on the basis of an education system of humanistic direction that could be referred to all the Olympic sports problems including doping. And to grow up these values is impossible by means of common distrust, total control, threats, sanctions, violation of human rights, and suppression of athletes' interests including those connected with their health care. Unfortunately the World Anti-Doping Agency took that very defective way to fight against doping.

There is a need in principally another methodology without subjectivism that is based on reliable scientific knowledge including wide educational programs that contain respect to an athlete personality, his rights, views, ethical principles, moral values.

The following directions can be emphasized as the main activities capable to normalize situation with doping use, to delete contradictions between anti-doping bodies and different structures of the international Olympic system (IOC, NOC, sports federations):

- cardinal revision of WADA Code on the base of methodology grounded on achievements of advanced sports and medical sciences, general international laws;
- conduct of wide scale scientific researches of elaboration of a system of allowed ergogene means and methods, minimization of a quantity of banned ones, creation of a distinct border between allowed and banned means taking into account the specifics of various kinds of sport;
- placing an opportunity to use all modern medicine achievements at athletes' disposal; not to limit them in usage of the most efficient medicinal means for treatment;
- establishment of alternative laboratories and centers for anti-doping control based on various methodology of solving the doping problem in sport;
- granting the ISF the right to invite for service of the competitions and kinds of sport those anti-doping laboratories and centers whose activities meet the specificity of a particular sport to the utmost extent;
- democratization of anti-doping struggle on the side of the IOC – support of alternative approaches of struggle against doping, assistance to the activities of anti-doping laboratories, shift of the accent in struggle against doping into the sphere of SF activities.

The work in these directions does not exclude the necessity to struggle against use of doping in sport. Its goal is identification of ways out of deadlock where this problem was driven by modern practice and existing laws in this sphere.

RELATIONSHIP BETWEEN THE PRESENCE OF GENU VARUS AND THE CROSS-SECTIONAL AREA OF LEG MUSCLES

Sogabe, A., Mukai, N., Miyakawa, S., Mesaki, N.

Konan University, Japan

[Objective] It has been proposed that the ratio of the cross-sectional areas of the four parts of the quadriceps femoris muscle may be related to development of PFP (patellofemoral pain) and AKP (anterior knee pain). In particular, the vastus medialis (VM) is thought to play an important role in pulling the patella medially, whereas the vastus lateralis (VL) acts by pulling the patella laterally. Furthermore, the presence of genu varus may result in differences in the power output of the VM and the VL, even when the knee is extended. Variation in knee alignment may lead to differences in the relative cross-sectional areas of the four muscles, and in this study we examined if genu

varus has an effect on these cross-sectional areas. [Methods] The subjects were 12 healthy adult males, including 6 with normal knees (FTA: 176.0° ± 0.9°) and 6 with genu varus (FTA: 180.2° ± 0.8°). The left thigh bones and left shin bones of the subjects were imaged in the supine position, using an AIRIS Mate 0.2T (Hitachi Medical Corporation, Japan) to obtain T1-weighted images. Cross-sectional areas of the adductor (Add), rectus femoris (RF), vastus lateralis (VL), and vastus medialis (VM) were measured at positions located 70% (Add), 50% (RF and VL) and 30% (VM) of the distance from the distal end of the femur. Cross-sectional areas of the gastrocnemius (GAS) and soleus muscle (SOL) were measured at the point of the biggest circumference around the lower legs, and the percentage of each muscle at the measurement point was also determined. The VM/VL ratio was calculated by dividing the VM cross-sectional area by that of the VL. [Results] The VM cross-sectional area expressed as a percentage of the total cross-sectional area of all the muscles was 25.1% and 30.7% in the normal knee group and the genu varus group, respectively. These data differed significantly ($p<0.025$); however, no significant differences were found for other muscles. The VM/VL ratio was significantly higher ($p=0.046$) in the genu varus group (1.56 ± 0.30) compared to the normal knee group (1.22 ± 0.23). [Discussion] The presence of genu varus may result in the patella being pulled more powerfully in a medial direction, and this may result in greater hypertrophy of the VM relative to the VL. The causes of knee pain include muscle weakness of the VM, along with patella misalignment and ageing, and the vastus medialis plays a more important role when genu varus is present, compared to the situation in normal patellae. Hence, we conclude that careful attention should be paid to VM muscle weakness.

ASSESSING THE RELATIONSHIP OF OXYGEN DESATURATION AND ISOKINETIC FORCE PRODUCTION USING NIRS

Ziesing, A. 1, Banzer, W. 1, Gibson, M. 2, Vogt, L. 1

1Johann Wolfgang Goethe-University Frankfurt, 2 University of Wisconsin, USA, Germany

Near-infrared spectroscopy (NIRS), based on differential absorption of oxygenated (Hb/MbO2) and deoxygenated forms of hemoglobin/myoglobin (Hb/Mb) in the near-infrared range, is a non-invasive method which allows continuous monitoring of the dynamics of tissue deoxygenation during exercise. The present study determines the relationship between the time course of Hb/MbO2 desaturation and isokinetic torque.

METHODS: Twelve healthy male subjects (age 52.9 ± 12 years, height 174.5 ± 9.4cm, weight 81.6 ± 9kg) performed 30 standardized repetitions at 120°/s of wrist extension/flexion isokinetic movements. NIRS signals were obtained by a commercially available unit (InSpectra Tissue Spectrometer 325, Hutchinson Technology, Netherlands). The NIRS probe was placed over the forearm flexor-group during the test. Subjects were verbally encouraged to produce their individual maximum contractions after 5, 15 and 25 repetitions. Oxyhemoglobin and deoxyhemoglobin values at a depth of up to 25 mm were recorded continuously with 4 specific wavelengths (680nm, 720nm, 760nm and 800nm). The temporal relationship between average Hb/MbO2 desaturation and flexor torque production were assessed using Pearson Product-moment correlation coefficients.

RESULTS: Findings demonstrated a significant negative correlation ($r = -.766$, $p<0.05$) between Hb/MbO2 desaturation and maximal isokinetic flexor torque values. Hb/MbO2 desaturation values increased from 45% to 80% of desaturation after 7 repetitions and then plateaued. Maximal torque increased from 6nm up to 7nm and then passed into a steady torque production. The maximal torque and the Hb/MbO2 values showed the greatest difference after 7 repetitions. Divided into three time intervals (0-40sec, 40-80sec, 80-120sec), it was found that the desaturation Hb/MbO2/torque relationship became more pronounced when exercise time increased. The third time interval showed the highest significance between Hb/MbO2 desaturation and maximum torque ($r = .824$, $p<0.001$).

CONCLUSION: The results demonstrate the temporal interrelation between Hb/MbO2 desaturation and force production at a constant angular velocity. Muscle deoxygenation measured by NIRS seems to be of increasing importance in the understanding of the mechanisms of local muscle metabolism during exercise. Future studies should evaluate the influences of muscle fatigue in more detail.

SINGLE AND/OR REPEATED EXERCISE AND THE AMPHETAMINE-INDUCED RELEASE OF DOPAMINE IN THE STRIATUM

Fontes Ribeiro, C.A., Marques, E., Pereira, F., Remedios, I., Morgadinho, T., Macedo, T.R.

University of Coimbra, Portugal, Egas Moniz Superior Health School

There is little information about the relationship between the effects of repeated exercise and the synthesis, release and action of neurotransmitters in the central nervous system. Moreover, in spite of the existence of many studies about amphetamines (AMPH) and the frequent use of these substances as doping, there is only a few ones about the influence of AMPH on neurotransmitter changes induced by exercise.

Being dopaminergic neurons essential in the motor system, this study aimed to verify the influence of exercise, acute and/or repeated, on the release of striatal dopamine (DA) induced by a single administration of AMPH.

Eight groups of male Sprague-Dawley rats (n=5-7) were used (no acute or repeated exercise; acute exercise after repeated exercise; only acute exercise; only repeated exercise; the same groups but after AMPH). Exercise was performed in a treadmill, being the training (of increasing intensity) performed for 8 weeks. Rats were anaesthetized with pentobarbital, placed into a stereotaxic frame and an intracerebral guide cannula was implanted into the caudate-putamen (CPu). On the day of the tests, a dialysis probe was slowly inserted through the guide cannula into the CPu. The probes were perfused with and artificial cerebrospinal fluid. Microdialysis in vivo in these freely moving rats was performed in a campanula and in the treadmill, being AMPH (5mg/Kg) or a saline solution injected intraperitonially. HPLC with electrochemical detection was used to quantify the DA present in the samples, collected for 6 hours.

Exercise, either acute and/or repeated, in the absence of AMPH did not increase extracellular DA concentrations above our limit of quantification for this amine. However, AMPH strongly increased the DA release. Regarding the maximal DA levels in the samples collected by microdialysis in the rats treated with AMPH, there was no significant differences (two tailed ANOVA) between the different groups treated with AMPH. However, analysing the behaviour of DA release along time, in the group with acute exercise after repeated exercise data show that there is a higher release of DA (for six hours, whereas in the group without acute and repeated exercise this release was for four hours). There is the possibility that a sensitization of these animals may occur towards the stimuli they were exposed during the training, being their response more intense to that same stimuli. In trained animals but without acute exercise, there appears to be a prolongation for half an hour of the effect of AMPH on the release of DA. Both types of exercise (acute or repeated) seem to delay the increase of extracellular DA release induced by AMPH. If drug abuse is related to DA reinforcing mechanisms, as has been demonstrated, repeated exercise may replace drugs of abuse. However, more studies are needed, at least with other doses of AMPH.

EXERCISE-INDUCED ANGIOGENESIS IS MISSING IN HETEROZYGOUS MNSOD-KNOCKOUT MICE

Brixius, K., Richters, L., Lange, N., Scharffetter-Kochanek, K., Treiber, N., Schwinger, R.H., Ghanem, A., Tiemann K., Bloch, W.

Institute of Cardiology and Sport Medicine, Germany

Only recently, a heterozygous mouse model has been described with a reduced expression of mangan superoxide dismutase 2. The MnSOD knockout mice (MnSOD_KNO) are characterised by an increased oxidative stress in the heart. It has been proposed that this model is suitable to investigate age-dependent alterations in heart failure (Strassburger et al. 2005).

Therefore, we investigated the influence of physical exercise on cardiac function in male MnSOD2_KNO (MnSOD_KNO_EXER, n=11) and wildtype mice (WT_EXER, n=6). Animals were trained for 8 weeks on a running wheel 1 h a day (15 m/min, 5 days/week, at an angle of 5°). Controls were untrained age-matched animals (WT_CON, n=7; MnSOD_KNO_CON; n=9). After the training period, an echocardiogram was taken from the animals. Heart frequency was measured in trained and untrained animals under conditions of acute physical exercise (running wheel, 10 min, 15 m/min, 5°) and 10 min after recovery. In addition, we measured heart-body weight ratio and the density of the cardiac capillaries.

Heart- and heart-body weight ratio was significantly increased in MnSOD-KNO independently from physical exercise. Left ventricular enddiastolic volume was ony increased in MnSOD_KNO_EXER. Under baseline conditions, heart frequency was similar in all groups. In the hearts of WT_EXER, a significant increase in capillary density was observed, whereas no alterations in capillary density were observed in MnSOD_KNO_EXER.

Conclusions: Physical exercise is able to induce a dilative cardiac phenotype under conditions of increased oxidative stress in the heart. Increased exposure to radicals seems to decrease exercise-induced angiogenesis.

IDENTIFICATION OF SATELLITE CELLS AND MYONUCLEI

Oka, K., Tayama, T., Morita, S., Takayanagi, S., Sakamoto, M., Muro, M.

Toho University School of Medicine, Japan

Introduction

Satellite cells are the stem cells of skeletal muscle and play an important role in the regeneration process. The satellite cells are located between the sarcolemma and the basal lamina of the muscle fiber. The cytoplasm of the satellite cell is extremely small and, therefore, the identification of the satellite cell and myonucleus is impossible using a light microscope. Immunological markers, antibodies, are used to identify satellite cells but to date, there is no consensus concerning the antibodies on what should be used for the marker (1). Presently, clear identification of satellite cells can only be achieved using a transmission electron microscope (TEM). However, it is difficult for TEM to handle satellite cells quantitatively because the observation area of the TEM specimen is small. The goal of this study is to identify satellite cells using a scanning electron microscope (SEM) and a paraffin section which is the most widely used technique for light microscope specimens.

Materials and methods

The gastrocnemius muscles of 3-week-old female ICR mice were used in this study. The excised gastrocnemius muscles were fixed in acetone for 3 hours at 5°C and embedded in paraffin in the usual manner. Longitudinal serial sections were made at 8 μm and the paraffin was removed from sections with toluene. After sputter coating with Pt-Pd, the specimens were observed with a Hitachi S-3500N scanning electron microscope at an accelerating voltage of 15 kV.

Results

 In this experiment, the cells in the interstitium were omitted from the subjects of study. Namely, the cells and nuclei surrounded by the basal lamina of muscle fiber were observed. All of the cells or nuclei surrounded by the basal lamina of the muscle fiber were divided into 2 groups. The structure with a double membrane is the satellite cell and that with a single membrane is the myonucleus. That is, in satellite cells, the outside membrane is the cell membrane of the satellite cell and the inside membrane is the nuclear membrane of the satellite cell. On the other hand, myonucleus has a single, nuclear membrane. Regarding the interior structure of the nucleus, that of myonuclei is simple compared to the nuclei of satellite cells.

Discussion

In this study, identification of satellite cells and myonuclei was achieved using SEM and a paraffin section. The paraffin section is the most widely used technique and it is easily made. The size of the paraffin section is large in comparison with the TEM specimen, and therefore, the technique in this paper is more appropriate for handling satellite cells quantitatively. Furthermore, the movement of the satellite cells is pursued regardless of the cell stages (quiescent, activated, proliferated, differentiated) because this technique is unrelated to immunological markers.

IMMEDIATE EFFECTS OF LASERNEEDLE STIMULATION ON MICROVASCULAR BLOOD FLOW MEASURED BY LASER DOPPLER SPECTROSCOPY

Hübscher, M., Banzer, W., Seib, M., Vogt, L.

J. W. Goethe-University Frankfurt/Main, Germany, Germany

Introduction

Biostimulatory effects of low level laser light therapy (LLLT) have been extensively reported. In clinical settings, LLLT has been proposed as a potential treatment in the management of musculoskeletal disorders and pain (Basford 2000). Furthermore, it has been shown that the application of low level laser light induces vascular relaxation leading to an improved microcirculation and oxygen supply (Litscher 2003, Maegawa et al. 2000). This is relevant since adequate blood provision is an important factor in the treatment of pain syndromes in sports medicine. Thus, the aim of the present study was to evaluate immediate effects of a standardised laserneedle stimulation over a defined acupuncture point on the microvascular blood flow in a randomised, double blinded, placebo controlled trial.

Methods

33 healthy non-smoking males were randomly assigned to a control group (n=15) with no laser irradiation and to a intervention group (n=18) for which laserneedle irradiation was performed on the right forearm at acupuncture point Pe6. Non-invasive blood flow meas-

urements (laser Doppler spectroscopy; LDS) were performed before, during and after intervention (depth of measurement approx. 1 and 8 mm) on the right forearm.

Results

Repeated measures MANOVA demonstrated a statistically significant interaction between time and group (p=0,034, partial eta squared=0,39) indicating that peripheral blood flow was influenced by laserneedle application. Simple contrast analysis showed that during intervention, average skin blood flow increased by 7,3% in the experimental group whereas in the placebo group, a decrease of 16,1% was demonstrated. After laser application skin blood flow increased by 8,1% in experimental group and decreased by 21,8% in the placebo group. In the deeper tissue, the perfusion increased by 2,7% in the experimental group whereas the perfusion was reduced by 13,0% in the placebo group after exposure to laser light, respectively.

Discussion/Conclusion

It has been demonstrated that laserneedle stimulation may improve peripheral microcirculation under standardized conditions. Further research is required to determine the influence of various parameter settings and irradiation treatments on the peripheral microcirculation. Anymore, different acupuncture points should be investigated in order to appraise the clinical effectiveness of laserneedle stimulation.

PLASMA HSP72 IN RUNNERS SUFFERING FROM EXERTIONAL HEAT ILLNESS

Ruell, P.A. 1, Thompson, M.W. 1, Hoffman, K.M. 1, Brotherhood, J.R. 1, Richards, D.A. 2

1 The University of Sydney, 2 Westmead Private Hospital, Australia

Exertional heat illness is a potentially fatal disorder that primarily affects fit young men. Plasma Hsp72 may be important in the aetiology of this disorder, acting as a danger signal to the organism and leading to an inflammatory response. The aim of this study was to determine whether patients with exertional heat illness following a 14 km fun run show a difference in their plasma Hsp72 concentration compared with control subjects who completed the event without incident. Patients (n=22) and controls (n=7) were all male. The patients were subdivided into 2 groups, one of which exhibited more serious symptoms indicating neurological impairment such as confusion (n=13) (CNS) while the other group exhibited mild symptoms (MILD) (n=9). The CNS group had a higher rectal temperature (Trec) compared with the control group (41.0±0.3°C versus 39.8±0.2°C, P<0.05). Immediately after the run plasma Hsp72 was significantly higher in the CNS group compared with controls and patients with mild symptoms (37.9, 17.0 and 20.9 ng/ml respectively) (P<0.01). There was a significant correlation between plasma Hsp72 and Trec measured immediately after the race (r=0.597, P<0.001, n=29). However, core temperature was not the only factor leading to increased plasma Hsp72 immediately post race. Plasma Hsp72 was still significantly higher in CNS patients compared with the control group (P<0.05) when Trec was included as a covariate. Plasma Hsp72 may be important in differentiating those patients most at risk of developing more serious clinical signs of heatstroke.

MONITORING MUSCLE OXYGENATION KINETICS AFTER EXERCISE-INDUCED MUSCLE SORENESS

Ahmadi, S., Sinclair, P., Foroughi, N., Davis, G.M.

The University of Sydney, Sport Knowledge Australia, Australia

Background: Delayed onset muscle soreness (DOMS) and impaired muscle function are common consequences of vigorous eccentric exercise (EE).The structural alterations or increased intramuscular pressures observed within muscle after EE may restrict local blood flow, and increase the diffusion distance of oxygen to muscle fibres (1). Near infrared spectroscopy (NIRS), is a simple and non-invasive method to monitor oxygen saturation within skeletal muscle. Hypothesis: We proposed that strenuous EE might impair muscle oxygenation and muscle blood flow in healthy adults. It was also hypothesised that biochemical, anthropometric and functional markers of DOMS might be closely time-associated with changes of muscle oxygenation assessed by NIRS. Methods: This study utilised a 7-day prospective time-series design. Ten healthy males, aged 18-35 yr, performed 2 bouts of 70 maximal elbow flexion eccentric contractions 6 days apart. Before and after EE on day 1 and over the next 6 days, maximum voluntary contraction (MVC), plasma creatinine kinase concentration (CK), elbow joint range of motion (ROM), subjects' perception of muscle soreness (SOR), arm circumference (CIR), and muscle oxygenation kinetics within biceps brachii were assessed. Muscle oxygen saturation, total haemoglobin, oxyhaemoglobin, deoxyhaemoglobin, muscle blood flow and muscle oxygen consumption were measured at rest on each day. In addition, muscle oxygen desaturation and re-saturation kinetics and volume during isometric contractions at 50 and 80 percent of MVC, as well as during arterial occlusion were quantified to investigate the hypotheses. Results: Repeated measures ANOVA revealed that MVC and ROM decreased while CIR, SOR and CK increased significantly (p<0.05) after acute EE. These changes were consistent with EE's effectiveness to evoke DOMS. Resting muscle oxygen saturation, total haemoglobin and oxyhaemoglobin increased, and deoxyhaemoglobin decreased after acute EE on both days 1 and 7. During super-systolic arterial occlusion, oxygen desaturation kinetics and volume increased significantly after EE on days 1 and 7, but the changes in re-saturation kinetics were not significant. Similar significant changes in desaturation and re-saturation kinetics/volume were observed during 50% isometric MVC. The changes in desaturation and re-saturation kinetics and volume during 50 and 80 percent MVC muscle contractions remained significantly different from the first day over the following days. In contrast, resting values of muscle oxygenation recovered towards pre-EE values over the six days after exercise. Conclusion: Although the volume and kinetics of desaturation and re-saturation during isometric contractions changed significantly after EE and these changes were present for several days, the alteration in muscle oxygenation kinetics did not always reflect an expected impaired oxygen delivery within arm muscles affected by DOMS. (1) Walsh, et al. (2001). Med Sci Sport Exer 33: 436-41.

ELECTROMYOGRAPHIC ACTIVITY IN BICEPS BRACHII AFTER ECCENTRIC EXERCISE-INDUCED MUSCLE SORENESS

Ahmadi, S., Sinclair, P., Foroughi, N., Davis, G.M.

The University of Sydney, Sport Knowledge Australia, Australia

Background: It is well known that strenuous eccentric exercise (EE) may result in delayed onset muscle soreness (DOMS). Although, the analysis of surface electromyographic signals (sEMG) had been used to characterise changes in the myoelectric behaviour of a muscle that could be associated with DOMS (1), there is a large controversy over the usefulness of sEMG signals in detecting DOMS. Hypothesis: We proposed that vigorous eccentric exercise would impair myoelectric activity of the biceps brachii in healthy adults, and that characteristic changes of sEMG might last several days afterwards. It was also hypothesised that biochemical, anthropometric and functional markers of DOMS would be closely time-associated with sEMG changes. Methods: This study utilised a 7-day prospective time-series design. Ten healthy males, aged 18-35 yr, performed two sessions of 70 maximal EE elbow flexion contractions, 6 days apart. Analysis of EMG activity was performed on the signals recorded during isometric contractions at 50% (IC50) and 80% (IC80) of maximum voluntary isometric contraction (MVC), deriving RMS and MDF as synthetic sEMG parameters. Linear regression of the RMS and MDF time-series (20 s sustained IC50 and IC80) was used to extract intercepts and slopes of these signals on each day. Plasma creatine kinase activity (CK), MVC, arm circumference (CIR), each subject's perception of soreness (SOR) and elbow joint range of motion (ROM) were measured to assess effectiveness of EE to evoke DOMS. Results: Plasma CK concentration increased over resting values until day 5 after EE (almost 7 times higher than the initial value), and remained significantly ($p<0.05$) elevated even on day 7. In contrast, MVC force had decreased to 50% of its initial value by day 2 after EE, and remained significantly depressed for the following days. Similar increases in SOR and CIR, and decrements in ROM supported the viewpoint that EE was highly effective to evoke DOMS. At IC50 and IC80, both MDF and RMS were significantly altered after acute EE on the first and seventh days. A significant shift (comprising a 15-20% decrease) of MDF intercept towards lower frequencies at IC50 was observed after EE in the exercised arm, and these values remained depressed over the next days. Both RMS slope and intercept during IC50 and IC80 were altered after EE, but showed an inconsistent pattern. Somewhat surprising was that RMS changes were present in the control arm as well as in the EE exercised limb. Conclusion: A prolonged reduction in MDF slope and intercept was a concomitant sign of DOMS, but this was not closely associated with biochemical, anthropometric or functional markers of DOMS. The downward shift of MDF slope and intercept could be related to lower recruitment of fast twitch muscle fibres after DOMS. Compared to RMS, MDF was a more reliable measure to reflect changes in sEMG after vigorous eccentric exercise.

IMCIDENCE AND DETERMINANTS OF RUNNING INJURIES IN LONG DISTANCE RUNNERS: A SYSTEMATIC REVIEW

Koes, B.W., van Gent, R.N., Siem, D., van Os, A.G., van Middelkoop, M., Bierma-Zeinstra, S.M.

ErasmusMC, Netherlands

Objective: to present a systematic overview of the literature on the incidence of lower extremity injuries in long distance runners and to identify rik factors associated with these injuries.

Methods: Medline data-base was search extensively for relevant studies meeting pre-determined inclusion criteria. Two reviewers assessed the quality of the included studies independently of each other. A best evidence synthesis was used in order to summarize the available data.

Results: 12 prospective and 4 retrospective cohort studies were included. Four of which were considered to be of lower quality. The incidence of lower extremity running injuries ranged from 19.4% to 51.5%. The most predominant site of these injuries was the knee. For many potential determinants only limited or conflicting evidence was found for an association with running injuries. Strong evidence was found for an association between a long training distance per week in male runners and running injuries. Also a history of previous injury is associated.

Conclusions: This systematic reviews presents a clear overview of the current state-of-science on the incidence of running injuries and its determinants in long distance runners. These injuries are not rare given the high incidence rates reported in the literature. For many determinants the association with the occurence of running injuries is yet unclear.

PREVALENCE AND INCIDENCE OF LOWER EXTREMITY INJURIES IN THE ROTTERDAM MARATHON

van Middelkoop, M., Kolkman, J., van Ochten, J., Bierma-Zeinstra, S.M., Koes, B.W.

Erasmus MC - University Medical Center Rotterdam, Netherlands

Objectives: The aim of this study was to describe the prevalence and incidence of lower extremity injuries of recreational runners running a marathon.

Methods: A cohort study was set up of recreational participants in the 2005 Rotterdam marathon. Out of 10000 recreational athletes who signed in for the Rotterdam marathon a random sample of 1500 athletes was made. One month before the start, demographic data and information on previous occurred injuries were obtained from a baseline questionnaire. Information on injuries sustained shortly before or during the marathon was obtained from a post-race questionnaire directly after the marathon.

Results: Of the 1500 random selected participants, 726 (48.4%) returned the baseline questionnaire. The one-year prevalence of running injuries was 54.8%. In the post-race questionnaire, 15.5% of all respondents reported at least one new lower extremity injury in the month preceding the Rotterdam marathon. The most frequent site was the knee (29.6%). The incidence of lower extremity injuries occurring during the marathon was 18.2% (n=118). Most of these injuries occurred in the calf, knee or thigh. However, the median score of pain intensity in rest (on a scale from 0-10) immediately after the marathon was 2 points and the median score of pain intensity during physical exercise was 5-points and the Interquartile Range was 4. Of all injured runners in the Rotterdam marathon 86.4% were able tot do all their work tasks within one week after the marathon. Also 88.1% of all injured runners were able to carry out their usual Activities of Daily Living within one week.

Conclusions: Running injuries are very common in recreational marathon runners. However, the pain severity and consequences for work tasks and Activities of Daily Living seems to be quite low one week after the marathon.

TRIAL FOR DEVELOPING A NEW INDICATOR FOR PREVENTING OVERUSE KNEE EXTENSOR MECHANISM DISORDERS IN ADOLESCENT ATHLETES USING A TISSUE STIFFNESS METER: RESULTS OF ONE YEAR PROSPECTIVE STUDY

Kinoshita, H., Miyakawa, S., Mukai, N., Kono, I.

University of Tsukuba, Japan

Introduction:

Overuse knee extensor mechanism disorders, such as Osgood-Schlatter's disease, in adolescent athletes are said to be related to increased tension in the knee extensor mechanism, which is elongated by rapid skeletal growth during the growth spurt period. Although it is important to check the tension of the elongated knee extensor mechanism for the prevention of overuse knee injuries, a simple and quantitative measurement has yet to be established. In a previous study, we found that elongation of the knee extensor mechanism can be evaluated using a tissue stiffness meter. In the current study, in order to develop a new indicator for preventing disorders in adolescent athletes, we investigated the relationship between knee extensor mechanism tissue stiffness and the incidence of knee disorders.

Methods:

A total of 190 legs of 95 adolescent male soccer players (9 to 17 years old, including the growth spurt period; mean age: 13.1 ± 2.6 years) were examined in the study. In the initial medical check-up we calculated the tissue stiffness of each knee extensor mechanism, and prospectively observed the occurrence of overuse knee extensor mechanism disorders for a period of one year. Each leg was measured for tissue stiffness at the knee extensor mechanism (the midpoint of the length from the anterior inferior iliac spine to the tibial tuberosity in the anterior thigh) in both supine and knee extended positions using a tissue stiffness meter, the Muscle Meter PEK-1 (Imoto Machinery Co. Ltd.: arbitrary unit).

Results:

During the observation period, knee extensor mechanism disorders occurred in a total of six legs from four players, including Osgood-Schlatter's disease (five legs of three players) and jumper's knee (one leg of one player). The mean value ± SD of tissue stiffness at the knee extensor mechanism in legs in which knee extensor mechanism disorders had occurred was 57.3 ± 2.5 (N=6), which is significantly higher (p＜0.05) than the value in legs in which no disorder had occurred, which was 54.8 ± 3.0 (N=184).

Discussion/Conclusion:

In a previous study, we found a positive correlation between elongation of the knee extensor mechanism and tissue stiffness, yielding tissue stiffness as an indicator for evaluating tension within the knee extensor mechanism. In the current study, tissue stiffness at the knee extensor mechanism was significantly higher among the legs in which knee extensor mechanism disorders occurred than that of the legs in which no disorder had occurred. In conclusion, evaluating tissue stiffness at the knee extensor mechanism can be used as a predictive index for the occurrence of overuse knee extensor mechanism disorders in adolescent athletes.

ANTHROPOMETRICAL CHARACTERISTICS OF THE CHILDREN AND ADOLESCENTS SELECTED AT THE HIGH PERFORMANCE COLOMBIAN TENNIS ACADEMY OF BOGOTA

Radut, D.S., Hernandez, A.

University El Bosque, Colombia

To assess the anthropometric characteristics, 60 children and adolescents between 6 and 14 years old have been studied, 36 male and 24 female, aspiring to enter the high performance Colombian Tennis Academy of Bogota. The shape was looked for according to the Heath-Carter methodology, the body composition using a Huang equation for Latin children and the proportionality with the Ross-Wilson method. The parameters found have been correlated with sexual development and training level. The statistical analysis was made with SPSS V13 program. Central measures of median, standard deviation, minimum and maximum values, averages comparison by T Student method, variances by the Levene test and correlation by Spearman test have been realized. 73% of the subjects previously participated in tennis trainings and 27% entered for the first time. The somatotype was located near meso - ectomorphy for men and near endo - ectomorphy for women. The fat mass and its percentage were found greater in women. The lean mass has been found greater in men. The proportionality revealed low weight and high fat percentage, especially at women. Not significant difference was found between old and new subjects, neither between the studied sample and the general population of Bogota of the same age, whose somatotype has been found closer to that recommended for tennis players. An inadequate caloric intake was concluded. The sportsmen selection criteria had a more economic quantitative tendency than a sports medical scientific qualitative one, inopportune for high performance tennis optimal selection.

FOUR YEARS OF UNIVERSAL PREVENTION IN PRIMARY SCHOOLS - EFFECTS ON BMI AND MOTOR ABILITIES IN CHILDHOOD

Graf, C., Koch, B., Dordel, S., Falkowski, G., Staudenmaier, K., Christ, H., Tokarski, W., Predel, H.-G.

German Sport University; University of Cologne, Germany

Objectives: Obesity in childhood is increasing worldwide. To combat overweight and obesity in childhood, the school-based CHILT project combines health education and physical activity. This paper examines the effect of intervention on the body mass index (BMI) and motor abilities after nearly 4 years in 12 randomly selected primary schools compared with 5 randomly selected control schools.

Methods: The anthropometric data were taken, BMI was calculated. Gross motor development was determined by a body coordination test (KTK) and endurance performance by a 6-minute run.

Results: No difference in the prevalence of overweight and obesity was found between the intervention (IS) and control schools (CS) either at baseline or final data (each p>0.05). There was no difference between the result of the endurance performance and the complete KTK, but the performance in lateral jumping and balancing backwards was better in the IS than in the CS (p=0.005; p=0.007), adjusted for age and test result of the entrance examination, gender and BMI-classification at final examination. Overweight and obese children produced significantly lower scores in all tasks than their counterparts (each p<0.05).

Conclusions: Preventive intervention in primary schools offers an effective means to improve coordinative skills in children, but overweight and obese children always produce significantly lower results. To improve motor skills in overweight and obese children and to prevent overweight and obesity, selective family- and school-based measures are necessary and parents should be included.

THE STUDY ON PREVALENCE OF MUSCULAR-SKELETON INJURIES IN ROCK CLIMBERS

Ahanjan, S.

Razi unhversity, Iran

The propose of this study was consider to prevalence of muscular - skeleton injuries in rock climbing, and determination of some individual - performance factors such as maximum grade of climbing, skillful hand and common type of climbing on existence and circumstance of the injuries . In February to September 2005 previous or present injuries among 50 young climbers via clinical examination was assess in fingers, palm, wrist, forearm, elbow, arm and shoulder girdle. After data gathering and statistical analyses to find these results about amount of muscular - skeleton injuries prevalence:

About half of injuries were in fingers and others approximately were divided equally between elbow - forearm and shoulder girdle. Most injury prevalence consist of collateral ligament strain of PIP joint, FDS and FDP muscle strain, rotator Cuff muscles strain and A2 annular pulley strain. Injury prevalence rate on the base of appearing in fingers orderly consist of ring, long, index and small finger. In subsequent process, inferential statistics results show that among mentioned factors, there was significant difference in the mean of climbing maximum grade between climbers group that sustain injuries and climbers group without injuries.($p=0.000$, $t=4.72$) In the same way there was significant positive correlation between maximum grade of climbing and intensity of A2 annular pulley injuries ($p=0.042$, $r=72.5$).

THE EFFECTS OF STRENGTH TRAINING ON MUSCLE MASS IN TYPE 2 DIABETES MELLITUS PATIENTS DETERMINED BY COMPUTER TOMOGRAPHY

Strasser, B., Cauza, E., Metz-Schimmerl, S., Leeb, G., Haber, P.

Medical University Vienna, Austria

Objective: This study was designed to evaluate the effects of a 4 month strength training (ST) on muscle mass and fat mass in diabetes mellitus type 2 (DM2) patients, measured by comutertomography (CT) and to relate these changes to changes in metabolic and anthropometric parameters.

Methods: Twenty-three DM 2 participants were included in a 4 months ST program. Muscle and fatt cross-section was estimated in 20 ST participants by CT volumetry with a Tomoscan AV before and immediately after the training of the quadriceps muscle. In all patients, laboratory data of blood glucose, hba1c, insulin resistance (IR) and lipid-parameters (total cholesterol, HDL-C, LDL-C, and triglycerides) as well as body mass index (BMI), fatt mass (skin fold measurements) and lean body mass were determined before and after the ST.

Results: We found significant increases in muscle CSA, as well as in muscle strength, while fatt mass and lean body mass were significantly reduced. A tendency towards a positive correlation between muscle CSA and changes in total body surface ($r=0.3$, $p<0.08$), and a correlation between left muscle CSA and improvements in systolic BP ($r=0.3$, $p<0.09$ left) were observed. Additionally, a trend towards a negative correlation between FBG and changes in % BF was found. We also found a trend in the correlation between left muscle CSA and increase in muscle strength, ie. bench press ($r=0.3$, $p<0.07$). A strong correlation between the change in left muscle CSA and the changes in pull sitting was observed ($r = 0.4$, $p<0.04$).

Conclusion: The ST in our diabetic patients was successful. However, the observed changes in muscle mass did not correlate significantly with the changes in metabolic parameters, probably due to the small sample size. Nevertheless, the CT evaluation of the training effect is safe, effective and highly available and therfore provides a suitable method for future investigations.

COURSE AND PREDICTING FACTORS OF LOWER-EXTREMITY INJURIES AFTER RUNNING A MARATHON

van Middelkoop, M., Kolkman, J., van Ochten, J., Bierma-Zeinstra, S.M., Koes, B.W.

Erasmus MC - University Medical Center Rotterdam, Netherlands

Objectives: The aim of this study was to investigate the 3-months prognosis and medical consumption of running injuries of recreational runners occurred shortly before or during a marathon. Also, possible prognostic factors for persistent complaints were evaluated.

Background: Previous studies have reported incidence rates of lower-extremity injuries for runners ranging from 19-75%. However, the medical consumption and prognosis of such running injuries is unknown. Also factors predicting the course of running injuries are unknown.

Methods: A cohort study was set up of 1500 random selected recreational participants of the 2005 Rotterdam marathon. Demographic data and information on previous occurred injuries were obtained from a baseline questionnaire one month before the start of the marathon. Immediately after the Rotterdam Marathon a second questionnaire was sent to all respondents. A third questionnaire was sent to all runners who reported a new running injury occurred in the month before or during the marathon. Baseline assessments included demographic characteristics, training factors, race events, lifestyle pre-race factors and history of running injuries. The main outcome measure was whether the injured recreational runners had persistent complaints or not at 3-months follow-up. Potential prognostic factors for persistent complaints were analysed by multivariate logistic regression.

Results: The third questionnaire was sent to 181 injured runners and was replied by 165 (91.2%) runners. At 3-months follow-up 25.5% of the runners reported persistent complaints. Thus about 75% were recovered after 3 months. The injured runners reported nearly no pain at rest while they reported little pain at exercise at 3-months follow-up. Of all 165 runners, 27 (16.4%) visited a general practitioner as a

result of their running injury. A total of 40 runners (24.2%) visited the physiotherapist, 218 times in total. Persistent complaints after 3 months were associated with non-musculoskeletal co-morbidities such as disorders on the nervous system, gastrointestinal tract and cardiac diseases (OR 3.89, CI 1.39-10.94) and calf injuries (OR 0.33, CI 0.11-0.99). Subgroup analyses showed that persistent complaints of knee injuries were associated with training on unimproved underground (OR 19.07, CI 2.10 – 173.25). There were no prognostic factors associated with persistent complaints of calf injuries.
Conclusions: In this cohort study, one quarter of the runners had persistent complaints of their initial running injury at 3 months follow-up. Persistent complaints were related to non-musculoskeletal co-morbidities at baseline. Calf injuries predict good outcome at 3-months compared to injuries at other locations.

Poster presentation (PP)

PP3-05 Biomechanics 1-3 - "Exhibition Hall"

INFLUENCE OF THE CONTACT TIME ON THE COUPLING TIME AND A SIMPLE METHOD TO MEASURE COUPLING TIME

Zameziati, K.F., Morin, J.B., Deiuri, E., Telonio, A., Belli, A., di Prampero, P.E.

Université Jean Monnet Saint-Etienne, France, France

The enhancement of performance in stretch shortening cycle exercises (SSC) has been attributed to the recoil of elastic energy stored during the stretching phase and depends on the duration of the coupling time (Tcoupling) (Thys et al. 1975; Bosco et al. 1981). However, instead of Tcoupling, the contact time (Tcontact) i.e., the sum of Tcoupling plus the duration of the stretching and shortening phases that precede and follow Tcoupling, is more easily and often measured. The aim of this study was to investigate Tcoupling changes within a large range of Tcontact, in order to put forward a possible relationship between Tcoupling and Tcontact, thus allowing accurate measures of Tcoupling only from tachometer and force data obtained classically in vertical jumps, jumps on sledge apparatus and running on force treadmills. 11 subjects performed SSC exercises on a sledge apparatus with a large range of Tcontact (400, 700, 1000, 1500, 2000 and 2500 ms).
Tcoupling and Tcontact were measured individually, from force platform recordings and the velocity of the carriage seat obtained by a tachometer. Though subjects were asked to maintain a static position, v was not exactly nil during this phase. As a consequence, we tested 4 velocity thresholds (10, 5, 1 and 3 % of maximal velocity (vmax) during upward and downwards motions of the sledge). As velocity was obviously not nil within the 10 % and 5 % thresholds and as the 1 % threshold did not allow very short (≤ 1 ms) Tcoupling determinations, we retained the 3 % of vmax threshold as the most accurate to determine both shortest and highest Tcoupling.
For the longest Tcontact (i.e., from 850 to 2500 ms), we observed a significant linear relationship between Tcontact and Tcoupling. This transition between Tcontact shorter or longer than about 850 ms seems to be important and to correspond to Tcoupling close to 300 ms. This limit could be explained physiologically due to a possible limit of the cross-bridges lifetime during an isometric contraction (Curtin et al. 1974). Furthermore, for Tcontact shorter than 850 ms, the clear linear relationship between Tcoupling and Tcontact values was not observed any more, and as a consequence, this point obviously does not allow us to speculate on any direct assessment of Tcoupling from Tcontact in a discriminating manner for these short Tcontact conditions.
In conclusion the results of the present study show that, for Tcontact longer than about 850 ms, Tcoupling can be accurately measured from force and velocity data.

CHANGES IN SPRING-MASS CHARACTERISTICS OF THE RUNNER IN FATIGUE CONDITIONS DURING REPEATED SPRINTS

Morin, J.B., Romeyer, F., Chevallier, B., Jeannin, T., Belli, A.

UR Physiologie et Physiopathologie de l'Exercice et Hanicap (PPEH), France

Many sport events such as team sports include sprint repetitions, and the ability to withstand fatigue in these conditions may be considered a key factor of performance. We investigated mechanical determinants of performance in fatigue conditions during field repeated 100m sprints through the spring-mass model (Blickhan, 1989). Indeed, a recently developed computation method (Morin et al., 2005) makes possible to measure spring-mass characteristics of the lower limbs during field running without resorting to dynamometers. The aim of this study was to measure changes in these spring-mass characteristics induced by four all-out 100m sprints. 8 males non-specialists performed four 100m separated by 2min of passive rest. Spring-mass characteristics of the lower limbs: maximal vertical ground reaction force (Fmax in N), vertical downward displacement of the center of mass (Delta y in m) and leg length change (Delta L in m) were calculated for each contact phase using the method cited earlier. These computations are based on flight and contact times measured at 400Hz by footswitches (FSR, Intelrink, UK), horizontal velocity measured at 35Hz by radar (Stalker ATS, Radar Sales, Mineapolis, USA), mass and leg length of the subjects. Then, vertical and leg stiffness (Kvert and Kleg respectively) were calculated as Kvert = Fmax/Delta y and Kleg = Fmax/Delta L and expressed in kN/kg. An ANOVA was used, and percentage changes calculated to study variations in mechanical parameters between the first and the fourth sprint. Leg stiffness, maximal vertical ground reaction force and leg length change did not show any significant variation with sprint induced fatigue, though the mean 100m velocity decreased significantly by 7.30±5.23 %. Vertical stiffness decreased significantly by 20.6±7.9 %, and this corresponded to a significant 21.2 % increase in the vertical downward displacement of the CoM, and not to a decrease in maximal force. From these results, it seems that the decrease in sprint velocity with fatigue coincides with a decrease in Kvert, Kleg remaining constant. Further, changes in Kvert were due to an increase in Delta y rather than a decrease in Fmax during contact. This latter point is not in line with the results of Weyand et al. (2001) that showed a significant relationship between Fmax and maximal running velocity, within a much larger range of velocities. This range of maximal velocities was much narrower in the present study, maybe explaining why Fmax did not change significantly whereas maximal velocity did. Further experiments may indicate whether fatigue induces a decrease in maximal velocity and consequently in Kvert, or whether these factors both depend on other parameters (neuromuscular activation, metabolical muscular fatigue, or else).

THE EVALUATION OF SIMULATED JUMP USING A FORCE PLATE

Tsunoda, K., Sasaki, T., Hoshino, H., Minouchi, Y., Ono, M.

Hokusei Gakuen University, Japan

INTRODUCTION: In ski jumping, athletes need to move their center of mass towards their intended direction. Athletes perform simulated jumping repeatedly to master intended direction. This training aims to stabilize crouching at approach, generation of maximum power and optimal movement of the center of mass at take-off. It is important to measure the forces that athletes exert during take-off. The values of Force impulse, power and center of pressure are mechanical quantities used to evaluate jump movements. These values can be calculated from simulated jumping using a force plate. The purpose of this study is to clarify the process of learning take-off motion by longitudinal measurements using a force plate.

PURPOSE: A world-cup class Japanese ski jump athlete voluntarily participated in this study. Measurement was taken three times about every 6 months from Dec. 2004. Reaction forces were measured using a force plate (AMTI co.). These data were digitized at 1kHz. And same time, simulated jump motions were recorded using a video camera (Photoron co.) at 120 fps.

RESULTS AND DISSCUSSION: Comparing the 1st and 3rd measurements, maximum force of vertical direction increased from 1258.1N to 139.0N. Maximum force of horizontal direction decreased from 278.1N to 253.0N. Force impulse of vertical direction changed from 137.9N•s to 160.7 N•s. Also Force impulse of horizontal direction changed from 90.7N•s to 72.3 N•s. The COP (Center of Pressure) at beginning take-off motion moved backward. After that COP moved forward again. The maximum displacement of COP was defined as the distance from toe to COP that had moved most forward. At the 1st measurement, the maximum displacement of COP appeared -0.246s, and the value was 17.5cm. At the 3rd measurement, -0.320 and 18.7cm. The displacement of COP became larger, and its appearance came earlier. It is important that the jumper not change the angle of the shank at take-off motion. We gave instruction on this point to the athlete. In dynamics theory, the force generated at the trunk and thighs applies to the shanks through the knee joints. If the applied force is directed parallel to the shank segment, the shank will not undergo rotation. Finally, the force is directed to calcaneus bone. Due to the progression of take-off motion, the point of reaction force appears and stays for a long time near by calcaneus bone at beginning of take-off motion.

CONCLUSION: In this study, these results suggest the following conclusions:

1. The inhibition of movement of the shank during take-off motion increased vertical force. 2. The inhibition of movement of the shank at take-off motion increased vertical Force impulse. 3. Due to the progression of take-off motion, the point of action of force moves backward at the beginning of take-off motion. 4. It is possible to evaluate take-off motion by the measurement of the point of reaction force.

AERODYNAMIC BEHAVIOR DURING THE FLIGHT PHASE IN SKI JUMPING

Sasaki, T., Tsunoda, K., Hoshino, H., Minouchi, Y., Ono, M.

Hokusei Gakuen University, Japan

Introduction: In ski jumping, jump athletes stay in the air after take-off. The longer jumpers stay in the air, the better prize they can get. The jumper cannot ignore the aerodynamic forces. Therefore, it is important to know how aerodynamic force affects the jumper during the flight phase. Sasaki (2000) pointed out that the aerodynamic forces affected jumpers with some periodicity. Vortex made periodicity of the airflow in the air (Gerlach, C. (1970)). Therefore, it is important to know the behavior of the aerodynamic force acting on a jumper during the flight phase. The purpose of this paper is to reveal the periodicity of the aerodynamic force during the flight phase.

Methodology: Measurements of acceleration during ski jumps were carried out by voluntary participants of 7 jumpers at the Hakuba in the year of 2001 Summer. Two dimensional accelerometer ("Trygal" , US Announce Co.) was set on the back position. The x-direction was defined as a parallel to the anteroposterior axis of the body and the y-direction to the longitudinal axis. The acceleration data were stored in the digital memory by 84Hz.

Results: The time at the edge of the take off platform was defined as the origin. The mean acceleration of the first period of a second and the fourth period of a second was as follows: the data for the first period of a second was 4.4m/s/s in the x-direction, and was -0.173m/s/s in the y-direction. The data for the fourth period of a second was 6.601m/s/s in x-direction and was 0.023m/s/s in y-direction. Aerodynamic forces were clearly larger in the x-direction than in the y-direction. The mean acceleration in the x-direction increased with time. The maximum frequency for each jumper during flight phase was analyzed by FFT. The mean values for peak power spectrum in both directions developed at almost the same frequency (9.16Hz:x-direction, 9.26Hz:y-direction).

Discussion: Perhaps resulting from the vortexes, The acceleration occurs in a periodic fashion. The acceleration of the x-direction increased with time course. It can be considered that jumpers' direction of motion progressively changes from a horizontal to a vertical direction. Therefore, jumpers should receive a large deceleration from air. From FFT analyses, the large power spectrums were shown to be approximately 9.0Hz. This can be considered as evidence that aerodynamic force acts on a jumper with 9.0Hz frequency.

Conclusion: In this study, the following conclusions concerning aerodynamic behavior on ski jumpers were: 1. Acceleration of the direction of the anteroposterior axis of the body increases during flight. 2. Aerodynamic force affects ski jumpers with some periodicity.

EFFECTS OF AGING ON THE CONTROL ABILITY OF THE ECCENTRIC CONTRACTION IN KNEE BENDING AND STRETCHING EXERCISES

Chihiro, E., Tomoyuki, I., Takeshi, M., Masayuki, K.

Kurashiki University of Science and the Arts, Japan

Introduction

When the elderly are requested to do eccentric contraction, such as descending stairs or sitting down on a chair, many elderly may feel uneasiness or even fear. However, there is no easy method to measure the ability to control muscle-tension during eccentric contraction. The first purpose of this study was to clarify the influences of aging on the ability to control muscle-tension during concentric and eccentric contractions. The second purpose was to establish the simple and easy method to measure the ability to control muscle-tension in elderly females.

Methods

Subjects were 126 elderly females (67.3 ± 9.2 yr old) and 8 young adults (21.3 ± 1.3 yr old) with no known neuromuscular deficits. They performed knee bending and stretching exercises on a force-plate while synchronizing the movement of the center of gravity (COG) with the movement of light emitting diode (LED) sign (sine wave, amplitude was 15 ~ 19.5cm (we adjusted the amplitude to the subject's height), the period was set 2.5sec) as good as possible. Time-series data of the vertical ground reaction force (GRF) were considered as a change of the vertical acceleration of COG movement. The vertical GRF was compared with the acceleration of LED movement. Three measures of the ability to control muscle-tension were studied; these were the cross correlation coefficient (CCC), the concentric contraction control ability (CCCA), and the eccentric contraction control ability (ECCA). CCC is a cross correlation coefficient of the vertical GRF to the acceleration of LED movement. CCCA is a correlation coefficient of the vertical GRF to the acceleration of LED movement while stretching the knees (concentric contraction). ECCA is a correlation coefficient of the vertical GRF to the acceleration of LED movement while bending the knees (eccentric contraction).

Results and conclusion

The following results were obtained: 1) CCC, CCCA, and ECCA were decreased with age. 2) Remarkable decreases in CCC, CCCA, and ECCA were seen in elderly females over 70 years old. 3) ECCA, especially, showed the functional decrease in elderly females over 70 years old. 4) In the eccentric contraction the drastic decrease of the ability to control muscle-tension was seen in females from around the age of 70. It implied that the age of 70 was a critical point to influence the ability to control muscle-tension during knee bending and stretching exercises. In conclusion, our study suggests that knee bending and stretching exercises are valid, simple, and also an easy method to measure the ability to control muscle-tension in the elderly female.

NEUROMUSCULAR BEHAVIOR IN OPEN KINEMATICS CHAIN IN ISOKINETIC AND ISOTONIC METHODS IN SOCCER PLAYERS

Garcia, L., Liotta, G., Argemi, R., Ortega Gallo, P.

Club Atletico Boca Juniors, Argentina

Objectives: The objective of the present study was to compare force, power and misbalances (relation of agonist/antagonist and dominant non dominant leg) in open kinetics chain, form quadriceps and hamstring muscle groups of soccer players of the Athletic Club Boca Juniors with isokinetic (IC) and isotonic (IT) devices.

Methods: Nineteen (19) youth soccer players of the Athletic Club Boca Juniors performed, in random order in two different days 2 maximal strength tests; the IC at 60, 180 and 300 grades per second of velocity, and IT with progressive load until exhaustion.

We evaluated knee extensors and flexors, in order to compare peak power and the relation of both muscle groups. we also compared the relation between dominant and non dominant leg, and the relation with a one leg countermovement and squat jump evaluation.

Results: The correlation, between IC and IT, of peak power was between 0.5 and 0.6 in the extensor of the dominant leg, and the extensor and flexor of the non dominant leg. In the flexors of the dominant leg it was less than 0.3.

We didn't observe a correlation between misbalances. In IT, but not in the IC, the flexor muscle group had 5 % more peak power in the dominant compared with the non dominant leg ($p < 0.05$) which correlates positively with the CMJ of the dominant leg.

Conclusions: IT shows that the dominant leg of soccer players have 5 % more power than the non dominant leg, probably produced for the adaptation to keep stability in driving the leg in the air during soccer play. The IC didn't show the ability to discriminate between dominant and non dominant leg.

LEVEL OF JUMPING ABILITY AT GIRLS PRACTISING RHYTHMIC GYMNASTICS

Polishchuk, T., Poliszczuk, D.

The Jozef Pilsudski Academy of Physical Education in Warsaw, Poland, Poland

Rhythmic gymnastics is one of the most difficult, and at the same time one of the most spectacular sport disciplines. One of the most significant motor properties that determine sport results achieved in artistic gymnastics is the jumping ability. The conducted study was aimed at finding an answer to the question: how does the dynamometric structure of jumping ability change with age, does it depend on the degree of fitness coordination of the subjects, and do changes take place in the level of jumping ability endurance in the ontogenesis.

The study comprised 32 gymnasts, who were divided into two groups, each with 16 subjects. The first group was consisted of gymnasts aged 9-12 years (training period experience 3 to 5 years). The second group was compose of girls aged 13-16 years (training experience – from 6 to 10 years).

Tests of the level of the jumping ability was performed using the tensodynamographic method, which is used to evaluate parameters that characterize strength and speed capabilities of the human motor system on the basis of a vertical leap off on a dynamometric platform. The tested persons performed 3 tests: leap off with sweeping arm motion, leap off without sweeping arm motion, performing a series of ten single vertical leap offs – without sweeping arm motion with an interval of 3 seconds between the jumps. The course of component force of base reaction was used to calculate the following: height of body mass centre elevation – height of upward leap off, maximum strength, maximum speed, maximum and average power, range of sweeping arm motion, force drive and performed work.

The obtained results have shown that values of particular parameters: maximum and average power and maximum strength and force drive depend on the age of gymnasts at the significance level of $p<0.05$. The obtained correlation indices demonstrated rather significant relations ($r = 0.83$) between the level of jumping ability, and coordination abilities of the subjects. Considerable differences between groups were recorded also in an executed leap off series. In gymnasts of the older age group a high level and stabilization of values of particular indices (including also the height of jumps) during performance of a series of 10 jumps was observed, while gymnasts from the younger group were characterized by a trend of decreasing values of the tested parameters.

PEAK VERTICAL GROUND REACTION FORCE IN STEP EXERCISE

Machado, M. 1, Santos-Rocha, R. 1+2, Veloso, A. 1

1 Faculty Human Movement-Technical Univ. Lisbon, 2 Sport School RioMaior-Pol. Inst. Santarém, Portugal, Portugal

Physical activities such as Step Exercise involve large weight bearing impacts on the feet. The rate and magnitude of skeletal loading, can improve the osteogenic potential of physical activity. The foot ground reaction force is affected by the mechanical properties of three bodies: the foot, the footwear, the ground and the sports equipment such as the Step bench. The assessment of biomechanical loading is quite important for exercise prescription and injury prevention in the scope of Exercise Biomechanics. Therefore, it is important to de-

termine if the differences on the mechanical characteristics of this system have any influence on the mechanical load applied on the musculoskeletal system. The study of ground reaction forces helps to understand the magnitude and pattern of loading experienced by the body while in contact with the ground. The purposes of this study were to analyse selected components of ground reaction forces (GRF) and to investigate the differences that exist between four stepping rate conditions (125, 130, 135 and 140 beats per minute - bpm) and between four Step patterns (basic step, knee lift, run step and knee hop), performed with right and left leading legs, in terms of vertical 1st peak (FZ), normalised to bodyweight (BW); vertical loading rate (LRZ), normalised to BW/s; and time to vertical peak (TFZ), in a group of 18 experienced females. These parameters were explored concerning ascending and descending phases. Concerning ascending phase, mean FZ ranged from 1.2 BW (basic step & knee lift) to 1.8 BW (knee hop) and 2.3 BW (run step); mean LRZ ranged from 4.9 BW/s (knee lift) to 10.2 BW/s (run step); mean TFZ ranged from 0.2 to 0.3 s. Concerning descending phase, mean FZ ranged from 1.6 BW to 1.8 BW; mean LRZ ranged from 7.4 to 8.5 BW/s; mean TFZ was 0.2 s. ANOVA repeated measures showed significant differences between conditions, from 125 to 140 bpm and between Step patterns, in FZ and LRZ, but not in TFZ. The results indicate that lower extremity external loading can be effectively controlled by varying stepping rate during Step classes. Assuming that walking or running are "safe" activities to be included in Exercise and rehabilitation programs, controlled stepping exercise appear relatively safe with respect to the magnitude of loading. The present investigation provides normative data of GRF parameters on the external forces of Step movements.

THE EFFECTS OF EXTENDED PITCHING ON BALL VELOCITY AND MOTION CHANGES IN BASEBALL PITCHERS

Miyazaki, M., Tsukada, M., Tanaka, S., Tsunoda, N.

Obirin University, Japan

The success of a pitcher over the course of a game is based on his ability to maintain his pitching motion as the innings progress. There were no reports to explain possible correlations between ball velocity, joint torques and motion changes. Therefore, the purpose of this study was to clarify kinetic and kinematic changes as a result of extended play in baseball pitching.

Six male baseball pitchers with no injury on the throwing arm voluntarily participated in this study. Mean age, baseball experience, height and weight were 22.2±3.5 (SD) yr, 12.3±1.0 yr, 175.9±7.6 cm and 66.3±10.1kg, respectively. Each subject pitched 140 times consisting of 7 sets of 20 pitches each. The velocity of each throw at the distances of 18.44m (Pitched ball velocity: PBV) was measured by Radargun (Mizuno). The relative velocity（VR）in each set was compared to the first set and the coefficient of variation (CV) in each set were calculated. The pitching motion was filmed by two high-speed video cameras (Digimo). The cameras were set at a nominal frame rate of 250 frames/s and at an exposure time of 1/2000s. Six landmarks (Ball, Wrist, Elbow, Shoulder, Pelvis and Knee) were manually digitized from video data. The analyzed phase was from stride foot contact to ball release in the pitching motion. Isokinetic shoulder internal-rotation (IR), knee extension (KE) and knee flexion (KF) torque at 140 of 20 times 7sets repetitive maximal contractions with velocity of 180deg/sec were measured using Isokinetic dynamometer (Biodex). The relative peak torque in each set compared to the first set was calculated in all the pitchers.

The following results were obtained: The PBV decreased from the first set to the final set. The VR of the final set had significantly lower values than the second, third and fourth sets ($p<0.05$). The Torque of IR and KF decreased from the first（IR: 32.8±7.3Nm, KF: 81.5Nm）to the final set (IR: 29.8±6.8Nm, KF: 73.8±16.4N-m). Acceleration of each joint decreased from the first to the final set. Acceleration on elbow joint in final set was significantly lower than the first set. The differences of time to maximal movement velocity in all the joints of upper extremity were shorter from the first set to the final set for the subjects who recorded decreased pitched ball velocity.

Decreases in the ball velocity from the first set to the final set were noted. Torque of IR and KF and acceleration of each joint decreased from the first to the final set. From these results, it was indicated that decreases in torque and acceleration of joint movements possibly influence a decrement of ball velocity. The differences of time to maximal movement velocity in all the joints of upper extremity were shorter from the first set to the final set for the subjects who recorded decreased pitched ball velocity.

INFLUENCES OF THE BUOYANCY AND THE VISCOUS RESISTANCE ON GAIT PATTERNS DURING THE TREADMILL WALKING IN THE WATER

Miyakawa, T., Onodera, S.

Kawasaki University of Medical Welfare, Japan

It has not been clarified how gait patterns change in the water yet. Therefore, the purpose of this study was to investigate the influences of the buoyancy and the viscous resistance on gait patterns during the treadmill walking in the water.

Two males and four females volunteered to this study. They walked on the treadmill in the following three conditions; these were on a land (LAND), in the water (WATER), and in the viscous water (VISCOUS). The duration and speed were set for 15 minutes and at 40m/min, respectively. The water depth set at the greater trochanter level. The viscousity of water was 1% solution of the carboxymethl cellulose (viscous coefficient : 470cps). The walking motions were videotaped using a high speed video camera(200Hz).

The step lengths on LAND, in WATER, and in VISCOUS were 42.8±3.6cm, 53.7±5.8cm,?and 53.8 ±4.6cm, respectively. The step lengths in WATER and that in VISCOUS were significantly longer than that on LAND ($p<0.05$). The flexion angles of the knee-joint on LAND, in WATER, and in VISCOUS were 65.2±4.9 degrees, 75.8±4.7 degrees, and 79.1±6.4degrees, respectively. There was a significant difference between LAND and WATER. A significant difference was also seen between LAND and VISCOUS. The angular velocities of the knee-joint during flexion on LAND, in WATER, and in VISCOUS were 123.2±12.7degrees/sec, 120.6±19.3degrees/sec, and 150.5±11.7degrees/sec, respectively. The angular velocity of the knee-joint in VISCOUS was significantlly larger than the other conditions. On the other hand, the angular velocities of the knee-joint during the extention on LAND, in WATER, in VISCOUS were 188.9±13.5degrees/sec, 148.1±21.7degrees/sec, and 124.5±22.5 degrees/sec, respectively. A significant differrence was observed in each condition. The flexion angles of the hip-joint on LAND, in WATER, and in VISCOUS were 24.5±5.3degrees, 32.5±5.3degrees, and 37.5±3.7degrees, respectively. There was a significant differrnce between LAND and WATER. A significant difference was also seen between LAND and VISCOUS. The angular velocities of the hip-joint during the flexion on LAND, in WATER, and in VISCOUS were 72.9±13.9degrees/sec, 74.5±11.5degrees/sec, and 84.6±15.4degrees/sec, respectively. There was a significant difference between VISCOUS and the other conditions.

We consider that the buoyancy may influence the step length, and the viscous resistance may influence the angular velocity of the joints while walking in the water. Furthermore, based upon our study, we believe that a human tend to use more hip reflexors while walking in the water as compared to land. It is, especially, obvious when the viscousity of water is high. The reason why is because the hip flexors

can generate more force than the knee extensors. In short, a human tends to use a body part in which one is able to exert the greater force in order to perform efficiently and effectively in the water.

DISCRIMINANT ANALYSIS OF MORPHOLOGICAL CHARACTERISTICS IN ELITE FEMALE ATHLETES OF THREE TEAM SPORTS

Noutsos, K., Rousanoglou, E., Bolatoglou, T., Bergeles, N., Bayios, I.

National & Kapodistrian University of Athens, Greece

Introduction: The morphological characteristics of athletes affect performance and reflect optimum sport-specific somatotype in each sport. The aim of this study was to identify the variables of body dimensions, body composition and somatotype that best differentiated elite female volleyball, basketball and handball players.

Methods: The characteristics of body height, body mass, the skinfolds of biceps, triceps, subscapular, suprailiac and the circumferences of mid-upper-arm and calf were measured according to the guidelines of Heyward & Stolarczyk (1996), in 79 volleyball (25.7±5.1 yrs), 70 basketball (23.6±4.6 yrs) and 101 handball players (23.2±5.3 yrs), all members of the first Greek National League. The body mass index (BMI) and the height to weight ratio (HWR) were calculated (Heyward & Stolarczyk, 1996). Body density was determined using the equation of Durnin & Womersley (1974) and body fat (%) entering the measurements of four skinfold into the equation of Siri (1956). Somatotype was determined according to Carter & Heath method (1990). Discriminant Function Analysis (DFA) was performed to ascertain the linear combination of anthropometric, body composition and somatotype variables that best differentiated the three groups. Wilks' lambda, percentage of correctly classified players and explained variance, as well as standardized coefficient, among other parameters, were calculated.

Results: DFA was conducted entering body dimension variables, body composition indicators and somatotype components. After validation, the analysis showed that 82.4% of the athletes were correctly classified in their respective sports. The DFA yielded two significant ($p<.001$) discriminant functions. The first discriminant function explained 73.5% of the total variance, mainly described the differences between handball and volleyball players and the highest standardized coefficients were shown for BMI (8.741), ectomorphy (4.951) and fat free mass (-2.593). The second discriminant function explained 26.5% of the total variance, mainly described the differences of basketball players from both the volleyball and the handball players and the highest standardized coefficient were those of BMI (10.410), ectomorphy (8.266) and body mass (-6.219).

Discussion: The main finding was that elite female volleyball, basketball and handball players are primarily discriminated by BMI and secondly by ectomorphy, as shown by their high standardized coefficients. This is in agreement with findings that lower BMI and high ectomorphy favour athletic performance (Carter & Heath, 1990). The discriminant model confirms that the morphological characterists do distinguish elite female athletes of team sports.

DYNAMIC ASYMMETRY AND DIMORPHISM AT CHILDREN IN AGE 8-13 YEARS

Witkowski, K. 1, Stefaniak, A. 2, Migasiewicz, J.1, Kedzierski, J. 2

1 University School of Physical Education in Wroclaw, 2 Primary School No 94 in Wroclaw, Poland

Introduction

The girls differ from boys as far as construction of body (sexual dimorphism) and physical fitness are concerned. Many scientists indicate for differences present at both sexes in the field of morphological and functional asymmetry. At the same time, the evaluation

of dynamic asymmetry at representatives of the same as well as the opposite sex is still an open issue. The authors focus their attention on evaluation of dynamic asymmetry between girls and boys in the range of age 8 - 13 years in such areas as coordination and fitness.

Material and the methods of investigation

Among 105 investigated children, there were 52 girls and 53 boys. Both sexes were represented by almost equal number of representatives, which was a favorable situation

in the light of comparison between two sexes. For measurement of dynamic asymmetry, a set of 8 tests was prepared. Asymmetry of coordinative ability was examined by tests used for evaluation of movement accuracy and speed of the lower and upper limbs. Different kinds of asymmetry was measured by various acknowledged types of tests.

Results and their interpretation

On the basis of conducted investigations it was confirmed, that the examined children were characterized by greater physical efficiency of the right side of body than left.

In exceptional cases, some tests among girls proved superiority of the left side over the right. In the group of investigated children, statistically relevant dynamic asymmetry was present

in case of almost all examined motor abilities. The only ability, not diversified as far as the investigated asymmetry was concerned, was dynamic endurance of lower limbs. Among girls, the largest differences were exposed in movement speed as well as muscles strength of upper limbs. Among boys, the most essential differences concerned accuracy of movements

of lower limbs and - like at girls - speed of movements and muscles strength of upper limbs. When taking into consideration dimorphism within the range of estimated dynamic asymmetry, it indicates for lack of statistically relevant differences between sexes. Only within particular age groups, essential differences were shown.

Conclusions

1. The examined children are characterized by a high level of dynamic asymmetry within the range of investigated motor features.

2. At the examined children, significant superiority of the right side of body over the left was noted as far as the level of investigated motor features was concerned.

3. The examined girls do not essentially differ from boys by the level of dynamic asymmetry in the range of investigated motor features.

COMPARATIVE ANALYSIS OF DELPHIN KICKS AT THE UNDERWATER SWIMMING

Zahalka, F., Kuzvard, T.

Charles University, Czech Republic

The main task of this study was evaluating swimming technique of swimmers with the different swimming specialization. Working of lower limbs are the main driving force for the performance this swimming technique. The general movement of lower limbs is divided to several phases. One movement cycle consists of the lower limb's movement nose-up to the water surface (upbeat) and the lower limb's movement down from the water surface (downbeat). We consider the bottom dead center of the lower limbs as the beginning of the movement phase. This moment is the end of the previous phase and the muscles are released and lower limbs are inactive at this time. Next movement starts with the flexion at the hips joints. Lower limbs are stretched and their movements are in the direction up to the water surface until they reach the highest vertical position. The next phase is starting at this time. Downbeat is starting with the flexion at the hips joints and lower limbs are bending at the knee joints. Propulsive forces are created by fast dynamic extension at knee joints (Maglischo 2003).

We observed the group of four swimmers. One woman SW1 and one man SW2 are swimmers specialists, one man SW3 is triathlon specialist and one man SW4 is swimmer with flippers specialist. For the evaluation of the movement we used 3D kinematics analysis. The movements were recorded under the water by 3 digital video cameras with 50 Hz frame rate. In the centre of the swimming pool there were the calibration cubes and calibrating space was 1 x 1 x 4 m. The displayed space was 6 m long. For the calculation of the space coordinates DLT algorithm was used. For the trace a score of the selected points we used software TEMA Bio 2.3. We choose the significant point on the body of the swimmers: ankle, knee, hip, shoulder, elbow, wrist, and head. The swimmers had task to perform the selected technique with the maximal respect of performance regardless of the speed of swimming.

The results the trajectory and velocity of the ankle show that all swimmers reach the higher values of the velocity during the downbeat. Swimmer SW4 had the highest values of velocity during the both phases (downbeat, upbeat). Swimmers SW2 and SW3 had the longest time of ankle displacement from top dead centre to bottom dead centre (more than 1.1 s). The results of the velocity of the hip joints during the cycles showed big differences SW1(1.1 – 1.3 m/s); SW3 (0.5 – 1.1 m/s). This oscillation (SW3) could be considered as the wrong performance of the technique. We found the swimmers specialists with the high level of competition performance had not intraindividual stability of every cycle. Swimmer SW1 performed three cycles in sequence with the high stability of velocity (0.2 m/s) but with the different trajectories of the ankles, knees, hips and trunk. We can give reason for it by ability of swimmer to solve particular kick according the aqueous media.

THE EFFECT OF FOOT POSITION ON PEDAL SURFACE ON ANKLE, KNEE, AND HIP JOINT MOMENTS FOR TRIATHLETES

Hoshikawa, H., Takahashi, K., Ohashi, K., Tamaki, K.

Musashigaoka College, Japan

The settings of bicycle positions have a great influence on cycling performance. Although some studies examined the effect of foot position on heart rates, muscle moments and EMG activities (Ericson et al., 1985,1986, Mandroukas, 1990), those studies were limited to normal healthy subjects at low pedaling cadences from 50 to 60 rpm. No research on foot position has been performed for subjects trained in pedaling exercise at high pedaling cadences from 90 to 100 rpm. PURPOSE This study investigated the effect of foot position on ankle, knee and hip joint moments at widely changing pedaling rates for regularly pedaling-trained subjects. METHODS Four male university triathletes cycled with their feet in the anterior position (AP) and the posterior position (PP) on the pedal surface at four pedaling rates (40, 60, 90, 120 rpm) at a constant power output of 200 W. The AP was defined as the position that the center of the pedal was in contact with the metatarsal head of the great toe and the PP was defined as the 10 cm backward from the AP (Ericson et al., 1985). The bicycle ergometer equipped with force sensors on the both pedals was used in this experiment. The displacements of the crank axis, ankle, knee, and hip were recorded by a video camera. From those video data the motion analyzer was employed to extract necessary data points. The lower extremity was modeled as a planar, three-segment, and rigid body system. Based on a standard inverse dynamics method, the equations of motion for the three segments were solved using the pedal force and position data to calculate the moments of ankle, knee and hip joint. RESULTS & DISCUSSION Few ankle dorsiflexor moments were exhibited at all experimental conditions. The mean ankle plantar flexor moments in the PP were significantly lower than those in the AP at every pedaling rate ($p<0.05$). The differences in the mean ankle plantar flexor moments between the AP and the PP (d-Map) decreased as pedaling rate increased. There were no significant differences between two foot positions in the mean knee extensor and flexor moments at every pedaling rate. The PP showed significantly higher mean hip extensor moments at 40, 90 and 120 rpm compared to the AP ($p<0.05$). This result suggests that hip extensor would compensate the d-Map. Furthermore, the mean hip extensor moments in the AP decreased until 90 rpm as pedaling rates increased, whereas the values in the PP tended to increase above 60 rpm. The differences in the hip extensor moments between the AP and the PP (d-Mhe) were no statistically significance at every pedaling rate. As the result that the d-Mhe did not decrease in spite that the d-Map decreased as pedaling rates increased, hip extensor muscles at the PP would be overloaded at higher pedaling rates．These observations suggest that by effectively utilizing ankle movement, triathletes would decrease hip joint moments and reduce muscle fatigue in the lower extremity at higher pedaling rates.

THE EFFECTS OF ELEVATED FOREFOOT WALKING SHOES ON POSTURE, GROUND REACTION FORCE AND FOOT-PRESSURE DURING WALKING

Yi, K.-O., Kwon, B.Y., Lee, S., Lim, H., Lee, Y.

Ewha Womans University, Korea, South

Purpose

The purpose of this study was to analyze the effects of elevated forefoot walking shoes on posture, ground reaction force, and foot-pressure

Methods

Twenty female college students volunteered as subjects for the seven-week study. The structure of the shoes is analogous to the anatomical structure of the foot, with a distinct heel, arch, and ball of the foot. The forefoot of these shoes elevated the foot to an angle of 35 degrees, while positioning the toes at 50 degrees above the ground. In the sagittal plane, neck, hip, knee and ankle angle were all measured. Ground reaction force was measured via the Kistler force platform. Foot pressure was measured through the Insole (Novel). The paired-T test was used for statistical analysis.

Results

There was a statistically significant difference in the sagittal plane for the neck & knee angle. As with normal walking shoes, subjects experienced no impact with the elevated forefoot shoes. However, the active loading rate (both vertically and laterally) was two times greater with the elevated forefoot shoes. As expected, wearers of the elevated forefoot shoes placed pressure on their midfoot and heel for a longer time than wearers of normal walking shoes. In addition the maximum average pressure was less than normal walking shoes.

Conclusion

Bad posture places increased stress on the body and the constant repetitive action of walking can exacerbate existing problems. Elevated forefoot shoes can help counteract some of these negative factors. In the sagittal plane the posture of all test subjects improved in the neck & knee. The redistribution of weight on both the heel and the midfoot emphasized active stretching in the posterior of the leg. In contrast, in the front of the leg were accentuated with the elevated forefoot walking shoes. Furthermore, this redistribution of weight limited the range of movement during midfoot and heel striking. First, wearers of the shoes were unable to lean forward in order to walk. Secondly, wearers experienced active dorsi flexion during heel and midfoot contact, so they can not transfer ground reaction force into forward momentum. In order to compensate, wearers were required to move their center of gravity upwards in order to walk, utilizing greater active muscle force with each step. This can be seen in an active loading rate which is twice that of normal walking shoes. Thus, with increased contraction and stretching, blood circulation increases in the legs.

COMPARISON BETWEEN TREADMILL AND LEVEL WALKING -FOCUSING ON THE COMPLEXITY OF THE WALKING CYCLE-

Tomoyuki, I., Chihiro, E., Takeshi, M., Sho, O.

Kawasaki Univercity of Medical Welfare, Japan

Introduction

Walking is the most fundamental periodic movement. However, the complexity of the walking cycle is not clearly understood even though time series data has come to be quantified. Entropy is a concept which quantifies the complexity of the cycle of a system, and it has been used in various fields including physiology. To apply this concept to walking, it can be possible to clarify the complexity of the walking cycle. Furthermore, measurements of walking ability and gait training are done on a treadmill as well as on a level floor by many researchers. However, a lot of differences, such as body functions during walking, are observed in these different situations. Therefore, the purposes of this study is to examine whether walking on a treadmill and a level floor influences the complexity of the walking cycle by using Approximate Entropy (ApEn).

Methods

Thirty young healthy males and females volunteered as subjects for this study. Subjects walked on a motor driven treadmill and level a floor. The head fluctuation of the right-and-left direction during a walk was measured by using an accelerometer. Subjects walked on the treadmill with a walking velocity of 20m/min, 40m/min, 60m/min, 80m/min, 100m/min and 120m/min. Subjects walked for 3 minutes each in both conditions. While walking, subjects were instructed to look at the target, which was situated 3m ahead. In level walking, subjects walked 40 m, and they were instructed to walk "slowly", "a little slowly", "usual velocity", "a little fast" and "fast" depending on their subjectivities. The walking velocity was also measured. In addition, the complexity of the head fluctuation of the right-and-left direction cycle in the treadmill and level floor walking was calculated by utilizing ApEn. After the value of ApEn in both walking conditions was standardized at the walking velocity (20, 40, 60, 80, 100, 120 and 140m/min), these were compared.

Results and Discussion

The value of ApEn in the treadmill and level floor walking decreased with the increases in the walking velocity. This was remarkable until the walking velocity reached 100m/min. Nevertheless, the value of ApEn increased from the walking velocity a little faster than 100m/min in both walking conditions. The value of ApEn in the treadmill walking was significantly higher than that of level floor walking at 20, 40 and 60m/min. However, its value showed significantly lower than that of level floor walking at 120m/min ($P<0.05$). From our results, it is assumed that there are no differences in the complexity of the walking cycle at the free walking or a little faster than free walking velocity while walking on the treadmill and level floor. This is because walking affects nerves including the control of posture, which is optimized at the free walking velocity. In conclusion, it is clear that walking on the treadmill and level floor have influence on the complexity of the walking cycle.

WHY DOES POWER OUTPUT DECREASE AT HIGH PEDALLING RATES DURING SPRINT CYCLING?

Samozino, P., Morin, J.B., Hintzy, F.

UR Physiologie et Physiopathologie de l'Exercice et Handicap, Saint-Etienne , France

During sprint cycling, the power output-pedalling rate relationship is parabolic and presents a maximal power output (Pmax) and an optimal pedalling rate (PRopt). Using a dynamics modelling simulation, Van Soest and Casius (2000) explained these PRopt values from two factors influencing power output in opposite ways when pedalling rate increased. On the one hand, the potential for power production, as defined by intrinsic muscle mechanical properties, increased with pedalling rate and reached a maximum around 200 rpm. On the other hand, activation dynamics had a detrimental effect on increasing power production with pedalling rate. The aim of this study was to investigate the concrete expression of this detrimental effect to understand the decrease in power output beyond PRopt.

Eleven male cyclists performed four randomised 8s sprints against friction loads ranging from 0.5 to 0.9 N.kg-1 body mass. The friction-loaded cycle ergometer (Monark type 818 E, Stockholm, Sweden) used was equipped with an optical encoder for measurement of flywheel displacement and with a strain gauge for measurement of frictional force. Instantaneous crank angle and pedalling rate were obtained from flywheel displacement and velocity. Power output was the product of external force (sum of frictional and inertial forces) and flywheel velocity. Power output and pedalling rate were averaged over each pedal downstroke and related by 2nd order polynomial regression. Pmax and PRopt were determined by the first mathematical derivation of the relevant regression equation. During each

downstroke, crank angles corresponding to minimal (CAPmin) and maximal (CAPmax) instantaneous power output values were determined. Pedalling rate effect was tested with analyse of variance and Newman-Keuls post-hoc tests.

Mean Pmax and PRopt values were 9.55 ± 0.99 W.kg-1 and 120 ± 9.86 rpm, respectively. CAPmin and CAPmax ranged from -7.27 ± 4.26 ° to 17.7 ± 11.0 ° and from 80.8 ± 6.41 ° to 107 ± 15.2 °, respectively (0° corresponding to the top dead centre). CAPmin and CAPmax were significantly higher at pedalling rates higher than 130 rpm than at low ones ($P<0.05$).

To be efficient, power must be produced between 70 and 110°, i.e. at angles optimizing pedal effectiveness (Ericson at al. 1988). At low pedalling rates (<130 rpm), peak power production appeared at these optimal crank angles. However, with increasing pedalling rate, the beginning (CAPmin) and peak (CAPmax) of power production appeared at higher crank angles. Hence, power was produced later in the crank cycle, and therefore at less efficient crank angles. Consequently, even if muscle power applied to the pedals would increase (Van Soest and Casius 2000), power output decreased beyond PRopt.

OPTIMAL SLOPE FOR MINIMIZING ENERGY COST OF LOCOMOTION: INDIRECT ASSESSMENT BY HIGH ACCURACY GPS

Terrier, P., Wearing, S., Hills, A.P.., Schutz, Y.

University of Lausanne, Switzerland / Queensland University of Technology, Australia., Switzerland

The energy cost of human locomotion is significantly influenced by the slope of the terrain. The relationship of energy cost to slope may be expressed as a J-shaped curve with a minimum at about -10% slope. The underlying mechanics that explains such a relationship include: 1) the differential efficiency of the muscles used as force and brake generators 2) the residual positive mechanical work against gravity that occurs during downhill walking, as well as residual negative work during uphill walking.

Although uphill and downhill walking has been studied over decades in the gait laboratory, there is a lack of data concerning the effect of grade on the energetics of outdoor free walking. The objective of the present report, therefore, was to ascertain the slope at which the energy cost of locomotion was minimized under free walking conditions.

A high accuracy Global Positioning System (<1cm) was used to continuously monitor the vertical oscillation of the head in 25 young healthy non-obese women while walking along a 2.5km outdoor circuit, exhibiting a wide range of grades (-20% to +20%). The head oscillation was assumed to represent trunk oscillation. The step frequency, walking speed and vertical oscillation were subsequently used to estimate the energy cost of walking at various grades.

The observed vertical body oscillation (positive and negative, expressed per step) was +6.5/-6.5cm at 0% slope, +3.6cm/-10.6cm at -10% slope and +11cm/-4.0cm at +10% slope. The mechanical power induced by these oscillations was expressed as transport cost per unit body mass (i.e. the energy to transport 1kg mass over 1m). The physiological cost of walking was computed taking into account the theoretical well known difference in efficiency of eccentric/negative work (0.25) and concentric/positive work (1.25). By pooling the individual data sets (about 10hour walking) we found a J-shaped curve pattern with a theoretical minimal energy cost of locomotion at a decline of 10.4%.

Despite the use of a simplified model and the application of a new technology (GPS) which is still at its infancy, we confirm in our free-living conditions the literature results in the lab based on the analysis of treadmill walking over short duration. This highlights the utility of high accuracy GPS in monitoring outdoor walking under free living conditions.

FATIGUE EFFECTS IN GROUND REACTION FORCES DURING LANDING IN MALES AND FEMALES

Kouvelioti, V., Kellis, E.

Aristotle University of Thessaloniki, Greece

Jumping and landing are frequent movements in various sports. Foot impact with the ground during such activities can impose extreme loads on the musculoskeletal system [1,], which may lead to musculoskeletal injury. Muscle fatigue may also be of particular importance to injury [2]. This is supported by epediomiological and expirimental sudies which indicate that fatigue combined with extreme loads, may lead to injury[3].

The objective of this study was to investigate the effects of knee extension fatigue, on ground reaction force characteristics during landing, in males and females. Twenty healthy subjects, 10 males and 10females, (mean age 23.9±1.37years, height 174.8±10.3 cm, and mass 68.95±12.09 kg), performed 2 sets of repeated maximal concentric efforts of the knee extensors at 120º /sec, until they could no longer consistenly produce 50% of maximum torque. Αll subjects were asked to perform three single –leg landings from 30cm drop height on a force plate, before, in the middle and after the knee extensors' test.

The maximum GRF ,the mean GRF during the first 100ms after touch down and the mean GRF during 100-200ms after touch down, were determined before, during and after fatigue. The effects of gender and fatigue on GRF parameters were analysed using a two-way analysis of variance (2x3). The results indicated that the mean values of maximum GRF, the mean GRF during the first 100ms after touch down and the mean GRF during 100-200ms after touch down , did not significantly change with fatigue (all $p> 0.05$). Males and females landed with similar GRFs and all variables did not differ significantly (all $p>0.05$).

All variables after touch down did not change cignificantly. These finding suggest that a typical fatigue protocol of knee extension did not decline ground reaction forces. Further, no gender effect was observed whichs agrees with previous studies [4]. Further investigation is recommended in order to learn how does fatigue affects ground reaction forces during landing in males and females.

A COMPARATIVE KINEMATICS STUDY OF THE KARATE PUNCHING MOVEMENT (CHOKU-ZUKI) PERFORMED WITH TWO DIFFERENT STRATEGIES

Vences Brito, A. 1, Pezarat-Correia, P. 1, Pascoal, A. 2, Fernandes, O. 2

1 Sports Sciences School of Rio Maior P. I. S., 2 Faculty of Human Kinetics T. U. L. Portugal, Portugal

The study compares the upper limb kinematics on two different conditions of karate punching movement (choku-zuki): with (WI) and without impact (NI) against a makiwara (karate training instrument). The WI condition was performed with the maximal impact and the NI condition involves a voluntary interruption of the punch on the contact moment.

Ten male athletes of the Portuguese Karate National Team (age=25 +3yr, height=174,8 +0,062cm, weight=71,13+9,4kg, arm length=78,4+3,1cm, body fat %=14,07+3,6), performed choku-zuki to a makiwara from a karate stance of Hachiji-dachi. Each subject repeated 10 times the punch with the right side in the two conditions. The thorax, upper arm and forearm kinematics data were recorded with a six degree-of-freedom electromagnetic tracking device, Flock of Birds System (Ascension Technology Inc., Burlington, Vermont, USA). Was used a set-up of three sensors located on thorax over T1 process, on the humerus in the lateral face of the middle upper arm and in the dorsal face of distal forearm. A four sensor was mounted on the makiwara. Differences between conditions were tested by One-Way Anova. To statistical processing we use the SPSS 13.0 for a significance level of 0.5.

The choku-zuki WI condition movement sequence was: forearm pronation, arm flexion, arm abduction, thorax left rotation, arm internal rotation and forearm extension. The total punch sequence average duration was of 300+70ms. The choku-zuki NI, presented a short duration (288+79ms) and the movement sequence was: arm flexion, thorax left rotation, forearm pronation, arm internal rotation, arm abduction and forearm extension. This temporal different sequence between conditions reflects several significant differences on segments movements. In NI condition we found a significant ($p<0.02$) increase in movement amplitude (WI=57+14,9o; NI=77+13,8o) and a decrease ($p<0.001$) on maximum peak velocity (WI=3,57+1,51rad-1; NI=1,42+0,91rad-1) of arm flexion, significant ($p<0.000$) increase in the time interval between the instant of peak velocity and the instant of the impact (WI=11+10ms; NI=41+16ms) and in the movement amplitude (WI=5,54o+3,28o; NI=20,9o+5,89o) in the arm internal rotation, significant ($p<0,000$) increase in movement amplitude (WI=47,8o+21,17o; NI=69,62o+17,17o) on forearm extension, significant ($p<0.02$) decrease in the duration (WI=300+70ms, NI=210+90ms) and maximal peak of angular velocity (WI=2,17+0,95rad-1; NI=3,83+1,88rad-1) on forearm pronation.

Significant differences were found between conditions on kinematics of choku-zuki execution. The main differences were found on NI condition including a different sequential order of movements, longer movement amplitude and time anticipation on acceleration and velocity maximum peak in arm flexion, arm internal rotation and elbow extension. On further processing of this study, these kinematics differences will be related with the neuromuscular patterns of shoulder and elbow muscles, recorded by EMG.

THE VALUES OF SELECTED BIOMECHANICAL PARAMETERS OF SPRINTERS' LOWER LIMBS MUSCLES

Gabrys, T., Staszkiewicz, R., Ozimek, M.

Academy of Physical Education Cracov, Academi of Physical Education Warsaw, Poland

Introduction. The 100-metre sprint race belongs to sport discipline where a competitor's success depends on the level of speed abilities. The final result is conditioned also by a range of other parameters: body constitution, muscle fibres composition, muscles' strength and power output, race technique and the level of physical fitness. The functional condition of muscles of lower limbs influence on the abilities of increasing the speed during the race (Staszkiewicz et al. 2002). The aim of the researches was the measurement of selected biomechanical parameters describing the muscles of sprinters and the definition of connection of these parameters with the sport level of examined competitors.

Material and methods. Conducted researches involved the group of 10 sprinters specialized in 100-meter race. Among the examined sportsmen were competitors of international champion's class (MM), champion's class (M) and first sport class (I). In the isometric condition there were determined: maximal (Tmax) and relative (Trel) knee extensors muscle torque and the maximal rate of muscle's force development (F'max). In counter movement jump on dynamographic platform, the average (P) and relative (Prel) mechanical power output developed by muscles were calculated.

Results. The highest values of Tmax and Trel were noted in MM group (253 Nm and 3,43 Nm/kg, respectively). Maximal knee extensor's muscle torque in M group was 16% lower, while relative value – 25% lower. Sprinters from the weakest group (I) achieved the lowest values of Tmax and Trel (198 Nm and 2,77 Nm/kg). The differences between the parameters describing the muscles' strength of left and right limbs do not exceeded 4% for every sportsman. The value of maximal rates of muscle strength increasing (F'max) for M group was equal to 8236 N/s and 8392 N/s – for MM group; F'max in I group was equal to 7862 N/s. The rate of muscle force development in left and right knee extensors were similar for all the sprinters. The best examined athletes (MM) during counter movement jump achieved the highest values of power output in absolute formulation (P) as well as in relative formulation (Prel): P in this group was equal to 1740 W, while Prel – 23,6 W/kg. These variables in other groups of sprinters were: 1607 W and 20,6 W/kg (M group); 1401 W and 19,5 W/kg (I), respectively.

Conclusions. The values of biomechanical parameters describing muscles' force, speed and mechanical power output are increasing with improving of sport level of sprinters. The largest differences between the competitors from MM and M group refer to the relative muscle force (Trel), so it appears that it is necessary to aim at optimization of this parameter value during training process. Sprinters' training process is favorable to equalizing the values of variables describing the strength and speed abilities of left and right limb muscles.

TRAINING PROCESS INFLUENCE ON STRENGTH AND SPEED ABILITIES OF YOUNG FOOTBALL PLAYERS' MUSCLES

Szmatlan-Gabrys, U., Staszkiewicz, R., Ozimek, M.

Academy of Physical Education Cracov, Academi of Physical Education Warsaw, Poland

Introduction. The modern football makes high demands for competitors that make possible to reach the best results. The training process begins at more and more early ages and is assisted and controlled by professional scientific researches. As well as in all kinds of team games the result in football is determined by individual features of sportsmen (Komi 2000) and team factor. The aim of researches was the definition of the influence of many-years football training process on the level of strength and speed abilities describing the knee extensors of young football-players.

Material and methods. The mentioned researches involved 118 football-players at the age of 12-18 years. The aim of the measures was the determination of maximum muscle torque of knee extensors (Tmax) and the rate of muscle force increase (F'max). All tests were carried out under maximum isometric contraction in standard measuring positions. Strength parameters were also expressed in relative formulations (Trel).

Results. The lowest value of Tmax were characteristic for the youngest football-players (about 114 Nm), the highest one for 17 age competitors (196 Nm). The biggest annual increase (10-20%) was noted for competitors between 12 and 15 years old. In the analyzed age period (12-18 years old) the maximum moment of force increased about 70%, while Trel increased about 15%. The differences between force parameters values describing the muscles of left and right lower limbs do not exceed 7% and are not statistically significant. The maximal derivative of force (F'max) reaches the lowest value in the group of the youngest competitors (about 4900 N/s), while the highest one (about 6700 N/s) in the group of competitors aged 18. The difference of F'max value between aged 12 and aged 18 is about 37%. The registered Tmax values (sufficiently higher than for non-training boys of the same age) prove that the influence of training process on muscle strength of young football- players is more essential than it is considered. All the more so as in this process the strength aspect is not prevailing because the specificity of mentioned sport discipline does not demand the generating of maximal muscles' strength. In view of increasing of F'max value with the age of football-players, the oldest group of competitors develops the muscle strength of the maximal value that can be achieved with the highest speed.

Conclusions

1. Maximal and relative knee extensor's muscle torque are increasing up to the age of 17, while the value of Tmax increases in larger range.

2. The level of speed abilities (F'max) of examined muscles of football–players are increasing during the whole period of ontogenesis (12-18 years old).3Maximal annual knee extensor's strength increase and the rate of muscle force development increase are noted before the age of 15.

ASSESSING TECHNICAL LEVEL IN THE EXECUTION OF THE OVERARM THROW: IMPLICATIONS FOR THE STUDY OF MOTOR DEVELOPMENT

Marqués-Bruna, P., Lees, A., Scott, M.

Edge Hill College of Higher Education, United Kingdom

Introduction

The study of motor development has traditionally consisted of the description and categorisation of the different movement patterns observed in children (Stage Theory - e.g. Roberton, 1978). However, more recently Newell's (1986) constraints model postulates that individual, environmental and task constraints interact to encourage certain movement patterns. Thus, to study the technical adaptations associated with motor development, assessment of technical level, and not simply technique description, may be more meaningful. The term technical level is rarely used in the biomechanics literature, despite being suggestive of technical supremacy regardless of performance outcome. This study aimed to define, and study the development of, technical level in the execution of the overarm throw for a group of children.

Methods

A group of 187 children (106 males and 81 females; aged 5-11 years; mean age = 8.5, SD = 1.9 years) and a control group of 31 adults (20 males and 11 females; mean age = 21.5, SD = 5.9 years) were asked to perform the overarm throw for maximum distance; which was recorded on videotape. The technical level of the subjects in the execution of the throw was established using qualitative video analysis and hierarchical models developed for the purpose (Marqués-Bruna, 2005). Children were allocated to three age groups and two-tailed Chi square tests ($p < 0.05$) were used to infer an association between technical level and age of the children. Gender differences in technical level were examined.

Results

Generally, male children showed a higher technical level across the age range than female children. Male children showed also a faster rate of development of technical level (higher Chi square values) than female children (males: Chi square = 34.67, df = 6, sig. = 0.001 (significant); females: Chi square = 7.84, df = 6, sig. = 0.250). Compared to female adults, male adults displayed a higher technical level in the execution of the throw.

Discussion/Conclusion

Previous research on motor development (e.g., Roberton, 1978) has described how the movements of children increase in complexity with age of the children. However, the present study allowed the assessment of technical level in a group of children when performing the overarm throw. Some of the younger children displayed a high technical level, while some of the older children and adult subjects displayed low technical levels. This adds supports to Newell's (1986) constraints model. The findings have implications for future research into the technical adaptations associated with child development.

THE INFLUENCE OF UPPER BODY POSITION ON PELVIC AND LIMB KINEMATICS AND LEG MUSCLE RECRUITMENT DURING CYCLING IN NOVICE AND HIGHLY TRAINED CYCLISTS

Chapman, A.R., Vicenzino, B., Blanch, P., Hodges, P.W.

The University of Queensland, Australia

Trained cyclists are better able than novice cyclists to maintain cycling efficiency when shifting between riding positions, which involve different orientations of the upper body. Most notably, the decrease in cycling efficiency of novice cyclists is greater than that of highly trained cyclists when shifting from an upright riding position (i.e. grasping brake hoods) to the aerodynamic riding position (grasping drop bars or aerobars)[1]. Factors associated with less efficient cycling by novices in the aerodynamic riding position have not been investigated. We suggest that changes in pelvic and limb kinematics and muscle recruitment may be one mechanism by which upper body

position influences cycling efficiency. This study compared pelvic and lower limb kinematics and electromyographic (EMG) activity of tibialis anterior (TA), tibialis posterior (TP), peroneus longus (PL), gastrocnemius lateralis (GL) and soleus (SOL) muscles during cycling between upright and aerodynamic riding positions, in novice and highly trained cyclists. The aerodynamic riding position was associated with greater anterior tilt (sagittal plane pelvic position) of the pelvis and greater hip flexion in both novice and highly trained cyclists (but not greater ranges of motion) and a greater range of oblique motion (i.e. frontal plane motion) of the pelvis in novice cyclists, but no other kinematic changes. The aerodynamic riding position was also associated with increased variability of recruitment of three of the five tested muscles in highly trained cyclists. Riding position did not influence variability of leg muscle recruitment in novice cyclists and had no effect on other parameters of muscle recruitment (i.e. timing and amplitude) in either group. These results show that orientation of the upper body alters pelvic and hip kinematics, and therefore most likely the length of thigh muscles, which may influence cycling efficiency. Increased range of frontal plane pelvic motion may be associated with less efficient cycling by novices in the aerodynamic riding position. However, trained cyclists were less able to maintain a consistent level of variability of muscle recruitment between upright and aerodynamic riding positions, which may influence their cycling efficiency.

GEOMETRY OF RUNNING

Romanov, N., Pyanzin, A.

Romanov Academy of Sports Science, United States

Introduction

Muscular contraction is considered to be the main force moving and accelerating the runner on support. This assumption doesn't explain the so called "extensor paradox" (1), when the extensor muscles of the leg are off immediately after the runner passes the vertical position on support (midstance). This contradiction can be resolved, if we assume that gravity is the main moving and accelerating force in running. The role of muscles then is reduced to regulating the direction of gravity's action on the body, having one degree of connection with support and being in the state of unstable balance.

Methods

The movement of the runner on support, after it passes the midstance is nothing else, but tipping the body, rotating around the point of support. This type of movement can be described using the model of a falling rod. We modeled the process of falling of the rod from its vertical position on support, with a graphic analysis of the dynamics of vectors of forces participating in this movement (gravity, ground reaction, resultant forces) and their components.

Results

When the angle of deviation of the rod changed from its vertical position to its complete fall, the values of horizontal components of ground reaction and resultant force between gravity and ground reaction changed in the form of a bell-like curve from zero at its vertical position to maximum at 45° angle and went back down to zero at 0° angle. The dynamics of vertical components of the same vectors completely different with a constant increase from minimum at the vertical position to maximum at 0 ° degrees for the resultant vector of gravity and ground reaction and the same mirror-like symmetrical increase of the vector of ground reaction. Of most interest was the dynamics of correlation between the horizontal and vertical components of resultant vector between gravity and ground reaction, for every angle of deviation. The maximal prevalence of the horizontal component occurs at 22.5 ° angle, after which the vertical component starts dominating.

Discussion/Conclusion

The forward displacement of the runner's body is determined by the geometry of the falling body on support. The horizontal movement (acceleration) of the body is a function of the angle of deviation of the body from its vertical position that is a function of the vector of gravity and ground reaction force. Our analysis of the geometric relations of force vectors confirms our hypothesis of the leading role of gravity in the movement of the runner forward, and explains why support in running ceases at a certain angle of deviation of the body from its vertical position. On support the muscles do not work to push the body forward, they work to transform the gravity-force downward movement into a horizontal one.

BIOMECHANICS OF PROPHYLACTIC ANKLE TAPING DURING THE FEINTS: ANKLE KINEMATICS BEFORE AND AFTER TRAINING

Meana Riera, M., Alegre Durán, L.M., López Elvira, J.L., Aguado Jódar, X.

Universidad Católica San Antonio; Universidad de Castilla-La Mancha, Spain

INTRODUCTION

Feints are associated with ankle sprains mechanism of injury.

METHODS

The effectiveness of preventive ankle taping in the limitation of ankle supination and extension during a feint and the degree of loss of restriction after 30 minutes training was analysed.

The results of passive measures were compared with dynamic ones during a feint, using 3D digital video system (125 Hz).

The influence of individual characteristics on initial restriction and on loss of restriction was analysed in order to evaluate particular necessities of replacement.

RESULTS

Significant initial restrictions on passive supination and extension movements have been reported (64.45% and 59.07% respectively), while dynamic measures only show a significant restriction of 13.53% on landing supination, so taping provides no significant restriction during the feint on healthy subjects.

Although significant loss of restriction has been found after exercise on passive supination and extension (49.29% and 47.64% respectively) the feint showed no significant losses.

About the influence of anthropometrical characteristics, taller subjects suffered higher losses of extension restriction (r=0.590). Related with foot dimensions, subjects with pes cavus (r=0.679), narrow middle foot (r=0.614) and wide inner arch (r=0.643), suffered more important losses of restriction on supination and extension movements, so taping should be replaced more frequently.

CONCLUSIONS

The results show the importance of considering individual characteristics on taping construction and reposition, the useless of preventive taping on healthy subjects as well as importance of a fitted strength and co-ordination program.

COMPARISON OF THE MUSCLE-TENDON COMPLEX BEHAVIOR IN THE GASTROCNEMIUS DURING DIFFERENT HUMAN VERTICAL JUMPING MOVEMENTS IN VIVO

Fukashiro, S.

University of Tokyo, Japan

Behavior of fascicles and tendinous structures of the m. gastrocnemius medialis was quantitatively compared during several human vertical jumping movements in vivo. Eight male subjects performed maximal-effort 1: squat jumping (SQJ) from the squat position without countermovement, 2: counter movement jumping (CMJ) from the standing position, 3: ankle plantarflexion jumping (AJ) from the standing position without countermovement, and 4: straight legged drop jumping (DJ) from a height of 0.20 m. Kinematic and kinetic data were obtained using a high-speed camera and a force platform system. Selected parameters such as angular velocity, torque and power were calculated for the hip, knee and ankle joints. Furthermore, behavior of fascicles and tendinous structures were determined using ultrasonography and electromyography. The length of the muscle-tendon complex as estimated by the kinematic data consisted of fascicle and tendinous structures. Ultrasound data were used to calculate fascicle length and pennation angle. The tendon force was estimated by the ankle joint torque divided by ankle moment arm. The gastrocnemius medialis tendon force was determined by using the ratio of the physiological cross sectional area (PCSA) of triceps surae muscle group to the PCSA of the gastrocnemius medialis.

Vertical displacements of the body center of gravity from the standing position were 0.43m, 0.44m, 0.16m and 0.33m in SQJ, CMJ, AJ and DJ, respectively. During the latter take-off phase, there was no stretching of the fascicles of the m. gastrocnemius medialis in all jumping motions, including CMJ and DJ with countermovement. In SQJ and AJ without countermovement, on the other hand, the fascicles of the m. gastrocnemius medialis shortened in the early take-off phase. As a result, the elastic energy of 4.9J, 6.6J, 2.2J and 7.6J in the tendinous structures of the m. gastrocnemius medialis were stored, and 4.4J (86% of total muscle-tendon complex work in push-off phase), 3.8J (79%), 2.1J (47%) and 5.8J (75%) of the energy were reutilized during the push-off phase in SQJ, CMJ, AJ and DJ, respectively. The results quantitatively indicate that there was a large advantage from elastic energy use in human vertical jumping. The behavior of the muscle-tendon complex of the m. gastrocnemius medialis was also examined in terms of force-length and force-velocity relations. The fascicles of the m. gastrocnemius medialis operated within the optimal range of the sarcomere force-length relationship during jumping. Also, the fascicles worked in the relatively low shortening velocity region of the instantaneous force-velocity relationship in all jumping motions.

EQUILIBRIUM REGULATION BY ATHLETES'

Booban, W., Sadowski, J., Niznikowski, T., Mastalerz, A., Niznikowska, E.

Józef Pisudski Academy of Physical Education in Warsaw, Poland

Performance of many exercises by youth acrobats and athletes during training and competition required equilibrium regulation. Some results indicate slight effect of visual condition on the postural sway and describing effect of maintaining body equilibrium during hand stance. The human body is not rigid and its center of gravity and base of support can change with limb movements. Humans can thus control their stability by changing their stance and body position. The aim of the study was to describe the mechanism of equilibrium control by youth acrobats during three types of exercises. All exercises were performed on the Kistler force platform and recorded by JVC video recorder. Center of pressure and center of mass were selected for two planes: sagital - Y and frontal - X. Base of support, acceleration of COP, external work and time of equilibrium stability were also analyzed. 9 highly skilled athletes (height 170cm, ± 4.0cm, body mass 72.4kg ± 3.6kg, age 20.4years, ±1.7years) and 30 children (height 116 ±5cm, body mass 25kg, ±2kg, 7 years old) took part in the research. Individual manner of equilibrium regulation for selected exercises was affirmed. Most of our acrobats controlled their body position by trunk motion in sagital plane (37%) during all exercises. Quality of sway holding was the best for children who got it by micro fluctuations in hip joints. Expert opinions for first exercises were 36.9 % higher for children which got stability by micro fluctuations in hip joints. Similar notes for this regulation were obtained for second (39%) and third (38.9%) exercises.

BIOMECHANICS ANALYSIS EXECUTION OF DOUBLE BACKWARD STRETCHED SALTO WITH DIFFERENT TOUCHDOWN ELEMENTS

Sadowski, J., Boloban, W., Mastalerz, A., Winiowski, W., Niznikowski, T.

Józef Pisudski Academy of Physical Education in Warsaw, Poland

Based on the key components theory the aim of the study was to compare factors describing technique differences of double backward stretched salto with different touchdown elements. One 60 Hz (JVC GR-DVL 9800 NTSC) camera and APAS 2000 cinematographic analysis systems were used. One highly skilled acrobats – jumper (height 170cm, ± 4.0cm, body mass 72.4kg ± 3.6kg, age 20.4years, ±1.7years), champion of Poland in acrobatics jumps attended to this project. The studies were conducted on a standard acrobatic path (type PTS 2000). Two sequences with the following elements were analyzed: round-off - double salto backward stretched (A) and round-off - double salto backward stretched - tempo salto (B). The highest differences between the key components describing performance of presented exercises exist for joint angles during launching and landing posture, and resultant velocities during touchdown. Correct performance of double backward stretched salto is not depended on the sequence elements and its complexity.

Poster presentation (PP)

PP3-06 Psychology 1-3 - "Exhibition Hall"

THE MOTOR, FUNCTIONAL AND PSYCHOLOGICAL STATUS OF SELECTED JUDOISTS

Bratic, M., Nurkic, M., Mitic, D., Milojevic, A.

The Faculty of Physical Eduaction Nis, The Faculty of Physical Education, Leposavic, Serbia and Montenegro

Success in judo represents the result of the functioning of various components which are intertwined into a single activity, that is, a sum of anthropometric, motoric, functional, cognitive, connative and other factors. The determination of the motor, functional and cognitive dimensions is an important factor in the sport selection process and the creation of a model on the basis of which the training process of judoists is programmed. A high level of basic motor, cognitive and functional abilities is considered to be the basic requirement for the effective learning of motor structures, their improvement and successful application. Within the training process, the dominant aim has to do with the transformations of basic motor abilities and certain morphological characteristics. Yet, considering the fact that all basic motor abilities cannot be altered to the same extent, and besides that, are deeply rooted in the organized system of other anthropological dimensions, it is very difficult to alter them independently and individually in the desired direction. Due to that, there is no universal system of exercise by means of which it is possible to ensure such a level of basic motor abilities which would suit all the possible forms of movement. The purpose of this research is to determine the motor, functional and psychological status of selected judoists. The sample of subjects encompassed 40 selected judoists, aged 15 – 17. All the subjects had their names on the long list for the national team on the basis of their standing in the State Finals. For the purpose of evaluating motor abilities, 12 motor tests were used. To describe the structure of the judioists' personalities, the HSPQ personality test was used, and to evaluate competitive anxiety, the Martens questionnaire, SCAT (Sports Competition Anxiety Test). The results of the research have indicated that the measured motor abilities of the selected judoists are of a significantly higher value than those found among members of the general public of the same age. The results have also shown that the shortlisted selected judoists scored higher values in relation to the judoists on the long list. Due to continuous strain, where an alteration between the aerobic and anaerobic mechanisms of judoists occurs, functional abilities are also significantly higher in the case of selected judoists. An analysis of the results for the psychological status indicates that the majority of judoists have a balanced personality profile with a normally developed personal disposition. Most of the judoists are at the optimum level of sport-competitive anxiety, while a smaller number of them are characterized by an increased level of pre-competitive tension in the form of somatic and cognitive anxiety.

MOOD MONITORING WITH YOUNG ELITE SOCCER PLAYERS

Steinbacher, A., Kleinert, J.

Institute of Psychology, Germany

Introduction

Mood monitoring gives indices for stress states in individuals and teams, and therefore also for current injury dispositions. Despite this, continuous measuring of physical and psychological states (mood monitoring) is less investigated in sport injury research and prevention.

The purpose of the present study (founded by the Federal Institute of Sport Science, Germany) is to find out the applicability of handheld-assisted monitoring of perceived physical states with three different scale versions. Firstly, to survey, whether mood monitoring in young elite soccer players identifies injury dispositions. Secondly, whether the quality of healing process is traced in case of injury. Thirdly, whether information is received about the optimal date of re-entry into practice for the convalescent player. Furthermore it is to be verified, whether strains of the soccer season are reflected in mood processes.

Methods

Participants are 39 young male elite soccer players of the highest German league level regarding their age (15-17). During the season 2004/2005 38 measuring points took place. Usually once a week the perceived physical state (perceived activation, perceived fitness, perceived flexibility and perceived health) were measured using special software (moodmeter ®, module Bodyfinder) installed on handhelds (Acer N 10). Bodyfinder-items were taken from the questionnaire Perceived Physical State (PEPS, Kleinert, 2004). Three scale versions were used: (1) a typical six point Likert-scale, (2) a visual-analogue scale (VAS) with seven growing bars and (3) a special scale called "cognitive-dilemma-scale" (CoDi).

Results

The physical processes of the examined group reflected the strains of the season. Different results became obvious in closer examination of individual mood processes (perceived physical states). Perceived physical and psychological states decreased before an injury occurred. Furthermore the phase of healing and indices for an optimal re-entry after rehabilitation were recognisable. The different scale versions didn't have any significant influence on the data.

Discussion

Handheld-assisted monitoring of perceived physical and psychological states seems to be applicable in sport-psychological care of team sport athletes. Mood monitoring can give evidence of potential psychological injury dispositions in individual cases and injury prevention interventions seem to be possible by an early discovery of these dispositions.

PSYCHOLOGICAL PREDICTORS FOR BEHAVIORAL CHANGE - BASELINE VALUES OF READINESS TO CHANGE AND SELF-EFFICACY AS PREDICTORS OF ADHERENCE TO PHYSICAL ACTIVITY AFTER EXERCISE ON PRESCRIPTION

Bredahl, T.G., Roessler, K.K., Ibsen, B., Puggaard, L.

University of Southern Denmark, Denmark

Introduction

Studies have demonstrated that a sedentary lifestyle is related to increased risk of lifestyle diseases (1). Research emphasizes the importance and the difficulty of keeping the individual in a physical active lifestyle after intervention and establishes the fact that behavior change is anchored in a psychological and social context as well as physiological (2). Exercise on Prescription (EoP) is used to initiate

physical activity among sedentary individuals in risk of lifestyle diseases due to physical inactivity. After intervention, adherence to physical activity is crucial to the success of EoP. EoP is in the County of Funen and municipality of Frederiksberg divided into two central areas. a) A Treating Perspective (TP) aimed towards individuals with specific lifestyle diseases. The intervention involves physical activity counseling (baseline, and after 2, 4 and 10 month) and 4 month of supervised group training. The participants in the TP are referred to EoP by their general practitioner. b) A Preventive Perspective (PP) directed towards healthy citizens in risk of lifestyle diseases due to physical inactivity. The PP only involves physical activity counseling (baseline and after 2, 4 and 10 month). The participants in the PP are primarily included after self initiated contact to the physical activity adviser.

The aim of this study is to describe the baseline psychological values for the participants in the TP and the PP, respectively. The hypothesis is that participants in the PP will rate their Self-Efficacy (SE), their psychological Readiness to Change (RC), Self Reported Health (SRH), Self Reported Physical Condition (SRPC) and Self Reported Physical Activity (SRPA) higher than participants of the TP.

Methods

Subjects were 31 women and 10 men (age 51.2±14.8, BMI 32.8±6.2). RC, SE, SRH, SRPA, SRPC and BMI were assessed by a questionnaire. Mean values were compared using an independent-samples t-test. Data are presented as mean ± SD.

Results

The participants in the PP are younger than the participants in the TP (46.5±13.7 vs. 56.2±14.7, p=0.035). The participants in the PP scored higher in SRH (3.8±0.8 vs. 3.2±0.6, p=0.007) and SRPC (4.1±0.9 vs. 3.5±0.8, p=0.027). The participants in the PP scored lower in SE (50±13 vs. 68±19, p=0.003). No difference was found in RC, SRPA and BMI.

Conclusion

Psychological factors are very important to keep the EoP participants in a physical active lifestyle after intervention. At baseline the TP and PP group separates by age, SRH, SRPC and SE. Surprisingly no differences were found for RC and SRPA. A larger number of participants may be able to document potential important psychological differences of the PP and TP.

FROM BUILDING TO REBUILDING:AN ELITE BODYBUILDERS REFLECTIONS ON CAREER ENDING INJURY

Batey, J., Sparkes, A.C.

University of Winchester, United Kingdom

This work draws on the life history of an elite, black, male bodybuilder to explore how career ending injury has impacted upon his life. Following guidelines from Glesne and Peshkin (1992) and adopting an interpretive methodology, six in-depth interviews each lasting between 1.5 and 3 hours were conducted. The data was analysed using narrative analysis outlined by Maykut and Morehouse (1994). Numerous themes emerged from the data of which four will be discussed here. Using the theoretical lenses of Athens (1995), Charmaz (1983, 1987, 1995), and Frank (1991, 1995) attention is given to themes of bodily betrayal and negative pain and anger as they pertain to the psychological complexities of restorying the self after such a biographical disruption. Reflections on the process of being a life history subject are also provided.

ADAPTED PHYSICAL ACTIVITY IN OUTPATIENTS WITH ANOREXIA NERVOSA. PRELIMINARY RESULTS

Tolomio, S., Ferrara, S., Favaro, S., Travain, G., Zaccaria, M.

University of Padova, Italy

INTRODUCTION

Anorexia Nervosa (AN) is an eating disorder mainly affecting young women. With the purpose of losing weight these patients drastically reduce food intake and enhance energy expenditure by increasing physical activity. Most psychotherapists forbid exercise per se, instead of trying to correct its pathological features linked to the excess of physical activity, but whether to promote or withhold exercise is still controversial. To our knowledge a few studies reported the effects of individual exercise programs on inpatients with AN (Duesund L, 2003; Tokumura M, 2003) and only one study in outpatients (Thien V, 2000). No available data exist about group exercise programmes in anorexic outpatients.

AIM

To evaluate, in AN outpatients, the effects of an adapted group activity program, using exercises with low energy expenditure profile, combined with psychotherapy.

METHODS

5 young females (age range 17-31yr) with diagnosis of AN (DSM-IV) gave their informed consent to participate in this study, consisting of a 6-month adapted physical and psychotherapy program. To date, we completed only the basal and 3-month evaluations, using the tests specified below.

Anthropometric parameters: BMI and body composition by bioimpedance analysis (BIA).

Functional evaluations: maximal oxygen consumption (VO2 max) using a treadmill test, lower and upper limb maximal strength by leg-extension (LMS) and handgrip (UMS), respectively.

Psychological/psychiatric conditions: Body Attitudes Test (BAT), Eating Disorder Inventory (EDI), Rosenberg Self Esteem Test (RSE), Mackenzie Group Climate Questionnaire (GCQ).

RESULTS

After 3 months 4 subjects repeated the evaluations; one subject dropped out because of moving to a different town.

3 subjects increased while one decreased their BMI; Body Cellular Mass (BCM) increased in all patients. All functional parameters (LMS +61.1%, UMS +24.7%, VO2 max +16.7%), as well as several psychological/psychiatric items (self-esteem, body image, group climate, etc.) suggested a general improvement.

CONCLUSIONS

These preliminary results suggest that the association of adapted physical activity and psychotherapy programs, may contribute to enhance functional and psychological condition in outpatient anorexic females. Furthermore, they suggest that an exercise group activity could be a component of the existing therapeutic approaches to Anorexia Nervosa.

INVESTIGATION INTO THE SOCIOECONOMIC STATUS AND PHYSICAL ACTIVITY OF TEENAGERS: A CASE STUDY IN HUNGARY

Soós, I. 1, Hamar, P. 2, Biddle, S. 3, Murdey, I. 3

1 University of Sunderland, UK, 2 Semeilweis University, Budapest, Hungary, 3 Loughborough University, UK, United Kingdom

Introduction: The prevalence of teenagers' physical activity is influenced by the socioeconomic status (SES) of the family. SES is associated with parents' occupation, the number of rooms in the house and household electronic, entertaining and technical devices. In many developed countries, teenagers in the lower SES groups have the highest level of overweight and the lowest level of physical fitness. In contrast with developing countries, young people from higher SES groups have the greatest level of overweight and obesity, and are more likely to live sedentary lives. The aim of our study was to investigate physical activity and SES in Hungarian teenagers, thus investigating an important developmental transition period, and a country in "development".

Method: A free-time diary was used as the principal data collection instrument. The diary was broken down into two main sections, in order to collect demographic data (including personal details, family background, pubertal status of students, home environment and socioeconomic status) and time sample data (including the weather conditions and dietary habits). Students (n=114), 13-16 years of age, were asked to report their activities on three weekdays and one weekend day. Activities were recorded in 15-minute time slots, outside of school time, by answering the questions "what students were doing", "where they were", and "who they were with". Data were analyzed by SPSS 13.0.

Results: The current study showed no significant difference between SES groups (based on parents' occupation) for TV viewing, using the computer, playing computer games, active transport or sport and exercise. However, fathers' occupation was significantly associated with the number of TV sets in the home ($p<0.04$), number of video machines in the home ($p<0.034$), and number of internet computers in the home ($p<0.009$). Significant differences were found between both fathers' and mothers' occupation and the number of music stereos in students' bedrooms ($p<0.014$) as well as having their own skateboard or microscooter ($p<0.016$).

Conclusions: Time spent on electronic entertainment activities can be related to the number of TV sets, electronic devices and computers in the home, and especially if they are located in the bedroom, it may lead to an inactive and sedentary lifestyle. Nevertheless, in many cases, students do exercise and sports directly after school, and watch TV or use computer in the evening, consequently the interrelationship between sedentary and active behaviours requires further investigation.

THE POTENTIAL RELATIONSHIP BETWEEN ACHIEVEMENT GOAL ORIENTATIONS AND SPORTS ATTITUDES AMONG PORTUGUESE YOUNG ATHLETES

Gonçalves, C.E., Coelho e Silva, M., Cruz, J.

University of Coimbra, Portugal

Introduction

For the athlete, attitudes represent an effective and instrumental evaluation of the best behavior to addopt in a sport setting, without external interventions. For coaches and other significant adults achievement goal orientations would represent the link between individuals' attitudes and the ecological environment. The goal of this study is to examine the relationship between the dimensions extracted from the Task and Ego Orientation in Sport Questionnaire-TEOSQ [1] and those extracted from the Sports Attitudes Questionnaire-SAQ [5], among portuguese athletes aged 13-16 years old.

Methods

The sample is composed of 482 athletes (mean age: 14.1 years, 248 boys, 234 girls). Respondents fulfilled the Portuguese versions of the TEOSQp [2] and of the SAQp [4].In previous studies [3] [4], 2 dimensions of the TEOSQ, task and ego, and 4 dimensions of the SAQ: convention, commitment, cheating and gamesmanship, were identified. Both studies used exploratory and confirmatory factor analysis. Descriptive statistics for the 6 identified dimensions are presented. The bivariate coefficient of correlation is then determined using the SPSS, version 12.0.

Results

Task- and ego- orientations are uncorrelated (r=+.0.05, n.s.). Among the SAQ dimensions, two significant correlations were found between cheating and gamesmanship (r=+0.67, p≤.01) as well as between convention and commitment (r=+0.27, p≤.01). Ego orientation appears to be positively correlated with cheating (r=+0.30, p≤.01) and gamesmanship (r=+0.33, p≤.01), and negatively with convention (r=-0.16, p≤.01). Positive correlations between task- orientation and convention (r=+0.29, p≤.01) and commitment (r=+0.40, p≤.01) were also found.

Discussion/Conclusion

The present study suggests a bipolar link between ego- orientation and the antisocial dimensions of SAQ, cheating and gamesmansip, while task- orientation seems to be related to prosocial attitudes, as convention and commitment. Therefore, the research of the causal

effect of achievement goal orientations on the expression of sports attitudes would be of interest, using structural equations to confirm a hypothetic model.

A SITUATED ANALYSIS OF THE DECISION-MAKING ACTIVITY IN BASKETBALL

Hauw, D., Renault, G.

JE 2416 GP3S, University of Montpellier 1, France

Research in the domain of decision-making actually promotes an extensive use of video-based simulation of game situations (e.g., Caserta, Singer, Coombes, 2005). As suggested the situated cognition theory (Clancey, 1998 ; Greeno, 1998), this protocol reduced the complexity of the decision-making process. For example, it did not allow the study of meaningful teambuilding situations or the dynamics of the developing coupling between actions and situations. The aim of this study was to analyse the activity that consisted to create meaningful situations during decision-making.

Method

18 players, in groups of two, volunteered to participate in a specific task well-known in basketball: the screen play. Two offensive players had to be organised collectively in order to attack the basket, confronted with four defensive organisations that were performed twice by two defensive players. Each of the eight trials was recorded on video, then self-confrontation interviews were conducted with each offensive player. The course of action was analysed using the methodology of the theory of the course of action (e.g., Hauw, Berthelot & Durand, 2003)

Results

Four categories of action-situation coupling were identified: (a) action routines associated with familiar situations or referred to preceding situations experienced in the task, (b) waiting actions associated with uncomfortable or uncomprehending situations, (c) actions initiated without certitude associated with ill-known situations that players nevertheless decided to let unfold, (d) step-by-step orientating and building actions associated with situations that hold diverse possibilities. Four collective configurations of coupling were identified :(a) a deterministic mutualism organisation where the two players used the others' activities to reduce the non-deterministic nature of the situation, (b) a non-deterministic mutualism organisation where the two players' activity led to a new non-deterministic situation, (c) an individualism organisation where the two players' activity was independent of each other, (d) a waiting organisation where one player let the situation unfold in order to see what would happen and to reduce the non-deterministic nature of the situation.

Discussion

These results show that decision-making does not only process the input that is in context. By using possibilities of play, players develop the solution online. These actions are based on the determined or undetermined properties of the situation and manage differently the possibilities of interaction with the other players. These types of action-situation coupling are the processes that players display to organise themselves in such an environment. Decision-making is a situated process that should be analysed by taking into account the dynamics of this process of creating meaningful situations through action and using a large temporal horizon (Ward, Williams et Ericcson, 2005).

JUDGING BIAS IN AESTHETIC SPORTS: OPEN FEEDBACK LEADS TO NONPERFORMANCE-BASED CONFORMITY

Boen, F., Vanden Auweele, Y., De Geest, A., Feys, J., Claes, E., De Cuyper, B.

K.U. Leuven, Belgium

Introduction

Two experiments were designed to determine whether the open feedback system used in many aesthetic sports (i.e., the judges hear and see each others' scores after having rated each performance) leads to unwanted (i.e., nonperformance-based) conformity in the scoring of judges.

Methods

In Study 1, twenty judges in synchronized swimming were randomly divided into four panels of five judges. These judges had to rate 60 performances of the same imposed figure, the barracuda twirl: 30 performances in phase 1 and 30 performances in phase 2. Two independent variables were orthogonally manipulated: feedback (or none) during phase 1 and feedback (or none) during phase 2.

In Study 2, twenty-seven difficulty judges in rope skipping were randomly divided into panels of maximum five judges. These panels had to rate the same 30 videotaped individual performances: 15 in phase 1 and 15 in phase 1. Again, feedback (or none) during phase 1 and feedback (or none) during phase 2 were orthogonally manipulated.

Results

With respect to Study 1, the variation of the scores given in phase 1 was significantly smaller when the judges had received feedback than when judges had not received feedback. Moreover, the variation of the scores given in phase 2 remained significantly smaller among the judges who had received feedback in phase 1 but not in phase 2, compared with judges who had not received feedback in either phase.

With respect to Study 2, the results revealed that there was more score-conformity among those panels that were given feedback in phase 1 compared with panels that were not given feedback in this phase However, in contrast with Study 2, this conformity did not last when feedback opportunities were removed in phase 2.

Discussion/Conclusion

The results of Study 1 indicate that the scoring of judges in synchronized swimming is strongly and lastingly influenced by immediate feedback. Moreover, these findings suggest that normative rather than informational influences caused the observed conformity among judges in synchronized swimming. The results of Study 2 revealed that the scoring of judges in rope skipping was also influenced by immediate feedback. However, in contrast with Study 1, this conformity did not last when feedback opportunities were removed, suggest-

ing that informational rather than normative influences caused the observed conformity among judges in rope skipping. The implications for panel judging in aesthetic sports will be discussed.

ANGER RUMINATION AND SELF-REPORTED AGGRESSION AMONGST BRITISH AND HONG KONG CHINESE ATHLETES

Maxwell, J.P.

University of Hong Kong, Hong Kong

Previous work has determined positive relationships between provocation, anger rumination, and aggression in British athletes (Maxwell, 2004); however, the reliability of these findings and their generality across diverse cultures has not been examined. Eastern cultures typically discourage the overt expression of angry feelings (Bishop & Quah, 1998; Chen et al., 2005); therefore weaker relationships amongst provocation, anger rumination, and aggression might be expected. A comparison of British and Hong Kong (HK) Chinese athletes' propensity for rumination and aggression was undertaken to test this prediction. A total of 308 participants from Hong Kong and 376 from Britain completed a self report questionnaire detailing frequency of aggressive acts and provocation whilst participating in competitive sport. In addition, participants completed the Anger Rumination Scale (Sukhodolsky, Golub, & Cromwell, 2001), a 19 item measure of repetitive thoughts involving past anger invoking experiences. The ARS consists of four subscales that measure the content of ruminative thoughts (thoughts of revenge, angry afterthoughts, angry memories, and understanding of causes). Regression analyses suggested that provocation and thoughts of revenge were significantly associated with the self-reported aggression of both British and Hong Kong athletes. A multivariate analysis of variance demonstrated that mean frequency of aggression was similar across cultures except for a tendency for British male contact sport athletes to report greater frequency of aggressive behaviour. HK Chinese athletes tended to report higher frequencies of thoughts relating to understanding the causes of anger and higher incidence of perceived provocation. It was concluded that the pattern of aggressive behaviour was similar across the two cultures when opportunities for aggression are infrequent, but that HK Chinese athletes may inhibit aggressive responding even when opportunities are frequent.

STRUCTURAL AND PREDICTIVE VALIDITY OF THE BASIC PSYCHOLOGICAL NEEDS IN EXERCISE SCALE APPLIED TO COMMUNITY EXERCISE PROGRAMS

Vlachopoulos, S.P.

Aristotle University of Thessaloniki, Greece

The present study extended the use of the Basic Psychological Needs in Exercise Scale (BPNES: Vlachopoulos & Michailidou, in press) to community exercise programs and examined the structural and predictive validity of the scale's scores in this context. The BPNES assesses the extent to which the needs for autonomy, competence, and relatedness (Ryan & Deci, 2000) are satisfied in exercise. A total of 851 participants in community exercise programs provided data on the BPNES as well as on frequency of concentration during exercise, enjoyment, attitude toward exercise and intention for continued exercise involvement. The results supported the hypothesized dimensionality, internal consistency, and predictive validity of scale responses. The goodness-of-fit indexes of the 3-factor confirmatory factor analysis BPNES model revealed an excellent fit to the data: $X2 = 209.87$, $df = 51$, $p < .001$, NNFI = .97, CFI = .97, RMSEA = .06. The factor loadings ranged from .59 to .90. The alpha values (Cronbach, 1951) for each of the subscales were .84 for autonomy, .86 for competence, and .92 for relatedness. The predictive validity of the scale responses was supported through a number of structural equation models representing the prediction of concentration, enjoyment, attitude toward exercise, and intention from the three needs. All of the motivational consequences were predicted by the psychological needs. Overall, the results supported the structural and the predictive validity of BPNES responses of participants attending community exercise programs and extended the construct validity evidence of the scale into the community exercise context.

THE RELATIONSHIP BETWEEN COACHES LEADERSHIP STYLE & TEAM COHESION IN IRANIAN SUPER LEAGUE BASKETBALL CLUB

Moradichaleshtori, M., Jafari, A.

Tehran University, Iran

The purpose of this study was to investigate the relationship between leadership styles of coaches (according to multi-dimensional model in sport) and group cohesion in basketball teams present in Iranian premiere league. A number of 144 basketball players, therefore, responded to questionnaires, including Leadership Scale in Sport (LSS) (Chelladurai & Saleh 1980), and Group Environment Questionnaire (GEQ) (Caron, Widmeyer, and Brawly 1985). The two latter questionnaires were used to study players perception of coach leadership

styles and group cohesion in their own teams. For analyzing the collected data, descriptive and inferential statistics such as Pearson's correlation coefficient, independent T-test, and Factorial ANOVA were used. Results showed: 1) A significant direct relationship between leadership styles of instruction behavior, democratic, social support, and positive feedback as well as a sig. reverse relationship of autocratic leadership with social and task cohesion among players ($p<0.01$).

2) A sig. difference between leadership styles of coaches in successful teams and those in unsuccessful ones ($p<0.01$).

3) A sig. direct relationship between group cohesion and success of a team (i.e. win percentage of a team during the session) ($p<0.01$).

Based on the results it can be said that leadership style of coaches is one of the factors related to cohesion while cohesion itself is considered as a success factor of a team. In addition, those coaches using instruction behavior, democratic, social support, and positive feedback styles rather than autocratic behavior, will have more cohesive & finally more successful teams.

PERFORMANCE EVALUATION OF SELECTED IRANIAN COLLEGIATE SPORT ASSOCIATIONS

Salehi, S., Moradi, M.

azad university, Iran

The purpose of this study was to evaluate the performance of some selected Iranian collegiate sport associations, in terms of their effectiveness, from Viewpoints of stakeholder groups of these associations, including student-athletes as well as coaches of universities in Tehran, members of the selected associations, and experts of these selected sport types(i.e. Badminton, Football, Basketball, Wrestling, Handball, and Volleyball). A total of 546 respondents(270 student- athletes, 120 coaches,120 experts, and 36 members of associations) responded to two respective questionnaires developed for this study(one for students and another designed for other three groups). The collected data were analyzed by some statistical methods such as One-sample T-test, ANOVA, and Dunnett C as the following test of ANOVA . In Addition, for determining the consistency of questionnaires and normal distribution of collected data, Cronbach's alpha and Kolmogorov-Smirnov were used respectively. Results showed that student-athletes, coaches , and experts evaluated the performance of selected associations as weak(Means<3, p<0/05), as such did the members of wrestling association(Mean=2/78). Members of other associations, however, didn't evaluate it as weak (Means>3). There was also a significant difference between Viewpoints of members of associations and those of other groups in each sport type(p<0/05). Among the questions of 2nd part of all questionnaires, only items of 5 , 6, and 14 obtained acceptable means(Means>3), while they all are subscales of a total performance indicator(i.e. organizing intercollegiate games). Results indicate that from Viewpoints of all stakeholder groups, despite the sig. difference between members and other groups, performance of studied associations was not favorite.

THE RELATIONSHIP BETWEEN COACHES LEADERSHIP STYLE & TEAM COHESION

Moradi, M., Jafari, A., Salehi, S.

Tehran University, Iran

The purpose of this study was to investigate the relationship between leadership styles of coaches (according to multi-dimensional model in sport) and group cohesion in basketball teams present in Iranian premiere league. A number of 144 basketball players, therefore, responded to questionnaires, including Leadership Scale in Sport (LSS) (Chelladurai & Saleh 1980), and Group Environment Questionnaire (GEQ) (Caron, Widmeyer, and Brawly 1985). The two latter questionnaires were used to study players' perception of coach leadership styles and group cohesion in their own teams. For analyzing the collected data Pearson's correlation coefficient was used. Results showed: A significant direct relationship between leadership styles of instruction behavior, democratic, social support, and positive feedback as well as a sig. reverse relationship of autocratic leadership with social and task cohesion among players ($p<0.01$).

Based on the results it can be said that leadership style of coaches is one of the factors related to cohesion while cohesion itself is considered as a success factor of a team. In addition, those coaches using instruction behavior, democratic, social support, and positive feedback styles rather than autocratic behavior, will have more cohesive & finally more successful teams.

COPINGSTRATEGIES AS PREDICTORS FOR PSYCHOSOMATIC PATHOLOGY

Wippert, P.-M., Wippert, J.

TU Munich, Germany

Introduction: Experiencing a critical Life-Event entails coping behaviour adapted to the given situation. The problem posed in this study was whether the shown coping behaviour can influence the expression of psychosomatic pathology in the process of dealing with the event.

Method: The participants in the longitudinal study consisted of N= 19 athletes of the German national ski-team (Age= 20) who had to cope with an undesirable and unexpected career end. The participants were questioned once prior to the event onset and five times after the event onset (sampling times: 10 days/ 3 weeks/ 3 months/ 5,5 months/ 8 months after the event). Data collection for psychosomatic variables was carried out using Jenkins questionnaire on sleeping behaviour, Appels questionnaire on Vital Exhaustion (VE) and a modified Version of the Complaint List by Zerssen (B-L). The coping behaviour was measured 8 months after event onset using the German version of the World of Coping Checklist by Ferring and Filipp. The data was evaluated parametrically by regression analysis.

Results: The coping behaviour categorised as emotion-focussed coping displayed a medium significant influence on the scales for Vital Exhaustion ($ß = 3.09$, $p< .05$, $R2\ adj. = .17$, $R = .46$) and sleep ($ß = 1.80$, $p< .05$, $R2\ adj. = .23$, $R = .52$) 3 weeks after event onset. A further significant influence was found 5,5 months after event onset for the values in the Complaint List ($ß = 1.23$, $p< .05$, $R2\ adj. = .17$, $R = .47$), as well as after 8 months for Vital Exhaustion ($ß = 3.2$, $p< .05$, $R2\ adj. = .24$, $R = .53$). As the levels of emotion-focussed coping increased, so did the expression of psychosomatic disorders.

Discussion: Emotion-focussed coping, which the literature considers as being an unfavourable form of coping behaviour, indicates an increased expression of psychosomatic variables. However, due to the relatively small variance of maximally 24% and the small sample size these results are to be interpreted carefully.

A RESEARCH OF THE RUNNING ATHLETES IN COMPETITIONS

Laszlo, Z.

Universitiy of Pecs, Hungary

Introduction

The results of different studies in national and international levels give a comprehensive, multi-coloured view. Both previous and recent studies in the field of anxiety researh have made attempts to provide psychological and pedagogical review of anxiety and the reasons for reducing or, if possible, eliminating it. The interpretation and handling anxiety requires the understanding of physiological and psychological mechanism as well. For sport experts, one of the most important tasks is to determine and develop the most successful personality traits in competitive situations. The properly trired personalty can positively contribute to the management of anxiety before competition, and in the may influence the performance in it.

Methods

In the present paper, on the one hand, I studied the properties of the competitive performance anxiety of the middle-distance and the long-distance runners before and after the race, on the other hand, the related kinds of the competitive performance anxiety (cognitive anxiety, somatic anxiety, the degree of self-confidence of the achievement).

The metod of investigation is focused on psychological traits. This assessment was performed by the means of the Martens Competitive State Anxiety Inventory, CSAI-2 questionnaire and the reduced version of the Spielberger Competitive Performance Anxiety Test, PRQ1, PRQ2.

Redults

The averages and the scatterings of averages of the Martens (CSAI-2) indicators of the competition anxiety in different age groups showed that the somatic anxiety was higher in case of middle-distance and long-distance runners before the race both the cognitive anxiety and the self-confidence related to the result of the race showed lower values. The junior and adult age group stands out from the studied groups providing the highest averages, and in respect of self codfidence they can be characterized with higher values compared to the other two groups.

The averages and the scattering of values of the Sarason indicators (PRQ1, PRQ2) in the competitive performance anxiety yielded the following results, the reduction of lowest in the junior and adult groups before the race.

Conclusion

Since the previous investigations have not studied this, thus the anxiety level of competition performance of the middle-distance and long-distance runners can be approached from a new point of view in a given period of races.

I have received information about how far, before competition, the anxiety level of the sportsmen is infuenced by the types and personality traits of the problemetic sportsmen.

DETERMINING THE ROLE OF THE CLUB DEVELOPMENT OFFICERS, COACHES AND PARENTS IN PREPARING THE YOUNG ELITE PLAYER FOR A PROFESSIONAL CAREER IN THE AUSTRALIAN FOOTBALL LEAGUE

Gibson, B.

Edith Cowan University, Australia

With the expansion of Australian Rules Football into a national competition, and the development of the Australian Football League, the opportunity for players to undertake a full time professional career has become increasingly attractive. Sponsorship and television rights have provided the finance that is necessary for players to be contracted on a full time basis with attractive salary packages. This new structure has seen the introduction of the national drafting system and the competitive recruiting of the most promising young players across Australia. The intensity of the competition has led to players as young as 16-17 years of age becoming the targets of the recruiting agents. The outcome of being drafted by a club means a significant change to the life style and routines of these young players. In many instances it results in a change of location as the young recruits move interstate to take up the appointment with their new club. They also move from being part time athletes to full time professionals with significant salaries and major demands being made on their time. Inherent in these changes are numerous adjustments that must be made and these can result in both psychological and physical problems occurring with the young players. Therefore, the purpose of this study was twofold. Firstly, to identify the psychological and/or physical problems that continually arise with the young recruits, and secondly to investigate the role that the Development Officers, coaches and parents can undertake in assisting the young players in making the transition from the junior ranks to the full-time professional level. The sample that was interviewed for this study included twelve Development Officers and coaches from the AFL clubs and the parents of 30 players who had been drafted to AFL clubs. All were interviewed using the same standardised set of questions and interviews were tape recorded so as to permit an accurate post interview analysis to be performed. The problems that were identified were numerous and varied and in some instances would require additional professional assistance, for example, a medical practitioner, sports psychologist. However there were a significant number of common problems identified and this demonstrated the important role that the development officers, coaches and the parents should undertake. This role would change over time as the young player progressed through the ranks.Results have also shown that the administrators in the AFL clubs have a significant part to play in liaising between management and the families, thereby ensuring that all aspects are dealt with during this difficult transition period. Finally, the results of this study have enabled the author to establish a set of guidelines that are designed to assist administrators, clubs and parents in dealing with the psychological and physical problems that may prevent the young player from fulfilling his potential as a developing professional player.

THE MOTIVATIONAL PRIORITIES OF PARTICIPATION IN THE ELITE ATHLETICS OF KURDESTAN PROVINCE

Boroujerdi, S.S.

Kurdestan University, Iran

The purpose of this research was investigation the motivational priorities of participation in the elite athletics group sports of Kurdestan Province. This goals achieved through classification of motivational factors (development and improvement of skills , being with the friends , to gain success and to win , situational factors: (parents , close friends, coaches , equipment and facilities) get ride of energy , team spirit , to gain physical fitness, having hobby and recreation) with due attention to individuals characteristics of samples (age class , career – educational condition , record of taking participation in competitions , record of participation in sport , injury rate)

Statistical population include elite athletics assured of Kurdestan Province which their number were about 362 and 60 teenagers , 50 adolescents , 60 adults of theses were chosen according random sampling as the research samples.

The research method was based on description study. Data analysis includes descriptive statistics and ANOVA test.

The results of descriptive showed that: all the subjects addressed the motivational factor of gaining success and winning as the main factor in participation in sport and having team spirit having hobby recreation, situational factors as the least significant factors

Hypothesis test results showed in classification motive of:

Development and improvement of skills with due attention to career – educational condition, situational factors with attention to record of participation in sport having team spirit with attention to injury rate and record of participation in sport and having hobby and recreation with attention to age class and injury rate among subjects meaningful differences were observed.

PSYCHOLOGY HAS A LOT TO OFFER SPORT: THE USE OF HYPNOSIS AND HYPNOTHERAPY IN SPORT

Claasen, M.

Private Practice, South Africa

INTRODUCTION

The influence of the mind and mental preparation upon sports performance is widely acknowledges. More and more elite as well as recreational athletes, coaches and even officials, make use of mental skills to enhance their performances and to relieve emotional and physical stress.

Visualisation, relaxation and stress reduction are keys not only to reach goals and perform successfully but also to mental well-being and good physical health.

PURPOSE:

The utilisation of various hypnotic techniques and –phenomena can be of great value to enhance sport performance and gain inner strength, to mobilise energy, to optimise arousal levels, to speed –up recovery from injuries and to ease pain.

The use of hypnosis and ego-strengthening techniques can also alter the course of therapy (when necessary) in a very positive way. Hypnotic intervention and ego strengthening "has been shown to (1) shorten the course of therapy, (2) increase self-confidence, (3) enhance internal control and (4) produce a sense of mastery." (Phillips and Frederick, Stanton 1979, Hartland 1965,1971)

METHOD:

By making use of the various hypnotic techniques and by teaching the athletes self-hypnosis. Case studies to illustrate.

RESULTS:

Athletes experienced (1) increased confidence and self-belief, (2) enhancement of their general coping abilities, (3) reduction of fear, anxiety, worrying and muscle tension, (4) greater feelings of control and concentration and (5) increased ability to manage pain and fatigue.

CONCLUSION:

Hypnosis helps to prevent physical symptoms getting in the way of optimal performance. It can be amazingly effective to bring about improvements in physical performance and to strengthen mental well-being. It helps athletes to stay calm and in control under pressure and to establish a positive mind-set.

A STUDY ON GOAL ORIENTATION, PERCEIVED MOTIVATIONAL CLIMATE AND SOURCES OF SPORT CONFIDENCE IN PLAYERS OF JUNIOR VOLLEYBALL CHAMPIONSHIP OF IRAN

Bahram, Y., Poorya, Q.

Razi University, Iran

The purpose of this study was to investigate the relationship between Goal Orientation (Task-oriented goal vs. Ego-oriented goal) and Perceived Motivational Climate (Perceived Task-Climate vs. Perceived Ego-Climate) with Sources of Sport Confidence of volleyball players, competing in the 2004 Junior Champion Competition of Iran. Subjects of this study were 82 male volleyball players. For data gathering three questionnaires were used: Goal Orientation Questionnaire, Perceived Motivational Climate Questionnaire (PMCQ) and Sources of Sport Confidence Questionnaire. Prior the survey was administered; the researcher would explain the content of the inventories to the athletes. Researcher had informed the player that their responses were submitted anonymously. Significant findings were summarized as following: Among Sources of Sport Confidence, factors of Coach Leadership, Mastery and Demonstration of Ability had the highest average and athletes recorded higher score in Task-Orientation used more factors of Sources of Sport Confidence. According to this research the athletes who recorded higher scores in Task-Orientation selected Mastery and Social Support as factors to enhance their self-confidence. On the other hand the athletes who recorded higher scores in Ego-Orientation didn't mention those factors and selected Situational Favorableness as a factor to enhance self-confidence. Thus athletes who recorded higher scores in Perceived Task-Climate in their teams selected mastery as a factor to create self-confidence and who recorded higher scores in Perceived Ego-Climate selected Situational Favorableness and Physical Self-Presentation as factors to enhance their self-confidence.

ATHLETES RETENTION OF COACH'S INSTRUCTION IN TYPICAL INSTRUCTIONAL CONTEXT IN SPORT SESSIONS

Rosado, A., Breia, E., Mesquita, I.

Faculty of Human Movement, Portugal

The aim of the present study was to analyze athletes' retention of coaches' instructional episodes (task presentation, feedback and session closing instructions). We observed 32 gymnastic training sessions and 200 instructional episodes. The independent variables were age, gender, school level and practice level. The dependant variables were the quantity of information on coach instructions and the nature of the information (according with several categorical systems of codification, one for each type of instructional episode), the information's reproduction by the athletes, both in a quantitative (extension, number of ideas, density) and qualitative (coherency) approach. The coaches instructions were audio and video recorded and immediately afterwards athletes were asked (by interview) to reproduce the coach's information. The information given by the coach and the athlete's answers were analyzed through quantitative and qualitative (content analysis) procedures, being the data compared and correlated.

Globally, athletes perceived coaches the instructions. The retention of the information was inversely related with the number of transmitted ideas and its extension. The type of the instructional episode does not affect the reproduction and the retention of the information.Results suggest that the retention of the information depends, generally, on its structure and not on the athletes personal characteristics. Some personal characteristics, however, were associated with retention in task presentation and instructional feedback.

COACHES' CONCEPTIONS AND VALUES ABOUT YOUTH SPORT COMPETITION. COMPARISON BETWEEN NOVICE INTERMEDIATE AND EXPERIENCED COACHES

Mesquita, I., Graça, A., Pereira, F., Marcelo, C.

Faculty of Sport, Portugal

The purpose of this study is to describe and compare the conceptions and values concerning competition in sport at ages of 10-12 and 14-16 sustained by Portuguese coaches by considering the type coaching experience (novice; intermediate and experienced).

A 43 items questionnaire in a 5-point likert-type scale was developed to disclose the coaches' appraisal about competitions at both of those ages. A sample ranging from 274 coaches from several sports filled the pair of questions at each item. Data underlying structure and psychometric properties of the questionnaire were sought by means of an exploratory factor analysis (principal components method) and a reliability analysis (Cronbach alpha).

Coaches' Professional experience is a discriminating factor for some elements of coaches' conceptions. More experienced coaches emphasise more the pedagogical value of competition, and its consequences for lifetime commitment. Experienced coaches of team sports reject more vehemently premature specialization at 10-12 ages, and stress higher the alignment of developmental and competitive objectives at 14-16 ages. Experienced coaches differ from novices by supporting the regulatory role of sport governing bodies over contents and processes of game play appropriate to 10-12 and 14-16 competitions.

DIFFERENTIATION OF THE RISK FACTORS IN AGREEMENT WITH THE LEVEL OF PHYSICAL ACTIVITY

Lima, W.A., Glaner, M.F.

Catholic University of Brasília, Brazil

Several risk factors are associated to the development of cardiovascular diseases as the excess of relative body fat (%F), the accumulated fat in the trunk (%F trunk), arterial hypertension, dyslipidemia, physical inactivity, among others (Grundy, 1998). However, the objective of this study was to verify the risk factors if they differentiate in agreement with the level of physical activity (LPA). The sample for this study was 80 male individuals. The LPA was estimated by the questionnaire of habitual physical activities, developed by Pate (1995), being the individuals classified in four categories: Group 1 (G1)= inactive, Group 2 (G2)= irregularly active, Group 3 (G3)= moderately active, Group 4 (G4)= very active. The other risk factors measured were: systolic blood pressure (SBP), diastolic blood pressure (DBP), abdomen perimeter (AP), enzymatic glucose (EG), total cholesterol (TC), high density lipoprotein (HDL), low density lipoprotein (LDL), triglycerides (TG), %F and %F trunk. These last two were estimated for the dual energy X-ray absorptiometry. The blood was taken after fasting for 12 h and the sanguine analysis was made by the enzymatic method. The groups, by LPA were compared through analysis of variance between groups and Scheffé's test ([a]p<=.05). The results obtained for G1, G2, G3 and G4 were: SBP= 133.0 +/- 12.7; 133.0 +/- 19.3; 130.9 +/- 18.2 and 128.5 +/- 19.6 mmHg; DBP = 90.0 +/- 10.5; 86.5 +/- 14.0; 83.3 +/- 14.0 and 84.1 +/- 17.1 mmHg; APa= 94.0a +/- 3.8; 89.3ab +/- 9.3; 87.9ab +/- 9.1 and 82.9b +/- 10.7 cm; %F= 25.6 +/- 3.7; 21.9 +/- 7.2; 19.7 +/- 7.8 and 17.8 +/- 9.2%; %F trunk= 29.7 +/- 4.9; 23.1 +/- 9.0; 22.5 +/- 9.4 and 19.9 +/- 10.6%; EG= 97.7 +/- 10.7; 93.6 +/- 15.7; 95.2 +/- 9.3 and 95.1 +/- 27.3 mg/dL; TC= 179.5 +/- 27.7; 159.8 +/- 39.0; 161.3 +/- 36.9 and 149.2 +/- 32.2 mg/dL; HDLa= 36.4 +/- 7.5; 41.5 +/- 11.7; 38.1 +/- 9.9 and 46.0 +/- 13.7 mg/dL; LDLa= 114.7 +/- 27.7; 92.5 +/- 35.4; 100.2 +/- 29.7 and 82.2 +/- 29.5 mg/dL; TG= 143 +/- 62.8; 134.1 +/- 59.6; 116.8 +/- 70.1 and 107.9 +/- 64.3 mg/dL, respectively. The individuals from the moderately and very active group apparently presented less expressive mean values for the factors of cardiovascular risk in all the variables, but, this difference was only shown significant for AP, HDL and LDL. However Scheffé's test evidenced differences between inactive and very active individuals in AP. In spite of limited questionnaires to estimate LPA, the obtained results are good indicators as how the physical activity can be beneficial to reduce and/or to control the risk factors for the cardiovascular diseases.

GENERAL DIRECTIONS OF DEVELOPMENT OF OLYMPIC EDUCATION SYSTEM IN UKRAINE

Bulatova, M., Platonov, V.

National University of Ukraine on Physical Education and Sport, Olympic Academy of Ukraine, Ukraine

Expansion of knowledge about the Olympic movement and Olympic sports has being done in Ukraine in two relatively independent (though to some extent interconnected) directions – general education and special education.

General education direction deals with the knowledge promotion on Olympic movement background (from Ancient Greece up now), about development of modern Olympic sports, Games of Olympiads and Winter Olympic Games, about main principles of Olympism including not only special sports aspects but humanistic, social, moral and ethic ones etc. This Olympic education direction in our country is intended for wide population segments, especially youth, and thus in first turn it is realized at school and collegiate levels though naturally is not limited by these spheres.

Special attention is paid here to the effective forms of implementation of Olympic education at school level. E.g.: The Olympic Academy of Ukraine issued and spread a series of 11 color posters devoted to main principles of Olympic movement, its history, ancient and modern Olympic Games, symbols and signs etc.; there were published hand books, table games for younger children, magazines. Annually the Olympic lesson is conducted at the primary schools with keeping of all the Olympic ceremonies and rituals.

Special education direction is an integral part of a created in Ukraine system of professional preparation for various branches of physical education and sport sphere – PE teachers, coaches in various sports, specialists in sport management, and recreation. Here Olympic education is implemented through various forms: at special profile teaching courses on university curriculum; by participation in scientific forums, congresses, conferences, symposia; by means of publication of more than 70 books, several journals and other various printed materials by the publishing house "Olympic Literature"; through research work of 5 Olympic Study Centers (dissertations), with help of propaganda work in cooperation with mass media - lectures, quizzes, meetings with famous athletes, and art and literature contests.

For practical realization in Ukraine each of two above mentioned directions provides creation of an appropriate system, elaboration of methodological, organizational, material-technical and other fundamentals without which the process of Olympic education in the country could hardly be efficient.

Taking into consideration all these factors in Ukraine there has been created and realized a considerable complex of various endeavors aimed to development of both – general education and special education – directions of the Olympic movement.

DO ALTERNATIVE INSTRUCTIONAL APPROACHES RESULT IN DIFFERENT GAME PERFORMANCE LEARNING OUTCOMES?

Tallir, I., Lenoir, M., Musch, E., Valcke, M.

Ghent University, Belgium

The primary goal of games teaching is enhancing pupil's game playing ability. This study examined the effectiveness of two instructional approaches for basketball on pupils' actual game performance. Two experimental classes were assigned at random to the traditional game teaching approach and two classes received the experimental treatment based on the Invasion Games Competence Model (IGCM) (Musch et al., 2002). The study lasted 17 weeks, during which the 10 – 11 year old pupils received twelve 50-min lessons of basketball instruction. Data for the authentic assessment of basketball game performance were collected by means of video-analysis of 3 on 3 and 3 on 1 game play conditions. An at random sample of 21 of 97 participants was analysed. The software "Catmovie" enabled coding of the game performance on screen. Next to the cognitive decision-making component and the motor skill execution efficiency component, the motor skill execution effectiveness component was also coded. RMANOVA were carried out to check whether the IGCM instructional approach will have a significant positive impact on pupils' decision-making ability, while for the motor skill execution components better results are expected for the traditional instructional group. Authentic assessment of the game performance indicated that the three components significantly ($p<.005$) improved in both groups over time between the pretest and the post-test, but the IGCM group improved more over time (average increase of 15%) compared to the traditional instructional group (average increase of 5%). However, stability of these results in long-term (post-test vs. retention test) showed different results for both groups. For the traditional group the three components improved (average increase of 9%) after the retention period, while the scores of the IGCM did not change on these components. Moreover, it was found that for both groups game performance scores were significantly higher in the 3 on 1 condition than in the 3 on 3 condition. Finally, it was investigated whether decision-making ability during game play and the cognitive learning outcomes on a video-based decision-making test (Tallir et al, 2005) were related. The lack of correlations between the results on the video-based decision-making test and the decision-making during game play showed that these decision-making tests are not interchangeable.

EVALUATION AND GRADING IN PHYSICAL EDUCATION AT SCHOOLS

Vass, M., Prisztóka, G., Papp, G., Telek, I.

University of Pécs, Hungary

Introduction

Evaluation by grading has had a tradition for several centuries in the Hungarian public education. According to Ratio Educationis published in the 18th century, the students should be evaluated twice a year – at the end of the first term and at the end of the school year – by one grade summarizing all the grades as an average. In the course of history the number of grades used for evaluation has changed several times. At present, the evaluation of students in school subjects including physical education, too, is performed by a five-grade scale.

However, the Act of Public education permits ways of evaluation different from the five-grade scale to be used. In the first three classes, evaluation of pupils is permitted to be done only by verbal characterization. This method may be used in upper classes as well. The schools operating on the basis of alternative curricula, e.g. Waldorf schools, emphasize the efficacy of verbal characterization versus evaluation by grading.

The contexts of evaluation

First of all, evaluation can be associated with the notion of achievement. In the developed countries, achievement has become the focus of education policy. The results of great international comparative studies, e.g. PISA study, qualify the efficacy of the system of education through the achievement of the students in their studies.

The components such as success, efficacy and quality of achievement are closely associated with the mutual recognition of the degrees in the European Union.

"Equity" as one of the significant characteristic features of a system of education does not exclude the category of quality. Just on the contrary, the students of those countries are capable of achieving the best results, in which equal opportunity and equity for all are taken care of.

Study of the evaluation and its results

- Place of study: Hungary (10 counties)
- Date of study: April and May, 2005
- Participants: 1,479 fifth and eighth class pupils of 10-14

Method of study: questionnaire with open and closed questions,
simple mathematical and statistical analyses

Aim of study: * the students' stance on physical education
* evaluation of physical education as seen by the students

Results

- More than 90% of the students regard physical activities as significant. About the same number of students are fond of physical education.
- About the same number of students either regards grading important or is indifferent, whereas 25 % of the students regard grading as "not important".
- In their opinion, compared to other subjects, it is not difficult to get grades at physical education.
- Only 15% of the students would like to be evaluated by written characterization instead of grades.

PHYSICAL EDUCATION LESSONS. THE STUDENTS' VIEWS OF BASIC SCHOOL

Pereira, A.

Polytechnic Institute of Viseu - Higher Education School, Portugal

Physical Education is an essential element and an integral part of the process of continuing education and human and social development (Bowyer, 1996). The development of effective strategies to secure and further develop Physical Education is an essential component of education (Stelzer et al., 2004).

The schools should mobilise good practices in Physical Education, improve a good curriculum (aims, themes, content, evaluation and monitoring), resources (facilities, equipment and teaching personnel) and should be responsive to physically educated students (learning outcomes) according to new lifestyles and social needs (Tannehill & Zakrajsek, 1993; Treasure, 2001)

The aim of this study was to know students' perceptions of Physical Education lessons in the schools and if the perceptions are congruent with students' expectations.

We applied structured interviews to 9th-year students of both sexes (n=50) from some Portuguese schools. In order to inspect the material we applied content analysis technique (Strauss & Corbin, 1998).

The majority of the students (93.3%) like to have Physical Education lessons because they can practise some sports and engage with their colleagues. They like practising collective sports but don't like gymnastics and athletics. The most important aspects in the Physical Education lessons are to have "a good teacher" and "a good relationship between teacher and students". In their opinion, the best lessons happen when there is "a good relationship between all the students" and "all the students are involved in the activities proposed by the teacher". They would like to have "sports alternatives": water sports, climbing, mountain biking judo and aerobics. They would choose up-dated activities/sports, which they know outside school.

Perhaps a new curriculum is needed to agree to students' views and interests and should place them in a position to make choices about their engagement in Physical Education lessons.

SCHOOLS AND FREE-TIME ACTIVITIES. THE STUDENTS' VIEWS OF BASIC SCHOOL

Pereira, A.

Polytechnic Institute of Viseu - Higher Education School, Portugal

A growing number of students are becoming involved in antisocial behaviour, which has negative consequences that include teacher and peer rejection, school failure and dropout, delinquency and involvement with drugs and alcohol (Gilman & Meyers; Perez, 2004; Fletcher & Nickerson; Wright, 2003).

Preventive strategies are needed to help overcome these problems. Free-time activities represent one such strategy that potentially can help those students to develop a pro-social behaviour, engage with school and improve their academic performance (Larson, 2000; Mahoney, 2000).

The aim of this study was to know students' perceptions of free-time activities in the schools and if the perceptions are congruent with students' expectations.

We applied structured interviews to 9th-year students of both sexes (n=70) from some Portuguese schools. In order to inspect the material we applied content analysis technique (Miles & Huberman, 1994).

For 62% of the students there should be changes in the future. The schools offered free-time activities, but some changes are necessary. The most practised activities at schools were being with their friends and playing sports. They would like to have "more activities options" and "sports alternatives": water sports, climbing, mountain biking, judo and aerobics. The majority of the students of this study would like a change in the free-time activities offered by the schools: they perceive it too "repetitive" and "boring". They would choose up-dated activities, which they know and practise outside school.

Perhaps in some Portuguese schools, new free-time activities are needed. These schools must organize free-times activities which are preferred by the students, improve healthy life styles and develop their education and cultural and civic training.

GENETIC TEACHING OF GAMES - FOR MORE UNDERSTANDING

Loibl, J.

Technical University Munich, Germany

Since the late 1960's, the theory of teaching games has changed from technique orientation to game orientation, taught in Germany under the concept of "Methodische Spielreihen", in England and the USA as the "Teaching Games For Understanding" approach.

The basic reason for this change is a difference in the "didactic reduction" or "elementarization" of a game, which in the one case leads to the skills of a game as the elements which have to be taught out of the context of the game situation before the game can be tackled. In the other case, it leads to an elementary form of the whole game, which can be played solving moderately simplified, but still complex game situations with simplified skills.

In this game oriented approach, there are two points on which attention needs to be focused.

Firstly: Playing this simplified form of the game will at some time or other lead to a demand for improving the skills. Here it is important to prevent a reversion to the traditional teaching of skills as ideal techniques copied from top athletes, and to ensure their being taught as functional solutions of specific game situations, bearing in mind the players' physical condition. Thus, a two-handed shot in basketball can be the optimal skill for a player with small hands and little strength although it is not the technique used by top athletes.

Secondly: There is more to playing a game than just playing the game. Dietrich (1984) has pointed this out introducing a so called "general playing ability", meaning the ability to develop a game, to get and keep a game going when difficulties arise.

Both in the "Spielreihen" and the "Teaching Games For Understanding" approaches, this ability is not taken into consideration, actually the development of this ability is even prevented, or at least hampered. The reason for this is that the central activities - finding the simplified elementary form of the game and introducing alterations when problems arise - are in the hands of the teacher. Whereas, the didactic reduction must in fact be carried out by the students, in order to give them the chance to develop the desired abilities through solving these problems with help from the teacher. Questions like "May we alter the rules of the game?" will lead to understanding the functionality of the rules, which are used as "adjusting screws" to obtain optimum excitement and the typical dynamical action structure of a specific game. Discussing possible solutions leads to the development of social competences like, e.g. autonomy, critical faculty and ability to work in a team.

Both problems are included in the concept of "Genetic Teaching", as called for by Dietrich (1984) and put into effect in the game of basketball by Loibl (2001).

FIRST GRADE SECONDARY SCHOOL STUDENTS' ATTITUDES TOWARDS PHYSICAL CULTURE OBSERVED IN THE YEARS 1995 - 2001

Rokita, A.

University School of Physical Education Wrocaw, Poland, Poland

Introduction

By diagnosing the first grade secondary school students' attitudes towards physical culture as observed in the years 1995-2001, the author wishes to determine their changes. It was hypothetically assumed that the attitudes towards physical culture of boys and girls shall statistically and significantly differ and that the changes of attitudes in the subsequent years shall not differ statistically and significantly.

Material and methods

In our examinations, we have employed the method of a diagnostic survey (Supińska 1995). The research was conducted seven times (in first grades) in the subsequent years (1995-2001). We have diagnosed the attitudes of 1693 students (906 girls and 787 boys) of VII Secondary School in Wrocław. The average age of the examined students was 15 years and two months.

Results

By using the Pearson chi-square test and chi-square test of the highest variability, on the level of significance α=0.05, we verified the hypothesis of the independence of sex and the answers to the statements with regard to cognitive, motional and behavioural components. It turned out that the above hypothesis must be rejected in the range of all the three components. In the group of boys the index of the cognitive component reached a neutral value in the subsequent years (min. 3,59 in 1998, max. 3,64 in 2000), and in the group of girls a positive value (min. 3,74 in 1995, max. 3,78 in 1997). It was the contrary in the case of the emotional component. In the group of boys the index reached a positive value (min. 3, 83 in 1997, max. 3,88 in 2000), and the group of girls negative (min. 3,34 in 1997, max. 3,63 in 2001). The indexes of the behavioural component for both of the groups in all the seven years reached a neutral value (boys min. 3,60 in 1997, max. 3,65 in 2001, girls: min. 3,56 in 1995, max. 3,62 in 1997).

By using the Pearson chi-square test and chi-square test of the highest variability, on the level of significance α=0.05, we verified the hypothesis of the independence of the year of the examination and answers to the questions with regard to cognitive, emotional and behavioural components both for the group of girls and boys. It turned out that we cannot reject this hypothesis for all of the three components.

Conclusion

After conducting the analysis of the results of the examinations it turned out that, taking into account the index of the general result, the attitudes towards physical culture of boys of the first grade secondary school in the years 1995, 1996 and 1999-2001 are positive, whereas they are neutral in the years 1997, 1998. The attitudes towards physical culture of girls of the first grade secondary school in the years 1995–2001 are neutral.

PERFORMANCE EVALUATION OF SELECTED IRANIAN COLLEGIATE SPORT ASSOCIATIONS

Salehi Sadati, S.S., Moradichaleshtori, M., Jafari, A.

Islamic Azad University Tehran Markazi Branch, Iran

The purpose of this study was to evaluate the performance of some selected Iranian collegiate sport associations, in terms of their effectiveness, from Viewpoints of stakeholder groups of these associations, including student-athletes as well as coaches of universities in Tehran, members of the selected associations, and experts of these selected sport types(i.e. Badminton, Football, Basketball, Wrestling, Handball, and Volleyball). A total of 546 respondents(270 student- athletes, 120 coaches,120 experts, and 36 members of associations) responded to two respective questionnaires developed for this study(one for students and another designed for other three groups). The collected data were analyzed by some statistical methods such as One-sample T-test, ANOVA, and Dunnett C as the following test of ANOVA . In Addition, for determining the consistency of questionnaires and normal distribution of collected data, Cronbach's alpha and Kolmogorov-Smirnov were used respectively. Results showed that student-athletes, coaches , and experts evaluated the performance of selected associations as weak(Means<3, p<0/05), as such did the members of wrestling association(Mean=2/78). Members of other associations, however, didn't evaluate it as weak (Means>3). There was also a significant difference between Viewpoints of members of associations and those of other groups in each sport type(p<0/05). Among the questions of 2nd part of all questionnaires, only items of 5 , 6, and 14 obtained acceptable means(Means>3), while they all are subscales of a total performance indicator(i.e. organizing intercollegiate games). Results indicate that from Viewpoints of all stakeholder groups, despite the sig. difference between members and other groups, performance of studied associations was not favorite.

ARGUMENTS IN FAVOUR OF DIFFERENTIATED EDUCATION DURING THE PHYSICAL EDUCATION LESSON

Mihailescu, L., Gada, T., Gada, M., Folea, E., Dia, A.

University of Pitesti, Romania

INTRODUCTION

Physical education is a complex formative and educational process which consists of integrating the movement functions with personality; in school, this process must have as datum points the individual characteristics of every student. Romania is among the first countries in the world that made efforts in this direction since 1933, with the help of GH. ZAPAN and P. LAZAR.

Our research has as objective the following work hypothesis: we have considered that differentiated education of students during the physical education lesson is an objective necessity in the actual educational context, because it determines the achievement of movement abilities development objectives and the improvement of students' health through the increase of individual effort capacities and of after effort recovery abilities.

METHODS

The purpose of our paper is the research of differentiated education effects on students according to the above stated hypothesis. To this sense, we have organized an educational experiment during the 2003/2004 school year in four education units in Pitesti, Romania: three secondary schools (V-VIII years) and a national college (IX-XII years).

The experiment sample has the following structure: the primary level 480 students: 270 girls and 210 boys, the high-school level: 360 students: 212 girls and 148 boys.

During the research we have used the following physiological and movement testing: Harward test, Ruffier test, Dorgo test, and J.C.R. test; we have also determined the "z" index with mathematical significance for the differences in the comparisons we have made during our research.

CONCLUSIONS/ DISCUSSIONS

The results of the experiments confirm the research hypothesis and offer valid arguments in the sense of forwarding the differentiated education as the principal education method in school physical education.

- Differentiated groups education according to the differentiated objectives of lessons makes sure that every student goes through all the lesson themes in comparison with the frontal, direct education.
- Differentiated itineraries used in the physical education lesson respect the bio, psycho and movement characteristics of students generating motivation, active and aware participation, and satisfaction among the students.

COMPARISON OF MIDDLE SCHOOL STUDENTS' ATTITUDES TOWARD PHYSICAL EDUCATION WITH REGARD TO GRADE, STUDENT'S GENDER, TEACHER'S GENDER AND SPORT PARTICIPATION

Hunuk, D., Demrhan, G.

Hacettepe University Health Science Institution, Turkey

The purpose of this study was to compare attitudes of Middle school students toward physical education with regard to grade, student's gender, teacher's gender and sport participation. Totally 1260 students, who are selected according to random sample method from 22 middle schools;180 girls and 199 boys from the sixth grade, 246 girls and 155 boys from the seventh grade, 212 girls and 268 boys from the eighth grade, were voluntarilly participated to this study. To assess participants' attitudes toward physical education "The Attitude Toward Physical Education Scale For Children", that was developed by Sherrill and Toulmin (1977), and adapted by Özer and Aktop (2003) to Turkish, was administered. The Cronbach coefficient alpha reliability was found as .86 and the intraclass correlation coefficient was found as .83. The difference between attitude points of students was calculated by the Two way ANOVA analysis and result of analyseses showed that: for average attitude points of 6., 7.and 8. grade elementary school students participated to the study, there is a statistically significant difference among students of different grades. And a significant difference between girls and boys, with the boys scoring higher. Also when the results of this study was examined by sport participation, a significant difference between sport participants and nonsport participants ($p<0.05$). Additionally a significant difference between grade and sport participant or nonsport participant was observed. ($p<0.05$) Lastly a difference between grade x student's gender x teacher's gender ($p<0.05$) was calculated. Consequently, by the increase of the students' grade, the average of students' attitude scores decreases; meanwhile the boys' and sport participants' attitude scores are higher. In the view of this results, it can be concluded that grade, gender and sport participation may effect the attitudes related with physical education.

EXPECTED ACHIEVEMENT IN "GENERIC SKILLS" THROUGH PHYSICAL ACTIVITY PARTICIPATION OF HONG KONG PRIMARY SCHOOL STUDENTS

Sum, K.W., Hui, S.C.

Chinese University of Hong Kong, Hong Kong

The purpose of this study was to investigate the expected achievement in "generic skills" through physical activity participation of Hong Kong primary school students. A 50 items of generic skill development questionnaire was developed by the research team.

Results

The overall findings were the following:

1.Collaborating

Nearly half (47.9%) of the junior students had different assigned roles during their physical activity classes. Such experience increased to 63.1% upon progress to senior forms.

2.Communication

The junior students reported no problem at all communicating with their instructors/teachers (93.6%). The majority (75.9%) of them knew how to express their problems to their teachers.

3.Creativity

Close to 60% of the junior students had an experience in creating their own movements, while there is a decrease to 40% in such experience in senior forms. Only 47.9% of the junior students had an experience in designing activities outside their P.E. classes. This also decreased to 32.3% in senior forms.

4.Critical Thinking

About 70% of the students were able to analyze the reasons for winning or losing in games, and were able to provide suggestions for improvement. Meanwhile, close to 45% of the senior students criticized the truthfulness of physical activity information.

5.Information Technology

Less than half of the students (40.4% of juniors; 45.2% of seniors) were able to use the internet to obtain physical activity information; 25.1% of junior students communicated with others using I.T on matters related to physical activities, while only 14.7% of senior students had ever tried to use I.T. to complete sports-related assignments.

6.Numeracy

More than half (54.7%) of the junior students had the experience in handling numbers during physical activity participation. More than 10% of them found it difficult to differentiate sports-related symbols and court lines.

7.Problem Solving

Close to 70% of all students reported no difficulty in identifying the reasons for winning or losing a game, or in analyzing their performance.

8.Self-Management

Most junior students (71.8%) knew which kind of sports they were good at, while 55.5% knew their weaknesses. Close to 80% of all students were willing to take up their responsibilities.

9.Study

More than half (55.9%) of the junior students read materials related to physical activities, and 46.6% of the senior students had an experience in collecting information from materials related to physical activities.

Conclusions and Discussions

The Physical Education KLA provides a context for the development and application of generic skills. The findings revealed that there are plenty of rooms to improve the collaboration, creativity, and critical thinking skills of students, and that there is likewise a need to promote the information technology, numeracy, problem-solving, and study skills of Hong Kong primary school students through enhanced participation in physical activities.

TECHNOLOGY OF TEACHING SPORTS TECHNIQUE OF GYMNASTICS EXERCISES

Niznikowski, T., Sadowski, J., Booban, W., Mastalerz, A., Niznikowska, E.

Józef Pisudski Academy of Physical Education in Warsaw, Poland

The process of teaching coordinationally complex exercises along with a constantly rising level, quality and stability is getting more and more difficult. There appears a necessity to apply new techniques to a deeper analysis of the structure of sports exercises in order to identify the most significant elements of a particular movement. Information concerning the most characteristic and the most significant, from the point of view of teaching the movement, stages of a physical movement is necessary to prepare effective training programmes. Identifying such stages, described in literature as junction elements of sports technique, should be an initial step to prepare pedagogical training technologies.

Therefore, the aim of the paper was to study an effective pedagogical training technology of the process of teaching acrobatic exercises.

Pedagogical experiment, 60 Hz (JVC GR-DVL 9800 NTSC) camera and APAS 2000. Cinematographic analysis systems were used to analyse the round-off tucked back somersault (n=30).

On the basis of the research it was concluded that pedagogical teaching technology includes three components: the first one – a deep biomechanical analysis of phase structure of movement, the second one – didactic teaching structure, and the third one – contemporary teaching technology including algorithms as well as programmes of teaching acrobatic exercises.

ETHNIC PEDAGOGICAL CONDITIONS OF USE OF GAMES AND COMPETITIONS OF TRADITIONAL PHYSICAL EDUCATION OF NATIVE SMALL PEOPLES OF NORTH (ON EXAMPLE OF KHANTS)

Krasilnikov, V.

Russian state professional-pedagogical university (s. Yekaterinburg is), Russia

The article was prepared on the basis of the materials received in ten expeditions (1990-1993) in places of residing of one of ancient peoples of Siberia - Khants, and on the study of the literary and the archival materials also.

More than a hundred national games, competitions and original physical exercises which were classified in view of age features, the trade activity, traditional way of life were revealed by the author as the result of those field researches.

The national pedagogics of Khants has developed means and in parallel with it has generated the system conditions for an effective use of national games with the view of education of children. The use of national games, competitions in specially created ethnic pedagogical conditions will allow to enrich considerably the spiritual life not only of Khants, but also other peoples of the North and the whole Russia.

Poster presentation (PP)

PP3-08 Nutrition 1/1 - "Exhibition Hall"

EFFECT OF TOWER CLIMBING EXERCISE & ALPHA LIPOIC ACID ADMINISTRATION

Sanghyun, K., Kijin, K., Hongsoo, K., Yoonjung, S.

Keimyung University, Korea, Korea, South

The purpose of this study is to examine the effect of climbing exercise and alpha lipoic acid(ALA) administration on bone metabolism in ovariectomized female Sprague-Dawley rats, and for this study, climbing exercise was executed in the self-made vertical tower cage, and regular amount of ALA was administrated into the abdominal cavity of rat for 8 weeks. Followings are the results of analysis about weight, bone mineral density, bone mineral content, bone strength, and blood variables.

First, spayed group generally presented higher weight than the other group, and the SS group presented significantly lower weight than OA group from 6 weeks after administration, and OC group from 7 weeks after administration.

Second, in case of bone mineral density and bone mineral volume, OEA group showed significantly higher gross bone mineral density than SS group and OC group, and there was no significant differences between all groups in case of leg bone mineral density.

Third, as a result of measurement, the length, weight, bone density, and bone strength of all groups showed no statistically significant difference.
Fourth, there were no statistically significant differences between groups in case of blood osteocalcin, E2, PTH, and LH. so it is considered that more researches are needed to get significant results of other factors except weight, gross bone mineral density and leg bone mineral density.

EFFECTS OF CARNOSINE AND ANSERINE SUPPLEMENTATION ON EXERCISE PERFORMANCE AND INTRACELLULAR PH DYNAMICS DURING ISOMETRIC KNEE EXTENSION EXERCISE

Maemura, H., Suzuki, Y., Takahashi, H., Takahata, Y., Morimatsu, F., Takamatsu, K.

Nippon Meat Packers, Inc., Japan

PURPOSE: The purpose of this study was to investigate the effects of long-term chicken breast extract (CBEX) supplementation which was a rich source of carnosine and anserine on exercise performance and intracellular pH dynamics during isometric knee extension exercise. METHODS: Twelve healthy male subjects were divided into CBEX group (n = 6) and placebo group (n = 6). The CBEX group was orally administered 200 ml CBEX drink which contained 4g of carnosine and anserine per day for 30 days. The placebo group was orally administered 200 ml the same taste CBEX drink which contained no caronosine and anserine. Before and after the ingested period, the subjects performed isometric knee extension exercise (load: 40% maximal voluntary contraction) until the exhaustion to measure endurance time and intracellular pH using phosphorus magnetic resonance spectroscopy (31P-MRS). RESULTS: The endurance time was significantly increased after supplementation in the CBEX group (pre: 165 ± 14.7s, post: 193.3 ± 10.8s, P < 0.01). Subjects in the CBEX group who increased endurance time were inhibited degradation of intracellular pH during isometric knee extension exercise. Furthermore, a significant correlation was demonstrated between changes in endurance time and changes in degradation of intracellular pH (r = 0.852, P < 0.01). CONCLUSION: These results suggest that the long-term ingestion of carnosine and anserine can improve exercise performance resulting from inhibiting the degradation of intracellular pH.

EFFECT OF BIOLOGICALLY ACTIVE ADDITIVE "PALI - PALI" ON THE FUNCTIONAL STATUS OF ATHLETS AT PHYSICAL LOAD

Sukhov, S., Kulnazarov, A., Ivanov, A.

National Research and Practical Center of Physical Culture, Almaty, Kazakhstan , Kazakhstan

Introduction
A biologically active additive ((BAA) "Pali - Pali" replenishes the deficiency of micronutrients and essential substrates, improves tissue metabolism and exerts antihypoxia action. It consists of: succinic acid, fumaric acid, taurine, glicine, L-arginine, L-carnitine, extract of Schizandra chinensis Baill, vitamins В1, В2, В6. The goal of the study is to study the effect of BAA on the functional status and physical performance of athletes in physical load.
Methods
To register electric - physiological characteristics of biologically active points (BAPs), there was used the Electric-Puncture Diagnostic System (EDS) developed as a set of hard- and software. EDS allows measuring in several algorhythms. The study findings were expressed in conventional units (c.u). There were taken measures at 40 control (c) BAPs of all arm and leg meridians on both sides of the body. Along with measuring individual BAPs, there were determined the indicators proposed by us: sum of all cBAPs, sum of arm meridians cBAPs, sum of leg meridians cBAPs, sum of heart and lung meridians' cBAPs, sum of cBAPs of meridians of nervous and endocrine systems, an upper/lower factor which reflects the balance between the upper and lower parts of the body. Along with electric puncture diagnostics, there was conducted a complex testing. 10 mountaineers were tested twice with interval of one day. Examination was conducted in the rest and after a maximum aerobic load. At the second examination two pills of BAA were offered to the athletes 90 minutes before the physical load.
Results
It was found that the physical load resulted in some elevation of sums of cBAPs of all meridians, sum of cBAPs meridians of arms, sum of cBAPs of heart and lung meridians, sum of cBAPs of meridians of nervous and endocrine systems and the upper/lower factor, in comparison with resting state. Intake of 2 pills of BAA had a considerable effect on the results of electric-puncture diagnostics. The abovementioned indicators have significantly increased in comparison with the rest and to a higher extent than at the first examination. In particular, the sum of cBAPs of heart and lung meridians rose from 352.8±6.1 to 373±4.1 c.u. (P<0.05). The upper/lower factor has increased from 0.94±0.01 to 0.97±0.009 (P<0.05) demonstrating the better balance between the arm and leg meridians and good adaptation to physical load. At single intake of BAA the total volume of performed work and volume of work performed in the regimen of maximum oxygen consumption did not change. It seems that only prolonged administration of BAA might affect this indicator.
Conclusion
One can conclude that BAA "Pali-Pali", according to the findings of electric-puncture diagnosis, has a positive effect on the functional status of athletes. First of all, this is confirmed by the growth of the indicator "a sum of cBAPs of heart and lung meridians" which speaks about oxygen-transporting function.

EVALUATION OF RISKS IN CONSUMPTION BEHAVIOUR IN SPORT SCIENCES STUDENTS

Coquart, J., Mille-Hamard, L., Dehaut, F., Duhame, A., Garcin, M.

Laboratoire d'Etudes de la Motricité Humaine, EA 3608, France

INTRODUCTION
This paper presents the results of a study carried out in the framework of the Regional Health Programme concerning Risks in Consumption Behaviour (CCAR 2002-569). The goal was to evaluate consumption and the associated risk factors among athletes in the university environment.
SUBJECTS
A questionnaire was filled in by 984 students (67.18% men and 32.82% women) enroled at the Sports Sciences Faculty (from the 1st to the 4th year).
STATISTICS

Results were expressed as frequencies and percentages for categorical variables and as the mean + - SD (standard deviation) for continuous data. Comparative analyses were done using the chi-square.

RESULTS

The questions concerned the students' knowledge regarding the classification of different substances, whether they are legal or illegal, their effect on sporting performance, and their consumption habits. The substances presented were nutritional ergogenes, legal and illegal drugs, and different medicine likely to be consumed by a young and or a sporting population.

The students who have at least 70% of correct answers relative to knowledge are mainly men, enroled in the third year of studies or higher, and therefore more than 20 years old (P<0.05).

The substances most consumed with the unique aim of enhancing performance, with a frequence greater than or equal to 3 times in the last 3 months are cola-based drinks (24.7%), tea or coffee (22.6%), and vitamins (17.2%). The consumers of cola-based drinks are mainly men, students in years 1 and 2 at university (P<0.02).

Concerning alcohol consumption (in terms of frequency and quantity consumed on a particular occasion), or tabacco or cannabis, 36.8% consume at least 4 glasses or more of alcohol on a particular occasion, 13.3% and 11.2%, respectively, consume cannabis or alcohol at least 3-4 times per week, and 7.9% smoke more than 10 cigarettes per day. Harmful users of alcohol (frequence and quantity) and cannabis tend to be men (P<0.0001). There is no effect of age among these harmful users (P>0.05) except for consumers of alcohol in terms of frequency.

DISCUSSION

Students must be made more aware of the knowledge concerning substances and their effects and of the relevance of the consumption of nutritional ergogenes, as of the first year in university. These sport sciences students are mainly involved in heavy bouts of drinking but infrequently, corresponding to after-match parties. It would seen that the priority of a health policy must be the consumption of alcohol among this population of university athletes.

ACKNOWLEDGEMENTS

This study received financing from the regional authorities « Nord-Pas de Calais ».

COMPARISON OF ANTHROPOMETRIC AND DIETETIC EVALUATION BETWEEN THE MOST EXPERIENCED PLAYERS AND THE NEW PLAYERS OF CAPOEIRA

Soares, E.A., Costa, L.

Institute of Nutrition - Federal University of Rio de Janeiro and State University of Rio de Janeiro, Brazil

Capoeira, an African-Brazilian fight, was originally developed by slaves. It puts together martial art, dance, folcklore, acrobatics, and game. It is practiced in 156 countries and its tradition is preserved until nowadays. There are not many researches about the physical conditions of the capoeira players, so the proposal of this study was to compare the body composition, somatotype and dietary assessment between the most experienced players and the new players of capoeira. The anthropometric and dietetic assessments were applied to two groups of men between 18 and 30 years old. The first group held 30 experienced capoeira players (with more than 4 years of practice) and the second group of college students (n=30), new players from Federal University of Rio de Janeiro, Brazil. The anthropometric parameters examined were: height, body weight, skinfolds, circumferences and breadths (1) (2). The dietetic parameters examined were consumption of energy, macronutrients and micronutrients (24 hours dietary recall and 3 days food diary methods). The nutrients consumption was compared to the american recommendations (3) (4). The most experienced players of capoeira showed smaller fat percentage (8,55 ± 2,9% vs. 13,92 ± 2,7%) and sum of seven skinfolds (64,51mm ± 16,9 vs. 104,86mm ± 20,3) with significant differences (p<0,05) and showed balanced mesomorphy. They presented inadequate food habits with high-protein (1,8 ± 1,0g/Kg/day), low-carbohydrate (5,3 ± 2,5g/Kg/day) and unbalanced-lipid diets (34,2 ± 7,0% of the total energy intake), however adequate micronutrients levels were found. The new players showed a balanced-lipid diet (28,3±7,3% of the total energy intake) with signifficant differences (p<0,05) to the experienced players, high-protein (1,6 ± 0,6g/Kg/day) and low-carbohydrate diets (5,0 ± 1,8g/Kg/day), their diets tended to be low in vitamin C and calcium and they showed balanced endomorph. In conclusion the capoeira probably have positive effects on body composition and can be introduced like a physical activity to improve health. There is a need for the professional who gives nutritional orientations to both groups and also more researches about capoeira, effort intensity and nutritional status of the players could be done.

MONITORING OF NUTRITIONAL STATUS OF OBESE WOMEN SUBMITTED TO THE DIET AND PHYSICAL ACTIVITY INTERVENTIONS

Soares, E.A., Reis, V.C., Barbosa, R.M.

Institute of Nutrition - Federal University of Rio de Janeiro - State University of Rio de Janeiro, Brazil

Obesity is an important risk factor for the main causes of morbi-mortality and incapacitation in Brazil1. It is showing a progressive increase of its prevalence2. Many studies point out to a perceivable improvement in the nutritional status of obeses submitted to the diet intervention, being more notable when it is coming associated with the regular physical activity3. The objective of this study was to monitor the nutritional status of 16 sedentary obese women, aged 37 to 65 years and with Body Mass Index (BMI) from 30 to 45 kg/m2, submitted to the diet and physical activity interventions concomitantly, during the period of 20 weeks. The data at the initial moment of the research was collected by a convinience sample. It was realized the anthropometric assessment using measurements about body mass, height, triciptal skinfold thickness and waist, hip and arm circunferences. The BMI, the waist to hip ratio and the arm muscular área were evaluated. The biochemical assessment was obtained by the serum lipids profile, fasting glycemia, insulin and free fatty acids levels in the blood and the dietetic assessment was realized through the food history of each participant for comparison with the Brazilian Food Guide Pyramid4. The "t" Student test was used to verify statistical significance over two moments considering the significance level 5%. It

could be observed that the obese women showed modest reduction of body weight and not significant improvements in the others anthropometric parameters. There was a trend of improvement in the serum lipids profile, despite the results not had been significant. As the dietary assessment, there was an increased habitual ingestion of legumes, meats, fats and sugars, and reduced of vegetables, fruits and dairy foods consumption at the initial moment, and after the intervention, an increase in the consumption of fruits and vegetables, beyond a reduction in the consumption of total fat, with significant differences (p<0,05). In conclusion, the program and the nutritional education proposal resulted in effective improvements in the obeses food habits.

THE EFFECT OF SKIPPING A BREAKFAST ON BLOOD GLUCOSE LEVELS AND PERFORMANCE OF SWIMMERS

Soultanakis, H., Giatsiou, V., Afendra, E., Platanou, T.

Faculty of Physical Education and Sport Sciences, University of Athens, Greece, Greece

Fasting of different durations prior to exercise affects performance (Dohm et al., 1986; Zinker et al., 1990). So far, no studies have focused on the effect of an overnight fast on swimming performance. The purpose of this study was to determine the extend to which a 12-hour overnight fast can affect endurance, as determined by best swimming performance time of a 2000 meter swim trial, with (+Br) or without breakfast (-Br). Eight healthy male swimmers with a mean age of 21.4±1.9 years participated in this study. Under the +Br condition, all swimmers consumed the same breakfast, containing 690 calories, 110 gr of carbohydrate and 21.8 gr of protein. One day prior to both performance tests, all swimmers consumed balanced daily meals containing a total of 3045 calories (429 gr carbohydrate, 143 gr protein, 84.4 gr fat) under both conditions. Prior and post swimming, blood glucose, blood lactate and heart rates were monitored with or without the consumption of breakfast. Breakfast of the +Br trial, was consumed 120 minutes prior to swimming and a cross-randomized design was followed in terms of whether the swimmers performed the fed or the fasted trial first. Blood glucose, blood lactate and heart rates, didn't demonstrate any significant changes under the two different conditions and blood glucose never dropped to hypoglycemic levels at any condition prior or post the swim trials. Resting blood glucose level of the +Br trial was 94.75±11.8 mg/dl, while resting blood glucose level of the –Br trial was 86.5±6.2 mg/dl. Differences in performance time were observed by using a paired-t test with dependent measures. Mean performance time of the +Br trial was 26:05.28±2:53.23 min/sec, and significantly lower than the –Br trial which was 26:53.28±3:14.19 min/sec after an overnight fast (p≤0.01). The difference between the two 2000 meter trials was of a magnitude of 48 seconds. The maintenance of glucose homeostasis under short or even longer periods of fasting has been repeatedly demonstrated and is probably a result of increased gluconeogenesis and decreased utilisation of glucose in the muscle. However, this is not without a cost since the shift of metabolism caused by even an overnight 12-hour fast leads to decrements of swimming performance as also evidenced in our study.

EVALUATION OF ENERGY BALANCE AND NUTRITIONAL STATUS OF ARTISTIC GYMNASTS

Azevedo, B.A., Melo, C.M., Miyamoto, M.V., Ribeiro, S.M.

São Judas Tadeu University, Brazil

BACKGROUND: The intense training and inadequate food habits can cause deleterious effect in the nutritional status and consequently in the health of artistic gymnasts. OBJECTIVES: to evaluate some aspects of the nutritional status and the energy balance in girls practicing artistic gymnastic. CASUISTIC: 14 artistic gymnasts, between 9 and 14 years old, pre-menarche, from a Olympic Training Center of São Paulo- SP- Brazil. EVALUATED PARAMETERS: energy ingestion by 3 food diary, calculated from the NUTRI/UNIFESP software; body composition from bioelectric impedance (Biodinamics 450E®); weight, stature and BMI (body mass index), classified according WHO; resting energy expenditure from indirect calorimetry (VO2000, Imbrasport®), and from the Weir equation. The resting energy expenditure was transformed into daily energy expenditure multiplying the rest value by 1,82 (very intense activity level, WHO). RESULTS: from the stature/age index, 21.4% of the girls was below 3th percentile and 14.3% between the percentiles 3rd and 10th. From BMI/age index, the majority of girls (85,71%) was classified into the normality, but close to lower limit, and 14.29% was below of 3rd percentile. The average percentage of body fat was 11,64±3,16. The energetic balance, considering difference between the energy ingestion and energy expenditure, was negative for all of them, with average value of -758,21± 292,18KCal. The girls related story of muscular fatigue, pains and intense sleep frequently. No sexual characteristics that would demonstrate the beginning of the puberty (including girls next to 14 years old), have been observed. COMMENTARIES and CONCLUSIONS: The observed inadequacy of energy ingestion seems to be reflected in the sexual maturation and anthropometric parameters. Chronically, the negative energy balance would cause bone alterations (by retardation in the menarche), immune deficiencies, and others health problems. It is advised the urgent necessity of clarification to the professionals and persons involved with these athletes.

EFFECTS OF NEGATIVE ENERGY BALANCE FROM INTENSE TRAINING AND FOOD RESTRICTION ON BODY COMPOSITION PARAMETERS AND LEPTIN LEVEL IN FEMALE RATS

Silva, R.J., Santos, Z.A., Gonçalves, P.M., Ribeiro, S.M.

São Judas Tadeu University, Brazil

Background: the negative energy balance could cause body composition alterations that would be harmful to reproductive and locomotor systems. Objective: to evaluate the effect of negative energy balance from intense training and food restriction on body composition of

rats. Methods: wistar female rats, two months old, had been divided in 4 groups in accordance with the physical training and food restriction: RT (trained with food restriction), FT (trained and ad libitum fed), RS. (sedentary with food restriction), FS (sedentary and ad libitum fed). The physical training was carried out through a treadmill, two times/day with one hour sessions, during 8 weeks. 50% food restriction was applied on the ingestion of the fed group. The diet of fed groups was in accordance with AIN-93. Parameters evaluated: body weight variation (BWV), weight of brown adipose tissue (BAT), weight of perirenal adipose tissue (PAT), chemical analysis of the body composition and blood leptin level. Data analysis: ANOVA and Tuckey pos-hoc test have been used. Results: food restriction seems to have exerted higher influence than training in the reduction of the body weight, on the subcutaneous and visceral fat, and on the leptin levels. The values for each variable are: leptin (ng/dL): RT= 0,44± 0,43; FT= 3,77± 1,02, RS = 0,64± 0,37; FS = 4,40± 1,31 ($p<0,05$); BWV (g): RT = -45,72± 18,44, FT= 47,57 ±12,96, RS = -43,73± 16,40, FS = 43,53± 9,72 ($p<0,05$); BAT (g): RT = 0,38± 0,12, FT= 0,67± 0,32, RS = 0,26± 0,08, FS = 0,35±0,11 ($p<0,05$); PAT (g): RT = 0,17± 0,24, FT= 11,13 ±3,58, RS = 0,42±0,31, FS = 12,17±1,40 ($p<0,05$); % subcutaneous fat (%): RT = 2,80±1,37, FT= 11,57±2,34, RS = 4,30±1,77, FS = 13,06±2,20 ($p<0,05$). Conclusion: the food restriction, and therefore negative energy balance, significantly modified the parameters of body weight variation in female rats. This can represent risks to bone integrity and reproductive system.

RESTING ENERGY EXPENDITURE AND EPOC (EXCESS POS-EXERCISE OXIGEN CONSUMPTION): COMPARISON BETWEEN RESISTANCE EXERCISE TRAINED AND NON-TRAINED INDIVIDUALS

Rocca, S.M., Melo, C.M., Urasaki, R., Ribeiro, S.M.

São Judas Tadeu University, Brazil

Background: the energetic expenditure, in resting or in exercise, depends on many factors, including degree of training, body composition and exercise type. Objectives: (1) to compare resting energy expenditure (REE) between subjects trained (T) or non-trained (NT) submitted to a resistance training session; (2) to compare the EPOC (excess pos-exercise oxygen consumption) derived from a resistance exercise session in these subjects; (3) to compare the REE from indirect calorimetry with predictive equations from WHO (World Health Organization). Casuistic and methods: 10 men, 20 to 30 years old, BMI between 20 and 29Kg/m2, divided in two groups: 5 resistance exercise trained (T) and 5 non- trained (NT). Body composition was analyzed from bioelectric impedance (Biodinamics 450e®). The experimental protocol had carried through a resistance training session per 40 minutes, involving large muscular groups. The oxygen consumption (indirect calorimetry) was measured by metabolic analyzer VO2000®. The gas collection had been carried through 15 minutes interval, in the following instants: resting (R), before the exercise session (BE), immediately after the exercise (IA), 2h after (2h) and 4h after (4h). The t-student test and Pearson correlation coefficient were applied to compare the groups. Results: resting oxygen consumption from NT and T were 2.27+-0.77 and 2.69+-0.24 mL.kg.min, respectively. Immediately after the exercise, 2h after and 4h after, the values of the consumption of oxygen from NT were 2.92+-0.70; 2.28+-0.41 and 2.05+-0.31 mL.kg.min-1, and from T were 2.92+-0.40; 2.20+-0.49 and 2.38+-0.23 mL.kg.min-1. The predicted energetic expenditure was significantly higher than measured ($p<0,05$) in both groups. The lean mass correlated positively with the predicted resting energy expenditure in both groups ($p<0,05$). Conclusions: it can be concluded that the intensity of the exercise considered in the present study, was not enough to cause to significant differences between oxygen consumption from trained and non-trained individuals, at rest or pos-exercise.

DETERMINATION OF METABOLIC TRANSITION BY LACTATE MINIMUM TEST IN PROTEIN MALNOURISHED RATS DURING SWIMMING EXERCISE

de Mello, M.A., Voltarelli, F., Eliete Luciano

Sao Paulo State University, Brazil

Introduction: Protein malnutrition is a public health problem which affects grate part of world population, mainly in the developing countries. In Brazil, even in regions with high per capita income, there is a significative incidence of malnutrition (6%). In regions with low per capita income, the rates of malnutrition are even worse: 17% of population with under five years of age is malnourished. There is little information in the literature on the biochemical ability of malnourished organisms to perform physical exercise. Purpose: The present study aimed to determine the aerobic/anaerobic metabolic transition (MT) by lactate minimum test (LMT), adapted to rat condition in swimming exercise, in sedentary animals submitted to protein malnutrition. Methods: Male wistar rats were separated into two groups, according to the dietary protein level: Control (C),17% protein from 30 to 150 days old (n=10) and Malnourished (M), 6% protein from 30 to 150 days old (n=10). To demonstrate the efficiency of the low protein diet in inducing malnutrition we evaluated: a) blood albumin and total protein concentrations; b) liver lipids concentrations and c) body weight and length. For determination of the MT we used the LMT adapted to rat condition. Paired student t test was used to indicate statistical differences between groups ($p<0.05$). Results: The M rats showed hypoalbuminemia (3.8±0.4g/dL), hypoproteinemia (4.5±0.3g/dL); fatty liver (12.0±1.2mg/100mg); low body weight gain (222.9±53.3g) and low body length gain (7.3±0.9cm) when compared to C Group (albuminemia: 7.4±0.4g/dL; proteinemia: 7.5±0.2g/dL; liver lipids concentration: 4.4±0.5mg/100mg; body weight gain: 435.7±31.4g and body length gain: 11.8±0.8cm). M rats showed blood lactate concentration at MT (4.2±0.4mmol/L) lower in relation to C animals (6.2±0.1mmol/L), at the same exercise workload (C=4,9±0,3 e M=4,9±0,2% of body weight). Conclusions: The low protein diet used in the present study showed be efficient in inducing malnutrition. The lower values of blood lactate concentration presented by malnourished rats in relation to control animals, at the same exercise workload, suggest that protein restriction alters the kinetic of lactate during swimming exercise. Further studies are required in order to identify the factors involved in the blood lactate concentration decrease during swimming exercise performed by malnourished rats.

REDUCED STEREO VISION HAMPERS LEARNING IN ONE-HANDED CATCHING

Mazyn, L.I., Lenoir, M., Montagne, G., Delaey, C., Savelsbergh, G.J.

Ghent University , Belgium

While the mechanisms of stereopsis are well known today (Collewijn & Erkelens, 1990), its functional significance has, quite surprisingly, been given much less attention. With regard to traffic behaviour, Bauer et al. (2000) found that, in situations of limited car velocities and/or liberal time constraints, a lack of stereo vision was not detrimental to drivers' performance. Several other studies did not find adverse effects of a diminished stereo vision on the quality of life in general (Kuang et al., 2005). However, Mazyn et al. (2004) established that people with a congenital or early-onset lack of stereopsis do suffer from their visual restriction in a one-handed ball catching task, especially when temporal constraints are involved. The aim of this study was to investigate to what extent a lack of stereo vision interferes with the learning of a natural interception task. If stereopsis entails essential information for accurate catching performance that cannot be substituted by other informational cues, it is expected that catchers with low stereo vision will only make a limited, if any, progress during the learning period.

Poor catchers with good (N = 8; Stereo+) and weak (N = 6; Stereo−) stereo vision participated in an intensive training program spread over two weeks, during which they caught over 1400 tennis balls in a pre-post-retention design. A significant group x time interaction (F4,40 = 9.112, p < .001) indicated that while the Stereo+ group improved from 13% to 70% successful catches, catchers in the Stereo− group did not significantly improve (from 10% to 30%), this progress being indifferent from a control group (N = 9) that did not receive any training.

These results show that the compensatory strategies that people without stereo vision might have developed during their lifetime may not be sufficient to successfully deal with interceptive tasks under temporal constraints, not even by task-specific or extensive training. This finding is of particular interest for people that participate in ball sports or traffic situations (truck, bus or taxi drivers), who should be aware of their limited depth perception in situations where only small time windows are available for reacting adequately to external events.

SELF-CONTROLLED PRACTICE OF DECISION-MAKING SKILLS

Bund, A., Memmert, D.

University of Darmstadt, University of Heidelberg, Germany

Self-controlled practice of decision-making skills

Introduction

For a considerable time now, psychological research has concerned itself with the effects of self-initiated and self-controlled practice conditions. Numerous studies exist in the field of sport which analyze the influence that self-controlled activities have on the acquisition of motor skills (cf. Chiviacowsky & Wulf, 2005). Findings consistently show that giving learners control over the practice situation has a beneficial effect on the learning of motor skills. However, this effect occurs with a delay. Self-controlled practice conditions have not yet been used for the study of decision-making processes and of the com-parision between experts and novice performers. The main aim of this study was to investigate a self-controlled learning process with regard to the acquisition and improvement of simple, cognitive decision-making skills within the scope of the expert-novice paradigm.

Method

56 participants were allocated randomly to one of four groups. All subjects were given a three-minute period to get familiar with the game of tic-tac-toe. (4x4 fields, 3 fields per column, row/diagonal wins). The game was computer-programmed and presented on a PC. They were allowed five seconds per move, which was shown on the monitor. 28 participants (=experts) practiced the game in an acquisition phase (8 blocks of 20 games). Afterwards, 14 participants of this experts (Exp-Self) and 14 novices (Nov-Self) practiced tic-tac-toe in the treatment phase (8 blocks of 20 games) in a self-paced schedule. This means that the subjects had the op-portunity to reflect on solution strategies after each game as long as they wanted. Participants in both joked groups (Exp-Jok, Nov-Jok) had no control over the practice schedule. Each was yoked to a participant in the self-control group with the identical temporal structure. The dependent variables assessed with the tic-tac-toe test was game success (win, draw, lose) and mean decision-making time in a pre- and posttest (1 block of 20 games) as well as in tests of retention and transfer (each with 2 blocks of 20 games) one week later.

Results and discussion

Both expert groups improved their performance in their acquisition phase significantly, F(7, 364) = 3.78; p < .001; ε = 0.46, and , F(7, 364) = 3.21; p < .001; ε = 0.44. Therefore, significant differences were found between experts and novices at the beginning of the treatment phase, F(1, 54) = 4.12; p < .001; ε = 0.78, and F(1, 54) = 4.82; p < .001; ε = 0.81. First preliminary results revealed significant improvements for game success and mean decision-making time from the pretest to the posttest. The final results of the retentions test and the transfer test could not presented untill the ECSS conference.

MOTOR RECOVERY AFTER ACL RECONSTRUCTION: COGNITIVE AND VISUAL CONTROL OF BALANCE

Reininga, I., Lemmink, K., Mulder, T., Diercks, R., Stevens, M.

University Medical Center Groningen, University of Groningen, Netherlands

Rupture of the anterior cruciate ligament (ACL) is a common sports injury. After an ACL rupture the proprioception is reduced. Despite reconstruction of the ACL the proprioception remains decreased. During rehabilitation, motor programs adapt to the altered proprioceptive information through motor learning. Cognitive and visual control of movement are used in this learning process. Completion of the learning process can be read from the decrease in dependency on cognitive and visual control. To gain insight into this process, a balance test is developed that determines the progress in the learning process. The preliminary results are presented here.

Dependency on cognitive and visual control of balance can be measured by adding an attention-demanding task and restricting vision while performing a balance task. The decrease in postural control is a measure of the dependency on cognitive and visual control. The developed balance test consists of one-leg stance on a force platform with and without an attention-demanding task and restricted vision. The balance test is conducted in 6 patients, 1 and 3 months after ACL reconstruction. Control data were obtained from 37 healthy subjects.

In optimal condition (e.g. without an attention-demanding task and restricted vision), postural control of patients 1 and 3 months postoperative was comparable with the postural control of healthy controls. In case of one-leg stance with an attention-demanding task, patients performed worse than controls 1 month after reconstruction. Besides, the attentional demands of postural control seem to decrease over the period of rehabilitation; patients performed better at 3 months. With restricted vision, 1 month postoperative, 3 patients were not able to maintain one-leg standing balance without making touchdowns with the nonsupporting leg. Apparently the dependency on visual information was too high in this stage of rehabilitation to maintain one-leg standing balance. At 3 months postoperative, more patients were able to perform the balance test with restricted vision, indicating a decrease in dependency on visual control of balance in course of rehabilitation.

It can be concluded that the dependency on cognitive and visual control of balance after ACL reconstruction can be measured by means of the balance test. The dependency diminishes in course of rehabilitation, indicating a completion of the learning process in which the motor programs adapt to the altered proprioceptive information from the knee. In addition, the dependency on cognitive and visual control of balance increased for the patient's healthy and operated leg during the early stages of rehabilitation. This bilateral increase in dependency on cognitive and visual control of balance support the hypothesis that, after ACL reconstruction, motor programs for postural control have to be reorganized in accordance with the altered proprioceptive input from the knee.

EXAMINE THE LEARNING CURVE OF COMPLEX MOTOR SKILL

Chen, H.H.

National Taitung University, Taiwan

The purpose of this study was to investigate the behavior of learning the complex motor skill by examining the structure of multi-time scales of motor learning curves as well as the coordination assembling of movement form. The task in this study was the cascade juggling which is common in the show for entertainment. The performer tosses one ball in the air and catch another while keep the other aloft alternatively. For most of the people, the temporal and spatial pattern of juggling is quiet different from the intrinsic coordination of bimanual that a transition of movement coordination was expected to reveal during the process of learning.

Four adults without disability of movement and the experience of juggling volunteered as the participants learned to juggle over 4 weeks of practice. Two high speed cameras (120 Hz) and the motion analysis system collected the 3D trajectory of the position of three balls and the markers attached on the joint of arms and trunk of participants. The number of ball been caught was recorded as the outcome score of performance. The temporal structure of movement was derived from the duration of hand hold the ball—Th and the duration of hand unload—Tu. The principal component analysis (PCA) for the coordinates of 3 dimensions of balls and the joints of arms and torso was operated for the spatial structure of the movement.

The results showed that all participants learned to juggle and increase the score of outcome performance. The form of curves revealed different individually and the power law fitted better for the learning curves. The temporal and spatial structure also changes over practice. The numbers of components decreased and the structure of the elements of each components change accounted for the change of coordination of movement over practice.

ENHANCING THE USEFUL FIELD OF VISION IN NON-PLAYERS THROUGH A PERCEPTUAL-MOTOR PROGRAM

Matos, R., Godinho, M.

Faculty of Human Movement Sciences, Portugal

Literature gives us several examples of better visual information processing of expert compared to novice players (Kioumourtzoglou et al., 1998), better peripheral vision of people engaged in sports compared to those who are not (Matos & Godinho, 2005) and, probably, some advantage in certain aspects of driving performance (Hancock et al., 2002).

We conceived and developed a Program of training of the Useful Field of Vision and Peripheral Reaction Time to try to verify if these parameters are trainable.

We intended to find an answer to this question to allow us to conclude if the differences we found between young female basketball players, swimmers and non-players (Matos & Godinho, 2005) were due to sportive experience or any other factor prior to the engagement of subjects in sport.

The aim of this study was to see if a group, with no significant sport or driving experience, submitted to a Perceptual-Motor Program, would score significantly better in UFOV Test ®, and also detect more quickly peripheral stimulus in the CPVRT Test - Complex Peripheral Vision Reaction Time (Godinho et al., 2005), where subjects had to press a button as soon as they detect a ball entering their field of view in any of the two slopes positioned to their left or right.

The Program of training consisted of 5 half-an-hour sessions, where the experimental group subjects (N=11, Age=20,07 SD=0,85) executed several different tasks. They were instructed to focus there gaze in a place between the two objects they had to react to, in an unpredictable sequence and timing.

RESULTS AND CONCLUSIONS: the application of this Perceptual Training Program was successful, as the experimental group improved more than the control one, specially in the UFOV test. The results of this and previous experiments emphasise the fact that exercise and

sport practice increase perceptual skills that may be transferable for other tasks, that share some of these perceptual features, namely driving.

ANALYSIS OF VISUAL BEHAVIOR OF KOREAN BADMINTON PLAYERS FOR ENHANCEMENT OF ANTICIPATION ABILITY IN SINGLE´S MATCH

Gu, H.-M., Lee, S.C., Lee, S.M.

Korea Institute of Sport Science, Korea, South

The purpose of this study was to analyse visual behavior of korean badminton players for enhancement of anticipation ability in single's match. As subjects 10 male and 9 female players were participated in the experiment executed in real situation. In the experiment each subject tried to anticipate the direction of a shuttle and respond as good as possible over 36 times to a returned shuttle, and 4 normal(30Hz/s) video cameras(one for the movement of subject serving a shuttle and responding to a returned shuttle, one for the movement of player hitting a served shuttle, two from eye-mark recorder of subject) were used for analysing visual behavior and responding movement. These 4 videos from each video camera were synchronized and formed to a video by a device developed especially for this purpose. From analyzing frame by frame of this video, events like impact of a shuttle, response impact by a subject, begin of response were define, and dependent variables like reaction time of racket or knee and response time from impact of a shuttle by other player to a response impact by a subject were calculated and compared with each groups.

As results, subjects showed extra rapid response time, especially about 0.5 seconds(15 frames) to a smash. But there ware significant differences in response time to a smash between top-ranked players and not-top-ranked players and between successful responses and unsuccessful responses. And each subject showed his typical pattern of visual behavior, but all patterns were not appropriate to a good anticipation of a shuttle direction and a rapid response. A proper pattern of visual behavior recommended by experts was a shuttle-player's body-impact zone.

From results above it was concluded that for a good anticipation and good response every badminton player has to find out and correct his pattern of visual behavior to a proper pattern, if needed. And a proper visual perception training must be developed for enhancing anticipation ability to search proper informations in proper time.

CONTRIBUTIONS OF VISION-PROPRIOCEPTION INTERACTION TO THE POSITION ESTIMATES OF A MOVING HAND AND TARGET

Tanaka, H. 1, Worringham, C. 2, Kerr, G.K. 2

1 Tokyo University of Agriculture and Technology, 2 Queensland University of Technology, Japan

Motor tasks to manually intercept or track a moving target require estimates of both target and hand positions. In most cases, interceptions of a moving target are very accurate as compared to purely visual extrapolation of the target movement (Zago and Lacquaniti, 2005). This observation leads us to hypothesize that using only visual information may produce inaccurate estimates of target location. The present study investigated the relative importance of visual and proprioceptive signals in estimating the target locations in a dynamic environment.

Eighteen subjects performed a position estimation task in which a target travelled horizontally on a screen at a constant velocity and then disappeared from view. They were asked to estimate the target's invisible positions in two manners: passively observing or manually tracking. In the tracking trials, the visual feedback of a cursor representing the hand position was 1) always visible, 2) disappeared simultaneously with the target disappearance, and 3) always invisible. For both tasks subjects were required to verbally report the position of the "invisible" target at the time of a stimulus tone according to a scale displayed on the screen. Of interest was whether proprioceptively derived information could be used to improve the accuracy of visual estimates of the dynamic target positions, and how accurately the dynamic hand position was estimated with each of the vision and proprioception conditions.

Sensorimotor signals during manual tracking affected the performance in the visual estimation of target location. In the passive observing trials, target's invisible displacements were systematically underestimated. In the manual tracking trials, if vision of the cursor was given, the extent of the underestimation appeared to decrease. Continuous display of the cursor produced very accurate estimates of the target's invisible displacements, as if the subjects were seeing the target.

No vision of the cursor significantly increased tracking errors and this effect was magnified by the target disappearance. When vision of the cursor was presented, tracking errors became much smaller. Importantly, tracking errors were not influenced by removal of the cursor in the following interval after the target disappearance.

These results suggest that vision-proprioception interaction is critical for accurately representing the target-hand relationship in extrapersonal space. As long as the target-hand spatial relationship is accurately represented in the brain, it is efficiently updated using proprioceptively derived kinematic information. Such an online sensorimotor representation of hand kinematics would not only produce accurate estimates of the hand position, but also subserve a function in predicting the target position in the world.

CHANGES IN BODY COORDINATION IN CHILDREN FORM AZORES ISLANDS. A 3 YEARS LONGITUDINAL STUDY

Lopes, V.P., Ribeiro Maia, J.A.

School of Education, Polytechnic Institute of Bragança, Portugal

The purpose of this study was: (1) to analyse longitudinally the changes in body coordination (BC) in children during 3 years (6 to a 9 years old); and to analyse the stability of BC. Sample size comprises 142 girls (6,37±0,31 years old at the first evaluation and 8,42±0,35 at the third), and 143 boys (6,44±0,29 years old at the first evaluation and 8,34±0,39 at the third). BC was evaluated according to the body coordination test battery (KörperkoordinationsTest für Kinder) developed by Kiphard and Schilling (1974). The battery comprises four tests: backward balance (BB), jumping sideways (JS), hopping on one leg (HL), and shifting platforms (SP), from the 4 tests it is obtain a motor quotient (MQ) that permit the classification of children BC. A mixed ANOVA was used to analyze the changes along the 3 years and the differences between boys and girls. Intra-class correlation coefficient was used to analyze the stability in the all items test battery. In both boys and girls and in all items of test battery there were significant increases during the 3 years. In MQ the results show a linear increase in girls and no significant changes in boys. The BC level was higher in boys than in girls at all 3 evaluations, although in both boys and girls the level was low. It was found moderate (0.50) to strong (0.80) stability in both boys and girls. In summary: (1) boys had a higher BC level than girls; there were a linear increase in MQ in girls. BC shows moderate to strong stability.

INVESTIGATION OF FORCE CONTROL IN ADOLESCENT SOCCER PLAYERS

Karsai, I., Soós, I., Téczely, T.

University of Pécs, Hungary, University of Sunderland, UK, Hungary

Objectives: The aim of our study is to examine the feature of the force control ability and the awareness of the force exertion of young soccer players. Kicking and stopping the ball precisely requires a high level of force control of the motor system, which coordinates the movement of the lower limb. According to my hypothesis, the football players should present high level of accuracy and consistency in each measured parameters and they are able to express their performance in values. To investigate the perception -action circle and proof the hypothesis I used an isometric test. This test provides insight into the development and function of a part of the motor system which can play important role in the performance during the games.

Methods: The subjects were 13 soccer players (male), age: 14.1 ±0.55 y., weight: 55.2 ±11.55 kg, height: 169.0 ±11.14 cm. They attend training six days of the week and participate in the championship of the regional soccer association. After completing written consent, according the Ethical Committee of the University of Pécs, the participants exerted isometric force with the knee extensor muscles on a force measure device to learn how to execute the target force. The target force was given at 100 N. The duration of the familiarisation process was 30 sec., the actual magnitude of the force exertion was displayed, the participants sat in upright position, and knee angle was set at 90 °. After 5 minutes resting period they attempted to reproduce the target force without visual feedback from the magnitude of the exertion, and they repeated it in the same condition two times thereafter. They were also asked to estimate their actual achievement after each exertion. The magnitude of the execution was recorded using electronic force measure equipment at 33.3 Hz. The participants were asked to give voice sign when they felt to reach the target force level to stop the experiment. From the row data the constant error (CE) and the estimation error (EE) were computed. To test the hypothesis the Pearson's Correlations Coefficient was applied using SPSS 13 software.

Results: The result of the first trial 103.1 ±42.9N was the closest value to the target among the three attempts (2.trial 116.0 ±48.7N and 3.trial 109.3 ±46.6N). The 2.trial showed the largest positive deflection in the performance despite of the fact that they estimated their achievement higher than the target after the 1.trial (est. after 1. trial 102.9 ±6.3N). The estimation is in accordance with the expected trend after the 3.attempt but not with the real target value (est. after 3. trial102.3 ±42.9N) Relating the computed values the CE and the EE showed significant association r=0,992 n=13 p<0.001.

Conclusion: This result suggests that the noise in the performance arises from the not clearly defined nature of the stored information and from the competition between the automatic and conscious regulatory system.

SUBTLE MEMORY AND DYNAMIC ATTENTION DURING TWO TASKS OF COGHEALTH PROGRAM OF SHOOL CHILDREN

Nagata, A., Tajima, T.

Toyama International Research Center for Traditional Medicine, Japan

Introduction: This study was designed to evaluate with the cognitive performance of the school child and with the higher brain neurological system of human, quantitatively. We adopted CogHealth soft-program as this task of this experiment. Another object is to propose the evaluating function with the mild cognitive impairment of aging. Method: Twenty-six healthy adults (average age: 37.1yrs, AG) and fifteen children subjects (average age: 8.1yrs, CG) were employed to this study. Two tasks of the playing-card games of CogHealth were displayed on the CRO of PC. The first game is asked to determine whether a single pair of cards presented on the display was the same. If they were the same, subjects press the "K" yes key (memory M task). The second game are require to press the key as fast as possible whenever anyone of five cards may touch to two lines at the top- and bottom at the CRO (dynamic D task). These tasks require a rapid response correctly and to operate pushing the key on the random series of thirty cards. Those data of response times were processed to obtain estimating variables of their reaction velocity, the frequency rhythm, their mental fatigue, their integrated cognition and their subtle memory with using the time series analysis of the computer soft program (MEMCalc). Trajectory Charts and Power Spectrum of their reaction time were processed to get the motion (F), the locus-distance (LD), the gradient(β) and the total power spectrum (TPS). Furthermore these demographic and psychometric parameters were evaluated to compare with the aging and with one way of ANOVA, statistically. Results: As resulting of these processing variables, total reaction times of AG and (CG) were observed at average 475msec(846msec of pupils) of M task, and 438msec(730msec) of D task, individually. The subtle memory and the dynamic attention of CG showed inferior to those of AG ($p<0.05$). At the case of D task, parameters of F and LD appeared significant difference between two groups, and two values of β and TPS were obtained to average –4.4(-7.4) gradient, and 0.2mV・Hz(0.7) area, significantly($p<0.05$). Discussion/Conclusion: There have been appeared a developmental delay of the higher brain neurological system, and of a psychometric association with aging about CG. Data of the task rhythm (F), the short-term memory (β), the mental fatigue (TPS), and the psycho-saturation(LD) might display to evaluate with a cognition level related to aging quantitatively. These results seem to indicate that those variables should help to indicate the demented attitude and the attentive levels related to the calendar aging and the

activity habits in their life Then, we concluded that CogHealth program should be applied for human to be diagnosed an action of the cognition in the psychotherapy field.

THE EFFECT OF MASSAGE ON SOME OF FUNCTIONAL INDICATORS OF DELAYED ONSET MUSCLE SORENESS (DOMS)

Moradi, L., Tarverdizadeh, B., Behpour, N.

Islamic Azad University, Iran

Introduction: Delayed onset muscle soreness not only affects daily life of sedentary peoples but also is detrimental to athlete's competition or training participation. Various researches have reviewed different methods in treatment of DOMS's sign and consequences which their findings are conflicting and confusing. For example, "Megan et all" (2003) showed that massage has not significant effect on pain induced by DOMS but"Hilbert et al" (2003) demonstrate massage as a proper treatment for DOMS. With respect of the necessity of finding an appropriate, safe and fast treatment method for recovery and reparticipation of athletes in athletic events, this research has studied massage effect in DOMS treatment.

Methods and subjects: 20 female physical education students participated voluntarily in this study. In day 1 and in order to DOMS inducing, all of the subjects performed specific eccentric training for non dominant upper arm flexor muscles. In day 2, subjects divided randomly to two homogenous experimental (treated with massage) and control groups. Before, 24 and 48 hours after eccentric training in control group, and before and after massage treatment in experimental group, functional indicators of DOMS including perceived pain, elbow joint's flexion and extension range of motion, resting angle of elbow joint and arm circumference evaluated in two groups.

Findings: Eccentric training significantly induces DOMS. Massage has significant effects on signs and symptoms of DOMS and significantly reduces pain, increase flexion's ROM, and decrease resting angle and circumference of elbow.

Discussion: Massage, by stimulation of free endings of nerves, may reduce pain and spasm induced by DOMS and thereby, may increase ROM of elbow joint and decrease resting angle of elbow. On the other hand massage can increase circulation of blood and lymph and reduce inflammation and swelling.

THE EFFECT OF TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS) ON SOME OF FUNCTIONAL INDICATORS OF DELAYED ONSET MUSCLE SORENESS (DOMS)

Moradi, L., Tarverdizadeh, B., Behpour, N.

Islamic Azad University, Iran

Preface: Delayed onset muscle soreness not only affects daily life of sedentary peoples but also is detrimental for athlete's competition or training participation. Various researches have reviewed different methods in treatment of DOMS's sign and consequences which their findings are conflicting and confusing. With respect of the necessity of finding an appropriate , safe and fast treatment method for recovery and reparticipation of athletes in athletic events, this research has studied TENS effect in DOMS treatment.

Method and subjects: among the physical education students of Islamic Azad university central Tehran branch, 20 subjects participated voluntarily in this study. In day 1 and in order to DOMS inducing, all of the subjects performed specific eccentric training for nondominant upper arm flexor muscles. In day 2, subjects divided randomly to experimental (whose treated with TENS) and control groups. 24 and 48 hours after eccentric training , before and after TENS treatment, functional indicators of DOMS including perceived pain, elbow joint's flexion and extension range of motion, resting angle of elbow joint and arm circumference evaluated in two groups.

Findings: TENS, by inhibition of pain in presinaptic level of spinal cord's posterior horn or by endorphin secretion, may reduce pain induced from muscle fibers damage and predictable inflammation and swelling of muscle and thereby increasing elbow joint range of motion. With pain reduction and breakage of pain-spasm cycle in biceps muscle, as an antagonist to triceps, elbow joint's extension range of motion increased. Resting angle of elbow joint also decreased as pain and spasm of muscles decreased. Spasm reduction, circulation elevation, and inflammation reduction in muscle, which reported after electrical stimulation, accounted for arm circumference reduction.

MULTI-PURPOSE CYCLE ERGOMETER DEVICE

Netreba, A., Popov, D., Borovik, A., Vinogradova, O.

SSC RF Institute of Biomedical Problems RAS, Russia

Accurate assignment of physical load is an essential task of athletic training. Traditionally velocity of contraction is evaluated when working with free loads and force of contraction is determined in speed controlled devices. Worked out by our group multi-purpose cycling ergometer allows to automatically assign both parameters in concentric and eccentric regimes. The physiological testing of the device was performed using a training procedure directed at an increase of force, power and size of main muscle groups involved in pedaling. 16 healthy physically active males gave their consent to participate in the experiment. A group of 8 subjects was trained in concentric regime and another group of 8 subjects - in eccentric regime. The training sessions took place twice a week. Training session consisted of 7 exhaustive sets (50-130 s) with 10 min resting periods between them. Before and immediately after 9 weeks training period maximal anaerobic power was determined in Wingate test, maximal voluntary contraction (MVC) was recorded in isometric regime, and the volume of quadriceps femoris muscle was estimated using the MRI data. The blood lactate concentration was used as an index of intensity of a standard training session and an activity of muscle CPK in blood as an index of damage of muscle cells. The delayed onset of muscle soreness (DOMS) was determined as well. The significant increases of force, power and size of m. quadriceps femoris were obtained as a result of training with no differences between groups. However eccentric training turned out to be more efficient: the blood lactate increase after eccentric training session was noticeably lower than after concentric. The level of DOMS after an eccentric training at multi-purpose cycling ergometer was much lower than the effects of eccentric training described in the literature The "floating" seat of

ergometer device worked out by our group might damp down the stroke loads arising as a result of eccentric exercise. The obtained results allow supposing that the worked out training device may be used for training of disabled people.

LONG-TERM RESULTS OF FITOC (FREIBURG INTERVENTION TRIAL FOR OBESE CHILDREN)

Korsten-Reck, U., Korsten, K., Kromeyer-Hauschild, K., Bjarnason-Wehrens, B., Berg, A.

University Medical Center, University Freiburg, Germany

Hypothesis: Till now long-term results of outpatient intervention trials in childhood are rare. We examined the long-term anthropometric, leisure time and nutritional behavior data of the FITOC participants.

Methods: We included 53 adolescents (♂:24, ♀:29). The average age of the boys was 17.0 ± 3.3 years and the girls, 15.9 ± 2.8. Anthropometric data and data from questionnaires on leisure time and nutritional behaviour were summarized at the beginning, after the first control examination (after 8.7 months) and after the long-term examination more than 3 years later (6.2 ± 2.7 years). Statistics: Step by step multiple regression with backwards elimination (Exclusion criteria: p<=0.10 within a partial F-test).

Results: BMI-SDS (♂: p=0,001; ♀: p<0,001) decreased significantly after eight months of intensive therapy and physical performance increased significantly. Long-term examinations confirmed a significant decrease in BMI (♂: p=0,003; ♀: p=0,013). Between the beginning and the long-term examination, there is evidence of a significant increase in the levels of physical performance in boys (p= 0.002) but only a tendancy in girls (p= 0.065). Before taking part in the FITOC program, a third of children were inactive (31.4 %). At the long-term examination only 1.9 % had remained inactive. Nearly half of the adolescents reported (47.2 %) that they were active during more than 3 hours per week. Using multiple regression we can show that long-term BMI-SDS changes are dependent upon the mother's weight (p= 0.035) and level of physical activity (p= 0.004).

Discussion: Success after the intensive therapy phase could be stabilized long-term by a follow-up program. It seems that behavior patterns in adolescents can be established long-term by means of outpatient intervention.

MULTIPLE SCLEROSIS AND THERAPEUTIC CLIMBING: AN INTERVENTIONAL LONG TERM PILOT STUDY INDICATES BENIFICAL EFFECTS

Kern, C. 1, Bühlmeyer, K. 1, Käser, T. 1, Banik, B. 1, Eberhardt, U. 1, Kleinert, J. 2, Michna, H. 1

1Technical University Munich, 2 German Sport University Cologne, Germany

Introduction

Multiple sclerosis (MS) is a neurological disease of the central nervous system that often affects young individuals. It is characterised by various debilitating symptoms (Kesselring et al., 2005). So far most advices for patients with MS include only limited physical activity since fatigue and overexertion or activated immune cells (Peters3 et al., 1997). The aim of this study was to investigate if climbing might be an appropriate physical activity for patients with MS and has a positive effect on their mental state.

Methods

This pilot study consisted of ten patients (7 female, 3 male), with a mean age of 38 (+-6) years. Scales on the EDSS-scale ranged between 0 and 7 (mean = 3,9), mean age at diagnosis for MS was 26 years (+-6). All of the patients were interested in sports before their diagnosis, only 5 of them were actually doing sports (swimming, fitness, cross country skiing) at the beginning of the study. The study was undertaken on six 2,5h climbing sessions on consecutive Saturdays. Controlled top rope climbing and safety-standards were ensured. Questionnaires (perceived physical and psychological state, Kleinert1, 2001), scientific observation and interviews (group reflection and individual interviews) were used to detect alterations of their comfort, physical and mental condition.

Results

All participants describe an improvement of their physical and mental conditions significantly and enhanced their sense of balance and quality of life.

The perceived physical flexibility before/after increased significantly from session 3 to 6. Regarding the psychological state the same significant differences were found for the dimension self-confidence. While the fatigue in the first session was higher after climbing, it changed for the remaining 5 sessions.

Results from the observation papers, reflections and answers on the questionnaires and interviews revealed that all of the patients with MS felt "better" after climbing. The patients felt "more powerful" and "clearer in mind". Furthermore all of them reported to handle their problems of everyday life more easily. One patient stated to overcome the anxiety of altitude during the six times of climbing completely. A strengthening of self-confidence and a reduce of anxiety were registered.

Conclusions

In summary our climbing intervention improved physical and psychological functions in MS patients. Therefore, it might be appropriate to advise participation in regular exercise programs such as a climbing training. To prove long term effects we will do a follow-up-survey after a year and we are now engaged to extend the evaluation of mental and physical effects of climbing with MS-patients and incorporate further details on motor control.

EFFECT OF MUSCLE ATROPHY BY FIBER TYPE IN IMMOBILIZED MOUSE SOLEUS MUSCLE

Sakamoto, M., Maehara, A., Kurita, J., Harada, T., Futami, T., Oka, K.

Kitasato University, Japan

Introduction

Skeletal muscle shows high plasticity in response to external conditions. We previously reported that immobilized soleus muscles in a shortened position forms a degenerated structure called the wave-like structure. We also reported that the wave-like structure offers a sensitive marker of morphological change induced by disuse (Oka et al. 2003). Furthermore, frequency of wave-like structures induced by

immobilization was higher in type II fibers than in type I fibers. However, changes of fiber-type distributions and relationships between wave-like structures and extent of fiber atrophy in immobilized soleus muscles remain unclear.

The present study aimed to clarify changes in fiber-type distributions in immobilized soleus muscle and the extent of muscle atrophy induced by immobilization in the shortened position in both type I and type II muscle fibers.

Methods

The soleus muscles of 5-week-old female ICR mice were used in this study. Under anesthesia, the left hind limb was immobilized at the ankle joint in maximum dorsiflexion. Cross-sections of soleus muscle were made using a cryostat for controls and after immobilization for 3, 5, 7 or 10 days. First, the distribution of fiber types in soleus muscle after immobilization was investigated. ATPase activities of the soleus muscle sections were observed using the routine ATPase methods. All fibers were classified as type I or II and numbers of fibers were counted for each type. Next, fiber cross-sectional area (CSA) of soleus muscle was investigated in each group. Measurements of muscle fiber CSA were analyzed using image-analyzing software. Results were analyzed using 1-way analysis of variance. If statistical significance was achieved ($P<0.05$), pairwise comparisons were performed using Scheffe's method.

Results

1. Fiber-type distribution

Type I and II fibers were scattered in a checkerboard distribution in each animal. No deviation of distribution was observed and numbers of each fiber type were almost equal. Distribution of type I fibers did not differ significantly between immobilization groups.

2. Fiber cross-sectional area

In controls, CSA was larger for type I fibers than for type II fibers. After immobilization, CSA for both fiber types decreased with time. However, significant differences were observed between 10-day immobilization and controls for type I fibers. In type II fibers, CSA at 5, 7 and 10 days of immobilization was significantly decreased compared with controls.

Discussion/Conclusion

In this experiment, muscle atrophy was induced in both type I and type II fibers with time. However, atrophy occurred earlier periods for type II fibers than for type I fibers. Regarding relationships between wave-like structure and muscle atrophy, muscle atrophy was delayed compared to wave-like structures. Wave-like structures were thus observed in the early stages after immobilization.

TIME COURSE OF CHANGES IN MUSCLE PAIN DURING TWO DIFFERENT PHYSICAL TRAINING INTERVENTIONS IN FEMALES WITH TRAPEZIUS MYALGIA

Andersen, L.L., Søgaard, K., Hansen, P.B., Andersen, C., Skovholm, K., Rosendal, L., Sjøgaard, G.

National Institute of Occupational Health , Denmark

Trapezius myalgia (TM) is frequent in women engaged with repetitive and monotonous work tasks. Previously, strength training has been shown to relieve shoulder-neck pain, however, the time course of changes in pain has not been determined in detail. Further, specific recommendations of training are to be documented. In this context it has been hypothesized that training of large muscle groups can help alleviate pain in small non-involved muscle groups due to increased blood flow and release of central humoral factors. Aim: To investigate the effect of muscle specific strength training vs. cardiovascular training with large non-affected muscles on the time course of changes in trapezius muscle pain in females with TM. Methods: 13 females clinically diagnosed with TM (45±6 yrs, 166±6 cm, 72±14 kg) were randomized into two training groups; STR (n=6) trained specific heavy-load strength training for the shoulder and neck muscles with various dumbbell exercises with 8-12 RM loads; BIC (n=7) trained with their legs on a bicycle ergometer at 70 % VO2-max while keeping their shoulders relaxed. Training in both groups was performed for 20 min 3 times/wk for 10 wks. Pain from the trapezius muscle was determined by each subject on a 100 mm visual-analog-scale (VAS) during each training session. Acute effect of training on pain: comparison of VAS immediately before and after each training session. Longitudinal effect of training: the change over time in 2 pain parameters, general and worst pain since the last training session. Results: Prior to the training intervention pain in general during the last 3 days was similar in STR and BIC (28±15 and 39±25 mm, respectively). In response to training BIC tended to decrease pain acutely (26±16 vs 22±18 mm, P=0.07), whereas no change occurred in STR (11±9 vs 12±11 mm, P=0.58). Over the 12 wks of training STR decreased pain markedly (from 28±15 to 7±12 mm VAS general; and from 40±30 to 9±11 mm VAS worst) whereas no change was observed in BIC. In STR the decrease in pain occurred linearly with the number of training sessions. Discussion: The present study demonstrated that STR and BIC can have beneficial effects on muscle pain in females with TM, but that the time course of these effects are quite different. While BIC tended to decrease pain acutely but not longitudinally, STR showed a marked decrease in pain over a prolonged period of time. Furthermore, the decrease in pain in STR was linearly related to the number of training sessions, which indicates that strength training should be performed for a prolonged time period to be effective. Thus, different mechanisms may help to alleviate muscle pain in response to STR and BIC. Speculatively, the acute effect of BIC may occur due to a general increased blood flow, elevated core temperature and/or a release of central humoral factors, whereas the longitudinal effect of STR may be related to improved microcirculation and an enhanced intramuscular biochemical milieu.

ENERGY EXPENDITURE IN YOUTH OBESITY THERAPY: WHICH EXERCISE INTERVENTION BURNS MOST?

Thiel, C., Claußnitzer, G., Vogt, L., Banzer, W.

Johann Wolfgang Goethe-University Frankfurt/Main; medinet Spessart-Klinik, Bad Orb, Germany

Objective: Physical activity (PA) plays an important role in the prevention and rehabilitation of obesity in youth. To provide an evidence base for obesity intervention programmes and their quality, efficient and enjoyable exercise modes and doses need to be identified. This study assessed amount, energy expenditure (EE) and intensity (INT) of seven different structured exercise interventions during a 4-week rehabilitation.

Methods: Individual heart rate (HR) – EE relationships were obtained in 20 adolescents without comorbidities attending inpatient obesity therapy (13.6±1.4 years, BMI 31.8±4.1 kg/m2, peak VO2 30.1±4.9 ml/(kg*min)). Representative time intervals of seven exercise therapy programmes were selected for HR monitoring. According to the flex HR method, oxygen consumption (VO2) and EE were calculated using the individual HR-VO2 regressions.

Results: Adolescents completed 7.5h of exercise therapy per week, increasing EE by a net 1,871±533 Kcal/wk and accumulating 3.5±1.1h of moderate to vigorous PA (MVPA: >40% of oxygen consumption reserve, VO2R) corresponding to 47±15% of total exercise time. EE

[KJ/kg/h] and INT [%VO2R] of walking (14.0±2.9; 29±8) differed significantly from swimming (19.9±5.9; 47±17), 65-85W cycle ergometry (19.6±3.7; 46±8), strength/stability circuit (18.9±3.7; 44±9) small group games/relays (19.0±5.4; 45±16) and team sports (20.6±7.0; 48±19) (Friedman test, $p<0.05$), but not from water games (18.0±4.4; 42±14).

Discussion: Objective assessment of exercise intensity is crucial to provide evidence for the selection of efficient therapeutic interventions in obesity therapy. Three out of four adolescents accumulated more than 150 minutes of structured therapy-induced MVPA per week, fulfilling specific guidelines for cardiovascular health in obese youth‡, and reaching the upper end of the recommended range of general ACSM energy expenditure goals by spending more than 300Kcal/day. However, the interindividual differences - 5 subjects showed an average INT of 30%VO2R or less - indicate that exercise therapy needs to be tailored even more towards individual needs to increase its efficiency. Since EE and INT showed significant differences only between walking and all other exercise modes except water games, the choice of appropriate therapy programmes should mainly be guided by adolescents' preferences to promote long-term activity behaviour change.

IMPROVEMENT IN PHYSICAL FUNCTIONAL ABILITY IN PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE AFTER COMBINED AEROBIC AND RESISTANCE TRAINING

Pereira, A. 1, Santa-Clara, H. 1, Simões, I. 2, Cabri, J. 1, Fernhall, B.

1 Faculty of Human Movement, 2 Garcia da Orta Hospital University of Illinois Urbana-Champaign, Portugal

In patients with chronic obstructive pulmonary disease (COPD) aerobic exercise training has been demonstrated to reduce the functional limitations imposed by this disease. In general, resistance-training increases muscle strength and this may be related to the improved performance of the activities of daily living and also by improving endurance and functional capacity. Objective: The purpose of this study was to assess the effectiveness of combined aerobic and resistance training exercise in physical functional ability in patients with COPD. Methods: Forty men performed combined exercise training for 10 weeks, 3 times a week. Ten patients with moderate COPD formed the experimental group (EG) (age, 66±6 yrs; weight, 81.5±9.8 kg; height, 177±5.0 cm) and 30 healthy subjects matched by age served as a control group (CG), (age, 67.5±3.5 yrs; weight, 69.3±7.7 kg; height, 164,0±0,8 cm). The aerobic exercise was set at 60-70% HR reserve for 30 minutes and the resistance exercise was performed in 5 weight machines, 2 sets of 8-12 repetitions at 50-70% of 1RM. Assessment included a Maximal Graded Exercise Test, an one repetition maximum for each resistance machine used in the exercise program and the Furllerton's functional fitness test for older adults, before and after training program. Results: The pre-values of the functional fitness test were different ($p<.05$) between EG and CG groups (30-second chair stand 13,8±1,4 vs. 17,3±2,3; arm curl 10,0±4,1 vs. 15,8±1,5; 6-minute walk 480,7±47,3 vs. 592,4±43,6; chair sit-and-reach -5,8±12,2 vs. -1,08±4,2 respectively) and no differences were observed for the back scratch test (EC, -6,5±7,8 and CG, -4,2±4,5) and for 8-foot up-and-go (EC, 4,7±0,4 and CG, 6,3±1,3). Both groups increased ($p<.05$) values after combined exercise with modification rates in 30-second chair stand (EC, 42,2±22,0% and CG, 23,1±13,5%), arm curl (EC, 109,4±64,1% and CG, 19,1±13,1%) 6-minute walk (EC, 12,2±2,7% and CG, 7,1±10,1%). Conclusions: In conclusion, the combined exercise training seems to be effective for the physical functional ability of older healthy men and patients with COPD. As is true for healthy persons, exercise training for patients with COPD improves exercise capacity by optimizing global functional condition.

EFFICACY OF A SUPERVISED EXERCISE PROGRAMME IN PATIENTS WITH AN ACUTE LATERAL ANKLE SPRAIN: A RANDOMISED CLINICAL TRIAL

Koes, B.W., van Os, A.G., Bierma-Zeinstra, S.M., Kleinrensink, G.J., Bernsen, R.M., Verhaar, J.

ErasmusMC, Netherlands

Backgroud: Acute ankle sprains occur frequently. It is unclear whether conventional treatment should be supported by (supervised) exercises during the recovery period after an acute ankle sprain.

Objective: To assess the efficacy of usual care combined with a supervised exercise programme versus usual care alone in patients with an acute ankle sprain.

Methods: Randomised clinical trial. Adults with a acute ankle sprain were recruited in hospital emergency rooms and in general practices. They were randomized to receive usual care + supervised exercises or usual care only. Primary outcomes were subjective recovery and the occurrence of a resprain. Measurements were carried out at baseline and after 4, 8 and 12 weeks.

Results: A total of 102 patients were included in the trial. Both study groups improved over time. Although the improvement rate was somewhat higher in the supervised exercise - group there were no statistically significant differences between the studygroups on the primary outcome measures. There was a significant difference regarding appreciation the the treatment received in favor of the supervised exercise-group.

Conclusion: Combining usual care with a supervised exercise programme does not significantly improve subjective recovery or reduce the occurrence of re-sprains compared to usual care alone in patients with an acute lateral ankle sprain.

THE EFFECTS OF QIGONG GYMNASTIC EXERCISES AND MANUAL MANIPULATION THERAPY ON THE CORRECTION OF BAD POSTURE AND COBB ANGLE OF HIGH SCHOOL GIRLS WITH SCOLIOSIS

Park, G.D., Lee, T.H., Lee, W.J., Ju, S.-B.

Exercise Prescription, Korea, South

The purpose of this study is to evaluate the effects of Qigong therapy and manual manipulation therapy, which are not surgical procedures, performed on scoliosis patients in Y girls high school for 8 weeks. A total of 31 students, including 16 scoliosis patients aged between 16 and 19 and 15 normal students, made up the study population. Qigong therapy was performed on 8 scoliosis patients and manual manipulation therapy on the remaining 8 patients. The patients were treated with Qigong therapy and manual manipulation therapy for 8 weeks and the effects on Cobb angle and body balance have been evaluated. The results of the analysis have shown the following:

1. The effects of Qigong gymnastic exercises and manual manipulation therapy on Cobb angle:

A meaningful decrease in Cobb angle has been observed according to the period and to the interaction of the period with group when the patients are treated with Qigong therapy or with manual manipulation therapy ($P<.01$).

2. The effects of Qigong gymnastic exercises and manual manipulation therapy on the balance of body:

When it comes to the static balance of the body, a meaningful difference in the disturbed area has been observed with B1 (standing on both feet with eyes closed) and E1 (standing on the left foot with eyes closed) among groups and in the interaction of the period with the group (P<.05). A meaningful difference in the trajectory has been observed only in B2 (standing on both feet with eyes closed) in the interaction of period with the group (P<.05). As for dynamic movement, a meaningful difference in G1 (Sine wave L-R shift), H (Sine wave A-P shift) and I (oval) has been observed only in the period (P<.05). After 8 weeks of the treatments, compared with before the treatments, there has been a meaningful increase in stability in the Qigong group (P<.05) and a numerical decrease has been observed in the manual group.
To conclude, Qigong therapy has helped the scoliosis patients to improve body balance, and manual manipulation therapy has shown effect on Cobb angle on X-rays. Therefore, early detection of scoliosis during adolescence and steady Qigong gymnastic exercise or stretching, which improves muscles around the spine, may keep Cobb angle of students normal.

A CHANGE IN THE INTRAMUSCULAR OXYGEN HEMODYNAMICS DURING THE JET AQUA MASSAGE IS RECEIVED

Sudo, A., Akasaki, F., Tsunoda, N., Watanabe, T.

Kokushikan University, Japan

It is also known that water pressure increases the venous return, and decreases the hart rate (Arborelius et al., 1972; Larsen et al., 1994). And that the hart rate taken when the immersion level was stood at xiphoid, at a temperature of 36 °C was almost same as that measured in the lying on back position on land (Sudo,2001,ECSS). In this study we observed the circulation of the right vastus medialis muscle with a laser tissue blood-oxygen monitor during jet aqua massage is received when subjects were immersed to the xiphoid process in this water. 9 males and 3 females served as subjects. Measurements were made with the subjects in each of 4 conditions, that is in a standing on the ground before into the water, in standing position and during jet aqua massage (500 l/min) in the water in a standing on the ground after into the water. After the sensor of a laser tissue blood-oxygen monitor was installed over the right vastus medialis muscle, tissue oxygen saturation (StO2) level, tissue total hemoglobin (HbT) level, tissue deoxygenated hemoglobin (HbD) level, and tissue oxygenated hemoglobin (HbO2) level were measured. These results showed that blood pressure during the jet aqua massage was significantly lower than that a standing sitting on the ground, and StO2 level during jet aqua massage level was the highest while 4 conditions.

PHYSICAL FITNESS, FUNCTIONAL ABILITY AND HEALTH RELATED QUALITY OF LIFE IN CHILDREN WITH SEVERE HAEMOPHILIA: A PILOT STUDY

Takken, T., Engelbert, R., van der Net, J., Vos, R., van der Berg, M., Helders, P.

Univeristy Medical Center Utrecht, Netherlands

Objective

To investigate physical fitness, functional ability and health related quality of life of children with severe haemophilia, who are on prophylactic treatment.

Methods

Thirteen boys with severe haemophilia, treated at the University Medical Centre Utrecht,The Netherlands receiving prophylactic treatment (3 times a week 20-40 units per kg), mean age 11.0 yrs (range 7-15) were included. Body composition and joint health status (Haemophilia Joint Health Status) were measured. Aerobic exercise testing was performed using maximal exercise test with expired respiratory gas analysis until volitional exhaustion. Functional ability was assessed with the Dutch translation of the Activity Scale for Kids (performance and capability) and Health Related Quality of Life (HRQoL) was determined with the Haemo-QoL, a disease specific questionnaire.

Results

Body composition was comparable with healthy peers. Joint health status was almost normal (decrease (%): mean (sd) score: 1.1 (2.3), range 0-8).

Peak heart rate and peak respiratory gas exchange ratio's indicated that the children tested were able to perform at maximal or near maximal level (HRpeak 190 ± 9 beats.min-1 (range 171-206); RERpeak 1.22 ± 0.14 (range 0.86-1.33). VO2peak/kg was comparable to the normal population 47.42 ± 8.29 ml.min-1.kg-1 (Z-score mean (sd) VO2peak/kg/kg: -0.5 (sd: 1.4; range: -3.4 – 1.7). One child reported a joint bleeding in the right ankle the day after the exercise test.

Functional ability (performance and capability) was comparable to healthy controls (median; interquartile range: 100 (95.3-100) respectively 100 (94.5-100). In Health HRQoL, the correlation between patient report and parent report was high (R=0.73; p = 0.007). Mean (sd) in % HRQoL(normal: 0%, impaired: 100%) for child and parent was 12.4 (8.9, range: 3.2-12.4), respectively 11.8 (6.4, range: 2.1-11.8). The dimensions with most impact on HRQL were 'Friends', 'Perceived support', 'Treatment', and 'Dealing'.

Conclusion

Exercise testing seems to be a safe procedure under the current prophylaxis regime in most of the patient with a severe Haemophilia. The patients with severe haemophilia have a normal physical fitness compared to healthy peers. Joint health status, and functional ability were also found to be normal. The HRQoL revealed impact primarily on the psycho-social domains, rather than the physical domains.

SERUM CONCENTRATIONS OF ADHESION MOLECULES DURING RESISTANCE EXERCISE

Petridou, A. 1, Chatzinikolaou, T. 2, Fatouros, I. 2, Mastorakos, G. 3, Mitrakou, A. 4, Papassotiriou, I. 5, Mougios, V. 1

1 University of Thessaloniki, 2 University of Thrace, 3 Athens University, 4 Henry Dunant Hospital, 5) Aghia Sophia Children's Hospital, Greece

Introduction

Adhesion molecules are proteins expressed on the surface of a variety of cells (such as vascular endothelial cells, leukocytes, and platelets) and mediating leukocyte response to inflammation (1). Part of these molecules is released to the plasma as soluble forms and their

concentrations have been positively correlated to the risk for cardiovascular disease (2). Studies on the effect of exercise on the concentrations of soluble adhesion molecules have produced controversial results. The only study that measured soluble adhesion molecules after resistance exercise found a reduction in P-selectin 24-144 h postexercise but no changes in E-selectin, vascular cell adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1) 1.5-144 h postexercise (1). In this study we assessed the effect of resistance exercise on the concentrations of soluble adhesion molecules during and immediately after the exercise protocol.

Methods

Sixteen healthy young men volunteered to participate in the study. After an overnight fast, subjects executed a 30-min resistance exercise protocol selected so as to stress the major muscle groups. Participants performed 3 sets of 10 resistance exercises with 10-12 repetitions at 70-75% of 1RM, in a circuit training fashion. Participants were instructed to perform each repetition in 4-6 s with a 30-s pause between exercises and 2 min rest between sets. Blood samples were drawn from an antecubital vein at baseline and at the end of the first, second, and third sets. Serum concentrations of VCAM-1, ICAM-1, E-selectin, P-selectin, and L-selectin were determined using the Evidence® biochip array analyzer. Differences were examined through the nonparametric Friedman test, because not all parameters displayed normal distribution, as examined by Shapiro-Wilk test. The level of statistical significance was set at 0.05.

Results

There were no significant changes in the serum concentrations of the adhesion molecules determined during the 30-min resistance exercise, although all concentrations were elevated at the end of the third set by 3-10%: VCAM-1 from 440±95 to 463±73, ICAM-1 from 318±94 to 348±128, E-selectin from 11±3 to 12±4, P-selectin from 79±14 to 85±11, and L-selectin from 1177±185 to 1218±210 (mean±SD in ng/mL).

Discussion

Our data show that resistance exercise at 70-75% of 1RM did not affect the serum concentrations of adhesion molecules in healthy young males. Combined with the finding that resistance exercise did not affect most of the soluble adhesion molecules and decreased P-selectin for up to six days (1), and since elevations in the concentrations of soluble adhesion molecules are thought to hamper the immune response (3), the data suggest no considerable negative effect of resistance exercise on immune function.

EOSINOPHIL TRAFFICKING AND ACTIVATION AFTER DOWNHILL RUNNING

McKune, A. 1, Smith, L. 1, Semple, S. 1, Sibanda, E. 1, Mokethwa, B. 2, Wadee, A. 2

1 Tshwane University of Technology, 2 University of the Witwatersrand, South Africa

Introduction

Acute physical stress induces leukocyte trafficking from the circulation to the mucosal lining of the gastro-intestinal tract and lung (1). Although circulatory eosinopenia (3) and eosinophil activation (2) have been reported after strenuous exercise there is limited research in this area. The purpose of the study was to examine eosinophil responses to strenuous exercise and the role of circulating cell adhesion molecules in this response.

Methods

Eleven active, untrained males, mean (SD), age 19.7 (0.37)yr; weight 78.5 (3.06)kg; body fat 14.6 (3.2)%; VO2 max 47.8 (3.6)ml/kg/min, performed a 60 min bout of downhill running (-13.5% gradient), at a speed that would elicit 75% of each subjects VO2 max, on a level grade. Blood samples were obtained before, immediately post exercise (IPE), and every hour for 12 h after and every 24 h for 6 d. Eosinophil levels were determined using a Coulter Counter. Serum eosinophil cationic protein (ECP) concentrations were determined by a radioimmunoassay technique. ICAM-1 level was determined using an ELISA. Each dependent variable was analyzed using a repeated measures ANOVA, with significance set at $P < .05$. Where appropriate the Bonferroni post-hoc test was performed.

Results

Percentage eosinophils in the circulation were significantly reduced ($p=0.0006$) after the downhill run from IPE-8 h (-42% to -76%). ECP level increased after the run and was significantly ($p<0.0001$) elevated (+63%) at 12 h. ICAM-1 level was not significantly altered.

Discussion

The disappearance of eosinophils from the circulation suggests the trafficking of these cells to peripheral sites. The elevation of ECP suggests that eosinophils may also be activated. The ICAM-1 result was surprising considering that this molecule is primarily responsible for the firm arrest of eosinophils to the endothelial cell surface, before they move through the vessel wall to the tissues (5). Recently it was proposed that in response to strenuous exercise, eosinophils may migrate to, and become activated in, the upper respiratory tract and that repeated activation may be responsible for asthma-related airway symptoms in athletes (2). However, in addition to pathological effects, eosinophils have been shown to have protective (defence against parasites) and tissue repair functions (4). Therefore, eosinophil responses to acute physical stress have been suggested to be part of an evolutionary conserved protective mechanism to enhance "immune surveillance" in areas of the body more susceptible to pathogen invasion (1). Whether the results of the present study represent a protective or pathological eosinophil response to downhill running is unclear and requires further investigation.

NETTLE DIET AND REGULAR EXERCISE INFLUENCE RAT BRAIN LESION AND MEMORY

Stadler, K., Sasvári, M., Jakus, J., Jung, J.K., Chung, Y.H., Nyakas, C., Radák, Z.

Semmelweis University, Hungary

The effect of swimming training and that of enriched lab chow containing 1% (w/w) dried nettle (Urtica dioica) leaf were investigated on the prevention of severity of brain injury caused by N-methyl-D-aspartate (NMDA) lesion in Wistar rats.

The functional effect of lesion was tested by open-field activity and passive avoidance learning tests. The oxidative stress (reactive carbonyl derivatives, free radicals) and inflammation (nuclear factor-κB, NF-B, activator protein-1, AP-1) markers were determined in rat brains.

Results demonstrate that according to learning and behavioral tests, both treatments seem to improve the adverse effect of brain injury caused by NMDA lesion. Nettle supplementation decreases the level of reactive species and the DNA binding activity of NF-κB. Nettle was found to be an effective antioxidant supplement, down-regulator of inflammatory transcription, and could also promote learning performance in brain. Exercise increases the concentration of reactive species in cerebellum, and alters the activity of transcription factors. The additive effect of the two treatments were more profound in the down-regulation of inflammatory transcriptor processes in NMDA lesion.

EFFECT OF THREE DIFFERENT GRIP POSITIONS ON THE MECHANICAL EFFICIENCY IN HANDBIKING

Abel, T., Lindschulten, R., Thees, B., Strüder, H.K.

German Sport Univeristy Cologne, Germany

Introduction: Handbike as a wheelchair sport has gained increased popularity in Germany. It is a very attractive sport and important for the prevention of cardiovascular diseases. During the last 5 years race performance has increased enormously due to a systematic training and developments concerning the handbike itself. In 2005 the world record for a Hanbike City Marathon was 1:07:21 (Heidelberg). In comparison to wheelchair propulsion handbiking has a higher mechanical efficiency (ME). Actually a lot of different biomechanical aspects in handbiking are going to be examined to increase the performance of the athletes. The aim of this study was to examine the effect of three different grip positions on the ME in handbiking.

Methods: Fifteen male and six female participants (age 26.6  4.8 years, height 178.0  11.9 cm, weight 74.7  13.3 kg) performed three different stage tests until exhaustion sitting in a race handbike connected to an ergo meter (Cyclus II, Richter; Germany). All participants were able bodied persons with a good training status of the upper extremity. The angel between the grip and the crank was set by 90° (horizontal = H), 0° (vertical = V) and 10° (diagonal, common way of cranking = D). The initial load was 20 watts increased by 20 watts each five minutes. Expired air was collected continuously (ZAN 600, ZAN, Germany), blood samples to determine lactate concentrations were taken at the last 30 seconds of each stage (Biosen C, Eppendorf, Germany). Heart rate was monitored continuously (Polar X-Trainer, Polar, Finland), RPE-scale was used.

Results: The relative maximum functional performance (watts/kg), maximum heart rate (bpm) the associated lactate concentrations (mmol/l) and maximum oxygen uptake per kilogram body weight (ml/kg) for the different grip positions were: Horizontal 1.43  0.21 watts/kg, 170.14  12.81 bpm, 9.54  1.93 mmol/l, 30.86  4.57 ml/kg; Vertical 1.38  0.20 watts/kg, 171.81  13.87 bpm, 9.91  2.29 mmol/l, 29.75  5.13 ml/kg; Diagonal 1.40  0.22 watts/kg, 169.19  13.31 bpm, 9.34  2.36 mmol/l, 29.39  4.70 ml/kg;. In all grip positions the RPE values were 20 meaning a very heavy load. No statistically significant differences could be found between the mentioned physical reactions.

Conclusion: In opposite to the expectations there were no differences between three different grip positions (horizontal, vertical, diagonal) in handbiking at maximum load. The mechanical efficiency during a stage test until exhaustion showed no differences, so at this knowledge no grip position could be recommended for athletes. In further studies it has to be proven whether these findings are negotiable to prolonged work load durations and to athletes with a spinal cord injury. In addition it would be of particular interest to combine the test setting with EMG registrations.

SALIVARY FREE IGF-I AND TOTAL PROTEINS: EFFECTS OF AN ACUTE PHYSICAL EXERCISE ON CYCLISTS

Antonelli, G., Cappellin, E., Spinella, P., Gatti, R., Liviero, C., De Palo, E.F.

University of Padua, Italy

Introduction. It is commonly accepted that IGF-I influences and is influenced by physical exercise [1], but the literature data about the effects of physical exercise on the IGF-I system does not give the same uniform results [2]. We recently developed a new ELISA to measure free IGF-I in saliva [3]. Aim. The aim of this study was to investigate the effects of an acute physical exercise on the salivary free IGF-I (sIGF-I) levels and explore if a relation with the plasma IGF-I levels exists. We also examined the salivary total proteins (sPr) to verify if a relation with sIGF-I exists and if physical exercise has an effect on sPr. Subjects & Methods. Well-trained male cyclists were recruited (n=18, 19±1 ys, 70±4 kg and 179±4 cm). Saliva and blood specimens were collected from each cyclist at rest (B; 5-10 min before exercise) and at the end of a 45 min cycloergometer test at 50-60% of VO2max (E). sIGF-I and sPr measurements were carried out using ELISA [3] and colorimetric methods, respectively. Plasma concentrations of free IGF-I were assayed with the "Active free IGF-I ELISA" kit reagents. Results. sIGF-I concentrations demonstrated a significant difference before (B) compared with the end (E) of the physical exercise ($p<0.01$; 16.4±8.0 and 26.2±16.7 pmol/L respectively). The plasma free IGF-I concentrations did not demonstrate any difference comparing B and E (25.3±16.9 and 21.1±8.4 pmol/L respectively). The sPr level was significantly lower comparing B and E conditions ($p<0.001$; 326±156 and 629±345 mg/L respectively). A positive correlation between sPr and sIGF-I, both before and after exercise ($y=0.001x+0.039$, $p<0.01$; $y=0.001x+0.073$, $p<0.05$, respectively) was observed. A positive correlation between salivary and plasma free IGF-I was found only after the exercise ($y=1.448x-0.032$, $p<0.001$). Discussion. The literature data about the effects of a physical exercise in circulating IGF-I levels demonstrated mixed results. In this study, plasma free IGF-I concentrations did not differ comparing pre- versus post-exercise. A significant increase in sIGF-I after the exercise was observed ($p<0.01$). A correlation between saliva and plasma free IGF-I was found only in post-exercise. This could be explained by local synthesis of IGF-I in the basal condition, however, exercise might lead to a free diffusion from plasma to saliva. Little is known about the effect of exercise on salivary protein content and in this protocol we observed a significant increase of sPr. A correlation between sPr and sIGF-I both in pre and post exercise was also found. Further investigation would confirm the effect of a different type and duration of physical exercise on the sIGF-I concentration.

PARTICULARITIES OF ACID-BASE DEEP PICTURE DURING AEROBIC EXERCISE IN AN OLYMPIC CHAMPION GIRL (CASE STUDY)

Talaban, M.-D., Tocitu, D., Catanoiu, S., Dafinescu, C.

National Institute for Sport Research, Romania

Introduction

The acid-base equilibrium deep picture (ABDP) is a recent concept meant to the detailed tracing of oxygen status in patients under critical condition, i.e. the evaluation of how oxygen behaves along its entire passage, especially its employment in the tissues. In case of athletes for whose performance the acute response of oxygen to exercise is capital, examination of ABDP may clear up a little bit more of the complexity of the functional adaptations produced through physical training or, on the contrary, may spotlight unexpected particulars.

Methods

After 9 mths of systematic training with a view to her participation in the OG, a member rower of the Olympic squad, female, aged 27, height 182 cm, weight 61.5 kg, active body-mass 54.5 kg, VO2max 5700 mL/min, presented, under rest conditions, normal values: pH–7.411;pCO2-37.6 mmHg;pO2-69 mmHg;ABE–0.8 mmol/L;cLac–0.5 mmol/L;cGlu–72 mg/dL. The athlete was investigated for the ABDP, on blood samples collected after a 60 min session on water, at a rate of 16 bpm, and an atypical ABDP was discovered, suggesting at first sight a defective adaptation of the respiratory function at the intensity of performed exercise. Nevertheless, the athlete's evolution would demonstrate the contrary when, in a short time, she won the Olympic gold medal in the 2X LW event at the Games. The samples were analyzed with microAstrup analyzer, series 700 (Radiometer).

Results

Immediately after the aerobic training performed at about 50% intensity of VO2 max, at a HR of 156 bpm, pH increased to 7.459, pO2 rose to 107 mmHg, sO2 grew to 99.6% in the presence of a normal value for p50(a) with 25.12 mmHg, the lactate concentrations tripled to reach 2.7 mmol/L, cBase(Ecf)c climbed with 2 mmol/L towards the alkaline side, cGlu went up to 96 mg/dL.

Discussion/Conclusion

With this female rower, who trained systematically for a long period of time, we found that the exertion performed at an overload calculated to insure a lactate steady state determined a slight hyperlactatemia (2.65 mmol/L) in the presence of slight hypocapnia (35.3 mmHg), alkalemia (7.459) and hyperbasemia (1.6 mmol/L). The growth of lactatemia associated to hypocapnia and respiratory alkalosis induced through alveolar hyperventilation, respectively, although rare, is mentioned in the medical literature. The mechanism is supposed to imply the inhibitive effect of pCO2 decrease and pH increase on the piruvat carboxilase activity. In sport biology, pH and lactate simultaneous increase is unusual. We make it out with an Olympic elite rower just for the purpose of emphasizing that such a particular, especially blood alkalinisation during aerobic effort, does not affect high performance in sports with aerobic dominance but represents a limit of ventillatory threshold as marker for training monitoring.

EFFECT OF N-ACETYLCYSTEINE ON METABOLISM OF GLUTATHIONE, CELL DAMAGE AND ERYTHROPOIETIN PRODUCTION IN ATHLETES EXPOSED TO ENDURANCE EXERCISE

Zembron-Lacny, A., Slowinska-Lisowska, M., Witkowski, K., Szygula, Z., Szyszka, K., Stefaniak, T.

University of Physical Education Poznan, Faculty of Physical Culture Gorzow Wlkp., Poland

Introduction/Purpose: Glutathione is a ubiquitous thiol playing important role in cellular defense against oxidative stress. Previous studies have shown, that glutathione metabolism and production of erythropoietin (EPO) may be modulated by N-acetylcysteine (Hildebrandt et al. 2002, Sen and Packer 2000). The aim of this study was to determine whether an endurance exercise induces oxidative stress and whether intensification of glutathione metabolism by oral treatment with N-acetylcysteine reduces cell damage, results in changes of EPO level and inhibits fatigue in athletes performed incremental exercise.

Methods: A randomized, double-blind, placebo controlled design was used to determine the effect of N-acetylcysteine on glutathione metabolism, erythropoietin level and markers of cell damage. Subjects (n = 16) were given oral dose of 1200mg N-acetylcysteine (NAC) daily for eight days before exercise and 600 mg on the day of exercise test. Blood samples were obtained 5 min before a graded cycle ergometer exercise (VO2max), immediately post exercise and after 24 h rest. Protein carbonyls (PC), lipid peroxidation products (TBARS), erythropoietin (EPO), myoglobine (Mb) and glutathione (GSH) levels as well as glutathione peroxidase (GPx) and glutathione reductase (GR), creatine kinase (CK), lactate dehydrogenase (LDH) activities were evaluated.

Results: The applied exercise caused significant changes in some tested parameters (GPx, PC, TBARS, CK). The rest concentration of GSH (+33%), activities of GR (-22%) and GPx (-18%) were altered by NAC administration. After NAC, oxidative stress markers PC (-31%) and TBARS (-37%) as well as cell damage markers - CK (-31%) and LDH (-20%) were lower. NAC significantly increased Hb, Ht and EPO levels and reduced amount of erythrocytes. Nevertheless, maximal oxygen consumption and heart rate, lactate concentration and maximal work load did not change after NAC intake.

Conclusions: Our study has shown that an incremental exercise increases oxidative damage level and initiates changes in glutathione metabolism whereas, the N-acetylcysteine administration enhances antioxidant glutathione system, attenuates oxidative stress and influences hematological parameters level in subjects' blood.

EFFECTS OF REPEATED BOUTS OF SOCCER-SPECIFIC INTERMITTENT EXERCISE ON SALIVARY IGA AND CORTISOL

Sari-Sarraf, V., Reilly, T., Doran, D.A., Atkinson, G.

Research Institute for Sport and Exercise Sciences, United Kingdom

Lowered salivary immunoglobulin A (s-IgA), the predominant component in the secretions lining the mucosal surface, or chronic s-IgA deficiency has been associated with an increased incidence of upper respiratory tract infections (URTI). This association in elite athletes

may be due at least in part, to the repetitive intensive-exercise sessions undertaken without sufficient recovery between them. An imbalance between training/competition stress and recovery may lead to chronic fatigue, under-performance and more severe immunodepression. Competing and/or training hard frequently may compound the effects of a single session of exercise. The aim of the study was to identify the cumulative effects of soccer-specific intermittent exercise undertaken on different occasions 48 hours apart on secretory immune response. Nine males (mean ± se age: 25.7±1.6 years; height: 1.81±0.02 m; mass: 76.6 ± 2.6 kg; body fat: 14.7 ± 1.3 % and : 57.1 ± 3.7 ml·kg-1min-1) completed two trials of 90-min soccer-specific intermittent exercise performed 48 hours apart at the same time of day on a motorized treadmill. The participants were initially assessed for maximal oxygen consumption ( ). Unstimulated saliva samples were collected via passive expectoration before, immediately post-exercise, 24 hours and 48 hours post-exercise. The mean heart rate (149 ± 2 vs.147 ± 2 beat·min-1) and perceived exertion (13.4 ± 0.5 and 13.2 ± 0.6) for the two intermittent exercise trials did not differ significantly (P>0.05). The pattern of change in salivary responses, including solute secretion rate, IgA secretion rate, IgA to osmolality ratio and cortisol did not differ between the different time-points. The s-IgA concentration was increased immediately after both the first exercise trial (EX1) (215.7 ± 53.4 to 335.6 ± 81.9) and the second exercise trial (EX2) (144.2 ± 31.2 to 271.2 ± 61.9) and declined throughout the subsequent 24-48 hours (F6, 48 =3.85, P<0.05). The declines in saliva flow rate during EX1 were similar to EX2 (642 ± 120 to 502 ± 51 and 680 ± 95 to 502 ± 37 ml·min-1, respectively) (F6, 48 =4.82, P<0.05) and at the time period 24 hours after exercise, saliva flow rate after both trials was increased above its initial level (P<0.05). The saliva osmolality increased immediately after each exercise trial and this change after EX2 was higher than in EX1 (36.4 vs. 28.3) (F6, 48 =9.6, P<0.05), suggesting an increase in the amount of dehydration. The results suggest that performing soccer-specific intermittent exercise twice within 48 h did not significantly affect salivary IgA secretion rate and IgA to osmolality ratio or cortisol concentration and therefore did not compromise mucosal immune responses. In conclusion, a 48-h rest is sufficient for salivary IgA and cortisol responses to recover from previous soccer-specific exercise.

TRAINING AND OVERREACHING EFFECTS IN OXIDATIVE, ANTIOXIDANT, OXIDANT STRESS MARKERS AND HSP72

Zoppi, C.C., de Macedo, D.V.

Faculdade Social da Bahia and Universidade Estadual de Campinas, Brazil

Physical training is known to induce several adaptations that can be systemic or at skeletal muscle level. These adaptations are desired to increase athletic performance. Frequently athletes are submitted to hard training in order to push performance to its upper limit, although when training loads are excessive and the regeneration is not enough the athlete is said to be overtraining. Overtraining syndrome is the result from an imbalance between training loads and regeneration processes, and induces autonomic changes that impair performance. Overreaching is known as the initial phase of overtraining and occurs in consequence of metabolic imbalance leading to a decrease in ATP synthesis, inducing short term fatigue. Free radicals are high reactive molecules, that can oxidize intracellular structures and thus impair cell function, and strenuous exercise could increased their production. So the aim of this work was to study the behavior of oxidative stress, antioxidant defenses and oxidative metabolism markers in subjects submitted to a training protocol that tends to achieve overreaching process. 30 male Wistar rats were divided in exercise group (n=25) and control group (n=5). The exercise protocol consisted in 8 weeks endurance training and a 3 weeks overreaching protocol. During endurance protocol, animals were exercise once a day, while volume and intensity were smoothly enhanced, and at overreaching protocol, only frequency was increased untill exercise group reached 4 sessions per day, volume and intensity remained the same of the last week of endurance protocol. Thiobarbituric acid reactive substances (TBARs) and carbonylated proteins (PC) were measured as oxidative attack markers, glutathione reductase (GR), catalase (CAT) and citrate synthase (CS) activities were measured as muscle antioxidant and oxidative markers and also stress protein HSP72 were measured to ensure stress levels in soleus (SO), extensor digital longus (EDL) and semitendinuous (ST) muscles. Although endurance training induced significative increase in TBARs and PC levels (p<0.05), antioxidant and oxidative enzymes increased as well, and at the end of 8 weeks training protocol the stress markers TBARs, PC and HSP72 levels were back to baseline values. On the other hand, overreaching protocol induced oxidative stress situation leading to significative decreases (p<0.05) in antioxidant and oxidative enzymes, giving rise to TBARs and PC levels in all muscles, but mainly in the SO type I fibers muscle. Similar to other results, HSP72 was also highly expressed in all muscles studied, but at a higher level in SO muscle, suggesting a high stress imposed by the overreaching protocol. In conclusion, our data suggest that overreaching can be induced by oxidative stress mainly in type I slow twitch muscle fibers, and the measure of these markers could be a useful tool in sports field as markers of overreaching installation.

EXPRESSION OF UBIQUITIN PROTEOLYTIC PATHWAY COMPONENTS IN HUMAN SKELETAL MUSCLE FOLLOWING REPEATED BOUTS OF ECCENTRIC EXERCISE

Vissing, K., Nedergaard, A., Overgaard, K., Schjerling, P.

University of Aarhus, Denmark

Introduction

Muscle damage induced by single bout eccentric skeletal muscle exercise provides long-lasting protection from subsequent bouts of eccentric exercise (repeated bout effect) (1). Cellular mechanisms involved in such adaptations are undefined, but one theory involves the ubiquitin (UBI) proteolytic pathway. Accordingly, it has been shown that expression of UBI-components like ubiquitin and 20S-proteasome is lessened after a repeated bout of eccentric exercise (2). A number of pathway-specific enzymes, (collectively referred to as E3-ligases) are speculated to specify the myofibrillar proteins that are to undergo proteolysis. Furthermore the transcription factor FOXO is speculated to be involved in the expression of pathway-specific genes. Such ligases and transcription factors have, however, not been investigated during repeated eccentric exercise. The purpose of this study was, therefore, to investigate the expression of selected E3-ligases as well as other UBI-pathway components during repeated eccentric exercise. The hypothesis was a less profound overall exercise-induced expression after the repeated bout.

Methods

Biopsies were obtained from the vastus lateralis muscles of 14 untrained male volunteer subjects performing two bouts of 30 min step-down exercise separated by 8 weeks (3). Isometric knee extensor MVC was measured with a strain gauge transducer and soreness of

the knee extensor region was evaluated on a visual analog scale. mRNA levels for Ubiquitin (UBI), proteasome subunit alfa1 (PSMA1), FOXO and five E3-ligases, E3alfa, Murf1, Murf2, Murf3 and atrogrin1, were quantified by Northern blotting.

Results

Eccentric exercise reduced muscle strength, but strength was less reduced after bout 2 compared to bout 1 ($p<0.05$). Muscle soreness was lower following bout 2 as compared with bout 1 ($p<0.05$). UBI and PSMA increased compared to pre level and UBI showed an increase after bout 1, not evident after bout 2 ($p<0.05$). Murf2, Murf3 and atrogin1 all underwent regulation after eccentric exercise ($p<0.05$), but with no difference between bout 1 and 2. Murf1 underwent more profound regulation after bout 2 than bout 1 ($p<0.05$) and FOXO responded more to concentric than to eccentric exercise ($p<0.05$). E3alfa did not change.

Discussion/Conclusion

Patterns of strength reduction and muscle soreness were as expected. Among selected molecular markers of the ubiquitin proteolytic pathway, a repeated bout effect was observed for Murf1 and UBI, but not for other targets. The UBI-pathway might be involved in adaptation underlying the repeated bout effect, but this requires more investigation. In this regard the mRNA level for these genes may not reflect the alterations at the protein level.

EFFECT OF EXERCISE TRAINING ON ANGIOGENIC GROWTH FACTOR EXPRESSIONS IN THE AGED RAT HEART

Iemitsu, M., Maeda, S., Jesmin, S., Otsuki, T., Miyauchi, T.

Institute of Health and Sport Sciences and Center for Tsukuba Advanced Research Alliance (TARA), Japan

Exercise training improves aging-induced deterioration of angiogenesis in the heart. Vascular endothelial growth factor (VEGF), transforming growth factor (TGF)-beta1, and basic fibroblast growth factor (bFGF) are important angiogenic growth factors. However, it is unclear whether these angiogenic growth factors participate in the mechanisms underlying exercise training-induced improvement of capillary density in the aged heart.

PURPOSE: The present study was aimed to clarify whether angiogenic growth factors, such as VEGF, TGF-beta1, and bFGF, in the heart contributes to a molecular mechanism of exercise training-induced improvement of capillary density in old age.

METHODS: The present study investigated whether mRNA and protein levels of VEGF, TGF-beta1, bFGF, and fetal liver kinase (Flk)-1, which is a VEGF receptor, in the aged heart are affected by exercise training, using the hearts of sedentary young rats (4 months old), sedentary aged rats (23 months old), and exercise-trained aged rats (23 months old, swimming training for 8 weeks, 5days/week, 90 min/day).

RESULTS: Total capillary density and capillary to myocyte ratio in the heart were significantly lower in the sedentary aged rats compared with the sedentary young rats, whereas those in the exercise-trained aged rat were significantly higher than the sedentary aged rats. The mRNA and protein expressions of VEGF and Flk-1 in the heart were significantly lower in the sedentary aged rats compared with the sedentary young rats, whereas those in the exercise-trained aged rats were significantly higher than the sedentary aged rats. Additionally, cardiac bFGF mRNA and protein expressions in the heart were significantly higher in the sedentary aged rats compared with the sedentary young rats, whereas there were no significant differences in these expressions between the sedentary aged rats and the exercise-trained aged rats. The expression levels of TGF-beta1 mRNA and protein in the heart did not differ among three groups.

CONCLUSIONS: These findings suggest that exercise training-induced upregulation of cardiac VEGF angiogenic signaling may play roles, at least in part, in the molecular mechanism of the exercise training-induced improvement of angiogenesis in old age.

Supported by grants from the Ministry of Education, Culture, Sports, Science and Technology of Japan (17700484).

EFFECTS OF 6 WEEKS INTERVENTION OF DIET AND EXERCISE ON VEGF PROTEIN EXPRESSION OF SKELETAL MUSCLE FIBER TYPES IN DIET-INDUCED OBESE RATS

Changbae, H., Kijin, K., Wookwang, C., Nayoung, A.

Keimyung University, Korea, South

This study measured VEGF protein expression of different skeletal muscle fiber types after 6 weeks intervention of energy intake restriction and exercise in diet-induced obese rats. These changes were analysed the differences among the different 6 weeks intervention programs of diet, exercise, and diet plus exercise.

Subjects were consisted of 2 weeks-aged male Sprague-Dawley rats, and were divided into 6 groups as control, obese, and 4 intervention groups (diet alone, exercise alone, diet plus exercise type A, and diet plus exercise type B).

VEGF protein expression in skeletal muscle were measured in pre and post-treatment of 6 weeks by western blotting analysis. After intake of high fat diet of 6 weeks, diet-induced groups showed a significant higher body weight as compared to control group.

Exercise group and diet plus exercise type B group showed a significant weight loss after 6 weeks intervention, but diet alone group and diet plus exercise type A group showed no significant change of body weight after 6 weeks intervention. Diet plus exercise type B group showed a significant lower visceral fat volume after 6 weeks intervention, and obese group showed a higher visceral fat volume than the other groups. Diet alone group, and diet plus exercise type B group showed a significant higher VEGF protein expression in red gastrocnemius after 6 weeks of treatment as compared to pre-level of control group. Diet alone group, exercise group, and diet plus exercise type B group showed a significant higher VEGF protein expression in white gastrocnemius after 6 weeks of treatment as compared to pre-level of obese group, but these groups showed no significant differences as compared to pre-level of control group.

Exercise group showed a significant higher VEGF protein expression in soleus after 6 weeks of treatment as compared to pre-level of control group, and exercise group and diet group showed a significant higher VEGF protein expression in soleus after 6 weeks of treatment as compared to post-level of control group.

In conclusion, VEGF protein expression of type IIb fiber in gastrocnemius's white muscle showed a significant activation after exercise. However, VEGF protein expression of intervention groups showed a challenge to insufficient exercise duration and in obese rats. Further research is needed on the analysis of VEGF mRNA in muscle and adipose tissues before meaningful mechanism can be drawn in dietary and exercise intervention of obesity.

THE RELATIONSHIP BETWEEN EPSTEIN-BARR VIRUS REACTIVATION AND UPPER RESPIRATORY INFECTION DURING INTENSIVE TRAINING AND COMPETITIVE PERIOD

Yamauchi, R., Nakamura, D., Kimura, F., Suzuki, K., Kono, I., Akimoto, T.

Consolidated Research Institute for Advanced Science and Medical Care, Waseda University, Japan

It is well known that highly trained athletes suffer from a high incidence of upper respiratory tract infections (URTI). Thus, it is important for all athletes to manage risk of URTI through training and competitive periods. In some previous research, salivary secretory immunoglobulin A (SIgA) has been used for evaluation of the risk of URTI. However, there has been a moderate relationship between SIgA levels and URTI. Here we established a new index to monitor the risk of URTI in intensive training period on the field.

To establish the detection system that evaluates reactivation of Epstein-Barr virus (EBV), we examined the metrology of the amount of EBV-DNA appearance in saliva from three steps. First of all, method of extracting DNA from saliva was examined. Second was making of working curve that uses EBV-DNA fragment insertion vector by polymerase chain reaction (PCR). The last was quantification of the amount of EBV-DNA appearance based on working curve. We prospectively investigated the relationship between daily changes in EBV-DNA as well as SIgA level, and appearance of URTI symptoms in collegiate soccer players during a training period of 2 months.

The SIgA concentration did not significantly decrease before appearance of URTI symptoms. However, the saliva flow rate and SIgA secretion rate tended to decrease 3 days before the appearance of URTI symptoms compared to that in the non-infection period. For EBV-DNA, total DNA was extracted from the saliva samples. The working curve was obtained from the result of PCR that used the EBV-DNA inserted vector. It became possible to quantify the amount of EBV-DNA appearance by being based on working curve that we established. The detection system of the amount of EBV-DNA appearance was constructed. The appearance of EBV-DNA was also related to the appearance of URTI symptoms. Our findings suggest that monitoring of SIgA secretion rate and EBV-DNA may be useful for assessment of risk status of athletes for URTI.

POTENTIAL BIOLOGICAL SIGNIFICANCE OF TRAINING-INDUCED CHANGE OF HSP72 MRNA IN MYOCARDIUM OF RATS

Wei, Y., Chen, P.

Shanghai University of Sport , China

Introduction

This article's aim is to evaluate the effects of exercise on myocardial metabolism and mechanical performance with the concentration of myocardial enzyme in plasma, heart function and ultrastructure as the indexes.

Methods: SD rats were randomly divided into four groups: 1) control group, 2) training for 1 week period group, 3) training for 2 weeks period group, and training for 3 weeks period group. There were 9 rats every group. The rats were trained on treadmill in the intensity of 75%VO2max for 1 week,2 weeks,3 weeks separately. After training all rats were decapitated at intervals of 24 hr. The concentration of Creatinkidnase (CK) and Creatinekidnase Isoenzyme (CK-MB) in plasma was measured by the method of NAC, and that of Oxaloacetate Transnase (AST/GOT) in plasma was observed by the method of malate dehydregenase. The myocardial damage was examined with electron microscope. Mechanical function was assessed according to rate pressure product (RPP) and ±dp/dt max. The hearts were reserved for the detection of HSP 72mRNA expression by reverse transcription-polymerase chain reaction (RT-PCR).

Results: The HSP 72mRNA was expressed in all rats' myocardial cells.2)A significant increase in the concentration of not only CK, CK-MB but also AST was observed in 1-week-period group compared with control group. And with the increase of the exercise period, the concentrations of those three enzymes decreased gradually.3) The decrease of LVSP, dp/dt max and dp/dt min was more pronounced in 1-week-period group than in control group, while the decrease of LVEDP was not statistically different between the two groups ($p>0.05$). And with the increase of the exercise period, the decrease of LVSP, dp/dt max and dp/dt min recovered gradually, while the decrease of LVEDP continued to even lower level in rats.4) All of the ultrastructure of myocardial cells showed damage after one week exercise. And with the increase of the exercise period, the myocardial damage recovered gradually.

Discussion / Conclusions: Physical training-induced expression in HSP 72mRNA is paralleled with the heart function. Exercise could protect myocardial cells from damage by increasing the expression of the HSP72 protein.

EFFECTS OF DIFFERENT EXERCISE DURATIONS ON THE EXPRESSION OF HEAT SHOCK PROTEIN 72MRNA IN MYOCARDIUM OF RATS

Wei, Y., Chen, P.

Shanghai University of Sport , China

Introduction

This article's aim is to study whether exercises of different durations can effectively induce the expression of myocardial HSP72 messenger RNA (mRNA).

Methods: SD rats were randomly divided into four groups: 1) control group, 2) training for 1 week period group, 3) training for 2 weeks period group, and 4) training for 3 weeks period group. The rats were trained on treadmill in the intensity of 75%VO2max for 1 week, 2 weeks, 3 weeks separately. After training all rats were decapitated at intervals of 24 hr and HSP 72 mRNA expression of myocardium was detected by reverse transcription-polymerase chain reaction (RT-PCR).

Results: 1) HSP72 mRNA can be basically expressed in rats of control group.2) There is a significant increase of HSP72 mRNA in myocardial cells in 1-week-period group compared with control.3) A decrease of HSP72 mRNA was observed in 2-week-period group compared with 1-week-period group，but there was no statistical difference between the two groups. 4) The decrease of HSP72 mRNA was more pronounced in 3-week-period group than in 2-week-period or 1-week-period group.

Discussion / Conclusions

Exercise is a sufficient stimulus to induce or enhance the synthesis of heat shock and/or stress proteins in myocardial cells. HSP72 mRNA can accumulated in cells after long time exercise. But the accumulation decreases gradually and HSP72 mRNA recovers to normal level after some time.

THE EFFECT OF ENDURANCE EXERCISE TRAINING ON SKELETAL MUSCLE APOPTOSIS INDUCED BY MITOCHONDRION

Tsung-I, C., Ming-I, C.
Tzu-Chi University, Taiwan

Mitochondrion may play an important role in signals affecting skeletal muscle apoptosis involved a lot of mechanisms after exercise. Therefore, the purpose of this study is to investigate the influence of exercise training on skeletal muscle apoptosis induced by mitochondrial pathway. Animals, male Wistar rats, were randomly assigned to either a control group or an exercise group. Exercise group were trained 5 days weekly for 12 weeks on treadmill. An exhausted exercise test was performed after a rest period of 7 days after 12 weeks exercise training. Rats were sacrificed at pre-exercise (PRE), post-exercise 0 hour (PE0) and post-exercise 48 hour (PE48), respectively. The soleus and gastrocnemius were dissected out and frozen in liquid nitrogen rapidly. Muscle samples were stored at -80℃ until subsequent analysis. The citrate synthesis activity of soleus of trained was significantly higher than untrained at PRE, PE0 and PE48 ($p < .05$), respectively. The gastrocnemius weight-to-body weight ratio and soleus weight-to-body weight ratio of trained were significantly higher than untrained ($p<.05$), respectively. In gastrocnemius, the apoptosis index of trained at PE48 was significantly higher than PRE ($p<.05$); the untrained at PE48 was significantly higher than PRE and PE0 ($p<.05$), respectively. The apoptosis index of gastrocnemius and soleus of trained were significantly lower than untrained after PE48 ($p<.05$), respectively. These finding suggest that skeletal muscle may modulate their apoptotic signals expression and the oxidative activity of mitochondria after exercise training, lead to attenuating the time of skeletal muscle apoptosis or inhibiting the apoptotic signals expression, and then the probability of hypertrophy occurred.

CICLO LAZER - KNOW YOUR CITY RIDING A BIKE

Stanganelli, P.J., Sawaf, C.
Curitiba City Hall, Brazil

Introduction: Curitiba, Brazil, is a city with 1.5 million inhabitants, 52m² of green area per inhabitant, 170 km of cycleways and 23 parks, in this sense, counts with a structure that allows for the cycling activity and consequent democratization of options for people to go to work, go home or have some leisure time. Through cycleways and specific programs that stimulate the continuous use of bicycles and knowing the city, the citizens enjoy also the physical, mental and social benefits within a community. Methods The city of Curitiba offers a program called Ciclolazer, which promotes meetings with cyclists on Saturdays aiming to know typical neighborhoods, parks, monuments, events sites, historical streets and new locations while enjoying the activity of bicycle riding around the city. The rides are about 15 km long. It stars at 2:30 pm from a central point in the city and last three hours. Each participant must have his own bicycle and helmet. Also at the beginning and in reference points of the tour, the participants are informed about the characteristics of the places, such as their memory heritage and context. Results The data was collected on March 19, 2005 with 140 participants, before they started the Ciclolazer program. The age of the participants (71.5% males and 28.5% females) was distributed as follows: + 20 years old – 14.3%; + 30 years old – 28.5%; + 40 years old – 21.5%; + 50 years old – 35.7%. When the participants were asked if they knew who promoted the program, 7% did not know what to answer, 93% identified the City Hall as the promoter. Nevertheless, 7% of the respondents understood that the executive agency of the program was the City Hall, 7% thought that the Secretariat of Environment was responsible for the event and 86% mentioned the Municipal Secretariat of Sports and Leisure. Five other multiple-choice questions related to aspects of social inclusion by means of the project were also made to the participants. Conclusions: Upon the analysis of the answers given by the subjects we can verify that people over 30 years old are more assiduous and, thus, evidence a clear intention to make good use of their free time and an interest to know the city, having sport as a source of social regulation (Cunha 2002). It is worth mentioning that 71.5% of the participants feel themselves as "very much included" through Ciclolazer while a process of citizenship, and that the bicycle, used as a means of leisure, should also have its use as a means of transport better stimulated. The research shows that 93% of the participants could know new places and 100% of them made at least one new acquaintance. As seen by the participants, the main benefit from this activity is health, assuring that there is a process of social inclusion while riding a bicycle, which is, according to Driver (1980) one of the main forms of leisure today.

CHARACTERISTICS, POSITION AND ORGANISATIONAL FORMATS OF NEIGHBOURHOOD SPORT IN FLEMISH MUNICIPALITIES (BELGIUM)

Theeboom, M., van den Bergh, K.
Vrije Universiteit Brussel, Belgium

Introduction
In recent years, sport promotion on neighbourhood level has gained popularity in Flanders (Belgium). During the first years, neighbourhood sport was primarily aimed at underprivileged youth in urban deprived areas. However, as a result of the growing number of initiatives that have been set up in recent years in Flanders, this concept has now become more diverse. Consequently, it has become unclear how neighbourhood sport in its actual form, can be described in terms of general objectives, target groups, organisational formats, etc. By order of the Flemish Minister of Sport, an inventarisation study was set up in 2005 to determine the actual position of neighbourhood

sport in Flanders. All Flemish municipalities were asked to fill in an on-line questionnaire (response: 71.4 %). Also, in-depth interviews were held with 30 Flemish expert witnesses.

Results

Findings showed, among other things, that larger municipalities are more involved in the organisation of neighbourhood sport. There is a wide diversity of organisational formats, which is largely depending on the type of co-ordinating organisation, as well as on the aims and specific target group. Most municipalities are organising neighbourhood sport as a means of sport stimulation and aim at those groups that are not, or only to a limited extent, participating in (organised) sport. A part from sport stimulation, the larger municipalities (cities) also aim for social integration through these sport initiatives. The most popular target groups are children and youngsters, which are often recruited through schools. There is an increased interest of working together on the local level with other structures. While most organising municipalities encourage participants afterwards to become involved in organised sports (in clubs), there is only a moderate interest of sport clubs to co-operate in neighbourhood sport. Although there is an interest among a majority of the participating municipalities to include new sport activities, the actual programmes mainly consist of traditional sports.

Discussion

Neighbourhood sport can primarily be regarded as a form of sport stimulation and can be situated between unorganised (informal) sport and (traditionally, or alternatively) organised sport. The primary goal is to encourage people to become (more) sports active, be it in a more formal context (e.g., sports clubs), or through regular participation in neighbourhood sport. The choice of activities, as well as the organisational level and type of guidance approach, will vary according to the target group and specific neighbourhood characteristics. Finally, one can ask if neighbourhood sport can perhaps be regarded as a preamble for a future sport-for-all policy (e.g., locally organised, structural co-operation between a number of actors, demand-oriented approach, diversity in organisational formats, broad definition of sport, creative use of infrastructure, etc.).

BODY BUILD CLASSIFICATION AND PROFICIENCY IN COMPETITIONS OF ADOLESCENT FEMALE VOLLEYBALLERS

Stamm, R., Stamm, M.

University of Tartu, Estonia

There are several anthropometric studies of adolescent female volleyballers, but most researchers have confined themselves only to height, weight and body fat content, which, however, remains insufficient (Avloniti et.al. 2001, Martirosov 2001). The aim of the present study was more detailed research into adolescent female volleyballers' body build and finding its correlations with proficiency in competitions.

The sample consisted of 74 girls aged 13-15 years from the eight most successful volleyball teams of age group U16, who participated in Estonian championships in 2004.

All the girls were measured anthropometrically, 14 body measurements were taken. To record the games, the computer program Game was used. The performance of two opposing teams was recorded simultaneously; in total 56 parallel recordings of 28 matches were made.

The proficiency of each player in performing the elements of the game (serve, reception, block, attack and number of points scored) was related to anthropometric measurements and analyzed in the body build classification. The basis for creating the classification of girls with different age was the mean height, weight and their standard deviations for the whole sample. The 5 SD classification was made by three classes of concordant height and weight and two classes of disconcordant height and weight –pycnomorphs, leptomorphs. The girls' proficiency in the game for the whole tournament was assessed in the same body build classes. The most successful players belonged to the 3 body build class – girls with big height and big weight. The least successful were girls of the 1 class – with small weight and small height. The players of other classes – 2 (medium height, medium weight); 4 (pycnomorphous), 5 (leptomorphous) – occupied an intermediate position. Out of the total number of points (1823), the girls of class 1 scored 5.1% and the girls of glass 3 – 35.6%; classes 2, 4 and 5 – respectively 22.98%, 17.01% and 19.31%.

When we correlated all the anthropometric variables with individual indices of proficiency for elements of the game we found statistically significant correlations between wrist circumference and attack (r = 0.375). Reception of serve was essentially better in the case of smaller circumference of lower chest (r =-0.349), waist (r = -0.411) and hip (r= -0.343).

In summary, we can say that body build is in correlation with player's performance and our body build classification proved to be appropriate for simultaneous assessment of body build and proficiency in the game.

JOINT EFFORT OF MÉDIATERROR AND OLYMPIC BUSINESS ON WRESTLING

Barna, T.

Semmelweis University Faculty of Physical Education and Sport Sciences (TF), , Hungary

Introduction

As sport has become a business that is spectacle and intended for consuming, mass communication has almost annexed sport with the help of television. Nowadays a huge amount of sport rules are also modified according to the demands of television and this is true for wrestling as well. The power of the media is doubtless. But it could have become a wonderful means of democracy, e.g. in favor of increasing Olympic profit, but slowly it has been transformed to the symbol of oppression. The contextual values of wrestling started to be transformed as a result of the negative trends of the 90ies.

The sport has to pay a heavy price for these frequent changes in the rules lacking any scientific demanding.

Key-words: wrestling, media, roules , technical points

Methods

The followings were applied during 1250 bouts (WCh'85, Atlanta '96, Athen '04, WCh. 05)
Direct recorded information from the minutes of the bouts
- number of bouts
- duration of bouts
- number of falls
- number of technical points
Indirect observation methods
- simple attack
- complex attack
- attempted attack and completed attacks are registered on a special survey sheet
Results
1. As a result of the changing rules of the past years, wrestlers have minimised their actions initiated from standing, have decreased the number of their complex, but spectacular actions, have set themselves for holds worth one or two points. The number of falls has not changed, but technical falls decreased to half in the past years, so - although suitable to TV broadcasting - wrestling has gradually lost its spectacle and spirit.
2. The number of technical points for a time unit has not changed, which unambiguously means the devaluation of the contextual value of wrestling, although the length of the bouts shows a tendency to decreased.

THE PHENOMENON OF SPORT AS FONTAL FESTIVITIES

Hogenova, A.

Charles University , Czech Republic

Ethical spring of sportive activity. Phenomenological description of festivities. The mystery of festivities as a uncovered delitestence is the base of original meaning of phenomenon sporting activity. Medusa´s head as the manifestation of „logos" in the face of atlete in the moment of the highest performance. The highest performance as the form of sacrifice. Hermeneutical interpretation of sacrifice as „kenosis" (Greek word). Kenosis as the clearance from the shape. The highest performance in sport as „the clearance from the shape." The basic similarity with the base of sacrifice. The aproximation to the holiness. The holiness is identical with phenomenological description of festivities. The loss of festivity today and profane character of existence. The role of sport in the proces of conversion to the authentical life today. Fair play as the source of the clearence from the shape (sacrifice from phenomenological point of view). Sport as the possibility to the authentical life in the presence. Normal people are alive in the imaginings of the future, because the future is more important as the presence. The necessity of explanation of phenomenological character of sport as the access to the ethical education in the schools and in the life.

READINESS OF ENTREPRENEUR IN SPORT: A STUDY IN PHYSICAL EDUCATION STUDENTS

Tojari, F., Khodayari, A., Rezaean, S.

Azad University, Tehran Branch (Iran) ,Azad University, Karaj Branch (Iran) , Iran

The purpose of this study was to examine readiness of entrepreneur in physical education university bachelor students.75 voluntary students (M=24.23, SD=3.01) were completed entrepreneur readiness questioner (ERQ) .chi square test results indicated that don't significant relationship between entrepreneur in sport and sex . Descriptive statistics results show that 50persent of students was ready for entrepreneur in sport in next five years, 43.3 percent believed that their readiness for entrepreneur in sport is moderate, and 40.5 percent believed their information isn't sufficient for entrepreneur in sport and they must learn more.
